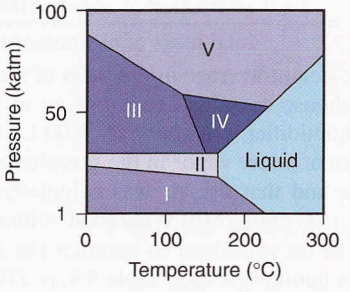
(b) Refer to Figure 12.9A (p. 435) and draw a curve for carbon dioxide as the pressure is continuously *increased* at −50°C.

12.121 Because bismuth has several well-characterized solid, crystalline phases, it is used to calibrate instruments employed in high-pressure studies. The following phase diagram for bismuth shows the liquid phase and five different solid phases stable above 1 katm (1000 atm) and up to 300°C. (a) Which solid phases are stable at 25°C? (b) Which phase is stable at 50 katm and 175°C? (c) Identify the phase transitions that bismuth undergoes at 200°C as the pressure is reduced from 100 to 1 katm. (d) What phases are present at each of the triple points?



12.122 In the photoelectric effect, the work function (ϕ) is the minimum energy a photon must have to remove an electron from a metal surface (see Problem 7.70). For a given metal, ϕ depends on where the photon strikes the crystal. Copper adopts the face-centered cubic structure. If the photon strikes perpendicular to a face, ϕ is 4.59 eV; if it strikes an edge, ϕ is 4.48 eV; and if it strikes a corner, ϕ is 4.94 eV (1 eV = 1.602×10^{-19} J). Find the wavelength (in nm) of the lowest energy photon that can remove an electron from copper, and state how it strikes the unit cell.

12.123 In making computer chips, a 5.00-kg cylindrical ingot of ultrapure n-type doped silicon that is 5.25 inches in diameter is sliced into wafers 1.02×10^{-4} m thick.
(a) Assuming no waste, how many wafers can be made?
(b) What is the mass of a wafer (d of Si = 2.34 g/cm^3; V of a cylinder = $\pi r^2 h$)?
(c) A key step in making p-n junctions for the chip is chemical removal of the oxide layer on the wafer through treatment with gaseous HF. Write a balanced equation for this reaction.
(d) If 0.750% of the Si atoms are removed during the treatment in part (c), how many moles of HF are required per wafer, assuming 100% reaction yield?

12.124 Methyl salicylate, $C_8H_8O_3$, the odorous constituent of oil of wintergreen, has a vapor pressure of 1.00 torr at 54.3°C and 10.0 torr at 95.3°C. (a) What is its vapor pressure at 25°C? (b) How many liters of air must pass over a sample of the compound at 25°C to vaporize 1.0 mg of it?

12.125 Mercury (Hg) vapor is toxic and readily absorbed from the lungs. At 20.°C, mercury (ΔH_{vap} = 59.1 kJ/mol) has a vapor pressure of 1.20×10^{-3} torr, which is high enough to be hazardous. To reduce the danger to workers in processing plants, Hg is cooled to lower its vapor pressure. At what temperature would the vapor pressure of Hg be at the safer level of 5.0×10^{-5} torr?

12.126 Polytetrafluoroethylene (Teflon) has a repeat unit with the formula F_2C—CF_2. A sample of the polymer consists of fractions with the following distribution of chains:

Fraction	Average no. of repeat units	Amount (mol) of polymer
1	273	0.10
2	330	0.40
3	368	1.00
4	483	0.70
5	525	0.30
6	575	0.10

(a) Determine the molar mass of each fraction.
(b) Determine the number-average molar mass of the sample.
(c) Another type of average molar mass of a polymer sample is called the *weight-average molar mass*, $\mathcal{M}_w$:

$$\mathcal{M}_w = \frac{\Sigma\,(\mathcal{M}\text{ of fraction}\times\text{mass of fraction})}{\text{total mass of all fractions}}$$

Calculate the weight-average molar mass of the above sample.

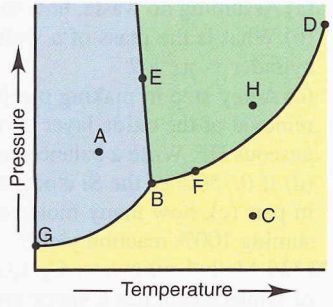
12.127 A greenhouse contains 216 m^3 of air at a temperature of 26°C, and a humidifier in it vaporizes 4.00 L of water. (a) What is the pressure of water vapor in the greenhouse, assuming that none escapes and that the air was originally completely dry (d of H_2O = 1.00 g/mL)? (b) What total volume of liquid water would have to be vaporized to saturate the air (i.e., achieve 100% relative humidity)? (See Table 5.4, p. 210.)

12.128 The packing efficiency of spheres is the percentage of the total space (volume) of the unit cell occupied by the spheres:

$$\text{Packing efficiency (\%)} = \frac{\text{volume of spheres in unit cell}}{\text{volume of unit cell}}\times 100$$

Using spheres of radius r and unit-cell edge length A, calculate the packing efficiency of (a) a simple cubic unit cell; (b) a face-centered cubic unit cell; (c) a body-centered cubic unit cell (volume of a sphere = $\frac{4}{3}\pi r^3$). (d) A solid consisting of identical atoms has a density of 9.0 g/cm^3 and crystallizes in a cubic closest packed structure. What is its density if the atoms are rearranged to a structure with a body-centered cubic unit cell? A simple cubic unit cell?

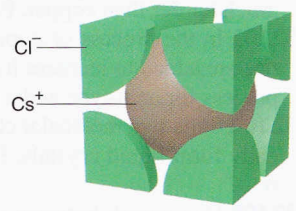
12.129 Consider the phase diagram shown for substance X. (a) What phase(s) is (are) present at point A? E? F? H? B? C? (b) Which point corresponds to the critical point? Which point corresponds to the triple point? (c) What curve corresponds to conditions at which the solid and gas are in equilibrium? (d) Describe what happens when you start at point A and increase the temperature at constant pressure. (e) Describe what happens when you start at point H and decrease the pressure at constant temperature. (f) Is liquid X more or less dense than solid X?



12.130 Some high-temperature superconductors adopt a crystal structure similar to that of *perovskite* ($CaTiO_3$). The unit cell is cubic with a Ti^{4+} ion in each corner, a Ca^{2+} ion in the body center, and O^{2-} ions at the midpoint of each edge. (a) Is this unit cell simple, body-centered, or face-centered? (b) If the unit cell edge length is 3.84 Å, what is the density of perovskite (in g/cm^3)?

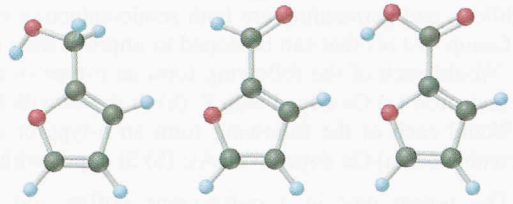
12.131 Why do uninsulated water pipes burst in cold weather?

12.132 The only alkali metal halides that do not adopt the NaCl structure are CsCl, CsBr, and CsI, formed from the largest alkali metal cation and the three largest halide ions. These crystallize in the *cesium chloride structure* (shown here for CsCl). This structure has been used as an example of how dispersion forces can dominate in the presence of ionic forces. Use the ideas of coordination number and polarizability to explain why the CsCl structure exists.



12.133 Hydrogen bonding often causes individual molecules to remain linked together under varying conditions. Each of the following has been identified in either the gas or liquid phase. Draw structures for each showing the H bonds: (a) $(HF)_2$, dimer; (b) $(CH_3OH)_4$, cyclic; (c) $(HF)_6$, cyclic.

12.134 Corn is a valuable source of industrial chemicals. For example, furfural is prepared from corncobs. It is an important reactant in plastics manufacturing and a key solvent for the production of cellulose acetate, which is used to make everything from videotape to waterproof fabric. It can be reduced to furfuryl alcohol or oxidized to 2-furoic acid.



(a) Which of these compounds can form H bonds? Draw structures in each case.
(b) The molecules of some substances can form an "internal" H bond, that is, an H bond *within* a molecule. This takes the form of a polygon with atoms as corners and bonds as sides and an H bond as one of the sides. Which of these molecules is (are) likely to form a stable internal H bond? Draw the structure. (*Hint:* Structures with 5 or 6 atoms as corners are most stable.)

12.135 The density of solid gallium at its melting point is 5.9 g/cm^3, whereas that of liquid gallium is 6.1 g/cm^3. Is the temperature at the triple point higher or lower than the normal melting point? Is the slope of the solid-liquid line for gallium positive or negative?

12.136 A 4.7-L sealed bottle containing 0.33 g of liquid ethanol, C_2H_6O, is placed in a refrigerator and reaches equilibrium with its vapor at −11°C. (a) What mass of ethanol is present in the vapor? (b) When the container is removed and warmed to room temperature, 20.°C, will all the ethanol vaporize? (c) How much liquid ethanol would be present at 0.0°C? The vapor pressure of ethanol is 10. torr at −2.3°C and 40. torr at 19°C.

12.137 On a humid day in New Orleans, the temperature is 22.0°C, and the partial pressure of water vapor in the air is 31.0 torr. The 9000-ton air-conditioning system in the Louisiana Superdome maintains an inside air temperature of 22.0°C also, but a partial pressure of water vapor of 10.0 torr. The volume of air in the dome is 2.4×10^6 m^3, and the total pressure inside and outside the dome are both 1.0 atm. (a) What mass of water (in metric tons) must be removed every time the inside air is completely replaced with outside air? (*Hint:* How many moles of gas are in the dome? How many moles of water vapor? How many moles of dry air? How many moles of outside air must be added to the air in the dome to simulate the composition of outside air?) (b) Find the heat released when this mass of water condenses.

12.138 A cubic unit cell contains atoms of element A at each corner and atoms of element Z on each face. What is the empirical formula of the compound?

12.139 The boiling point of amphetamine, $C_9H_{13}N$, is 201°C at 760 torr and 83°C at 13 torr. What is the concentration (in g/m^3) of amphetamine when it is in contact with 20.°C air?

12.140 Diamond has a face-centered cubic unit cell, with four more C atoms in tetrahedral holes within the cell. Densities of diamonds vary from 3.01 g/cm^3 to 3.52 g/cm^3 because C atoms are missing from some holes. (a) Calculate the unit-cell edge length of the densest diamond. (b) Assuming the cell dimensions are fixed, how many C atoms are in the unit cell of the diamond with the lowest density?

12.141 Is it possible for a salt of formula AB_3 to have a face-centered cubic unit cell of anions with cations in all the eight available holes? Explain.

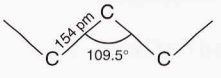
12.142 Substance A has the following properties.

mp at 1 atm:	−20.°C	bp at 1 atm:	85°C
ΔH_{fus}:	180. J/g	ΔH_{vap}:	500. J/g
c_{solid}:	1.0 J/g·°C	c_{liquid}:	2.5 J/g·°C
c_{gas}:	0.5 J/g·°C		

At 1 atm, a 25-g sample of A is heated from −40.°C to 100.°C at a constant rate of 450. J/min. (a) How many minutes does it take to heat the sample to its melting point? (b) How many minutes does it take to melt the sample? (c) Perform any other necessary calculations, and draw a curve of temperature vs. time for the entire heating process.

12.143 An aerospace manufacturer is building a prototype experimental aircraft that cannot be detected by radar. Boron nitride is chosen for incorporation into the body parts, and the boric acid/ammonia method is used to prepare the ceramic material. Given 85.5% and 86.8% yields for the two reaction steps, how much boron nitride can be prepared from 1.00 metric ton of boric acid and 12.5 m^3 of ammonia at 275 K and 3.07×10^3 kPa? Assume that ammonia does *not* behave ideally under these conditions and is recycled completely in the reaction process.

12.144 A sample of polystyrene (repeat unit $C_6H_5CHCH_2$) has a molar mass of 104,160 g/mol. A section of the backbone is shown with the average C—C bond length and angle. (a) Calculate the extended length of the polymer chain. (b) Calculate the radius of gyration of the polymer chain.



12.145 In a body-centered cubic unit cell, the central atom lies on an internal diagonal of the cell and touches the corner atoms. (a) Find the length of the diagonal in terms of *r*, the atomic radius. (b) If the edge length of the cube is *a*, what is the length of a *face* diagonal? (c) Derive an expression for *a* in terms of *r*. (d) How many atoms are in this unit cell? (e) What fraction of the unit cell volume is filled with spheres?

12.146 The ΔH_f^0 of gaseous dimethyl ether (CH_3OCH_3) is −185.4 kJ/mol; the vapor pressure is 1.00 atm at −23.7°C and 0.526 atm at −37.8°C. (a) Calculate ΔH_{vap}^0 of dimethyl ether. (b) Calculate ΔH_f^0 of liquid dimethyl ether.

12.147 The crystal structure of sodium is based on the body-centered cubic unit cell. What is the mass of one unit cell of sodium?

12.148 KF has the same type of crystal structure as NaCl. The unit cell of KF has an edge length of 5.39 Å. Find the density of KF.

12.149 The *intrinsic viscosity* of a polymer chain in a given solvent, $[\eta]_{solvent}$, is a measure of the intermolecular interactions between solvent and polymer. Generally, a larger $[\eta]_{solvent}$ indicates a stronger interaction. Intrinsic viscosities of polymer chains in solution are given by the Mark-Houwink equation, $[\eta]_{solvent} = K\mathcal{M}^a$, where $\mathcal{M}$ is the molar mass of the polymer, and *K* and *a* are constants specific to the polymer and solvent. Use the data below for 25°C to answer the following questions:

Polymer	Solvent	*K* (mL/g)	*a*
Polystyrene	Benzene	9.5×10^{-3}	0.74
	Cyclohexane	8.1×10^{-2}	0.50
Polyisobutylene	Benzene	8.3×10^{-2}	0.50
	Cyclohexane	2.6×10^{-1}	0.70

(a) A polystyrene sample has a molar mass of 104,160 g/mol. Calculate the intrinsic viscosity in benzene and in cyclohexane. Which solvent has stronger interactions with the polymer?

(b) A different polystyrene sample has a molar mass of 52,000 g/mol. Calculate its $[\eta]_{benzene}$. Given a polymer standard of known $\mathcal{M}$, how could you use its measured $[\eta]$ in a given solvent to determine the molar mass of any sample of that polymer?

(c) Compare $[\eta]$ of a polyisobutylene sample [repeat unit $(CH_3)_2CCH_2$] with a molar mass of 104,160 g/mol with that of the polystyrene in part (a). What does this suggest about the solvent-polymer interactions of the two samples?

12.150 At a local convenience store, you purchase a cup of coffee but, at 98.4°C, it is too hot to drink. You add 23.0 g of ice that is −2.2°C to 248 mL of the coffee. What is the final temperature of the coffee? (Assume the heat capacity and density of the coffee are the same as water and the coffee cup is well insulated.)

12.151 One way of purifying gaseous H_2 is to pass it under high pressure through the holes of a metal's crystal structure. Palladium, which adopts a cubic closest packed structure, absorbs more H_2 than any other element and is one of the metals currently used for this purpose. Although the metal-hydrogen interaction is unclear, it is estimated that the density of absorbed H_2 approaches that of liquid hydrogen (70.8 g/L). What volume (in L) of gaseous H_2, measured at STP, can be packed into the spaces of 1 dm^3 of palladium metal?

Everyday mixtures From mixed paint to brewed tea, mixtures surround us and influence nearly every aspect of daily life. In this chapter, you'll see why mixtures form, how we quantify their composition, and some of the remarkably useful ways their physical behavior differs from that of their components.

Parts of Solute by Parts of Solution
Interconverting Concentration Terms

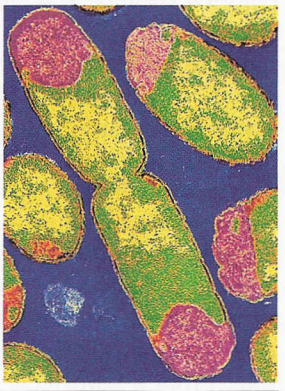
13.6 **Colligative Properties of Solutions**
Nonvolatile Nonelectrolyte Solutions
Solute Molar Mass
Volatile Nonelectrolyte Solutions
Strong Electrolyte Solutions

13.7 **The Structure and Properties of Colloids**

Nearly all the gases, liquids, and solids that make up our world are *mixtures*—two or more substances physically mixed together but not chemically combined. Synthetic mixtures, such as glass and soap, usually contain relatively few components, whereas natural mixtures, such as seawater and soil, are more complex, often containing more than 50 different substances. Living mixtures, such as trees and students, are the most complex—even a simple bacterial cell contains well over 5000 different compounds (Table 13.1).

Table 13.1 Approximate Composition of a Bacterium

Substance	Mass % of Cell	Number of Types	Number of Molecules
Water	~70	1	5×10^{10}
Ions	1	20	?
Sugars*	3	200	3×10^{8}
Amino acids*	0.4	100	5×10^{7}
Lipids*	2	50	3×10^{7}
Nucleotides*	0.4	200	1×10^{7}
Other small molecules	0.2	~200	?
Macromolecules (proteins, nucleic acids, polysaccharides)	23	~5000	6×10^{6}



*Includes precursors and metabolites.

Recall from Chapter 2 that a mixture has two defining characteristics: *its composition is variable,* and *it retains some properties of its components.* In this chapter, we focus on two common types of mixtures: solutions and colloids. *A solution is a homogeneous mixture,* one with no boundaries separating its components; thus, a solution exists as one phase. A *heterogeneous mixture* has two or more phases. The pebbles in concrete or the bubbles in champagne are visible indications that these are heterogeneous mixtures. A *colloid* is a heterogeneous mixture in which one component is dispersed as very fine particles in another component, so distinct phases are not easy to see. Smoke and milk are colloids. The essential difference between a solution and a colloid is one of particle *size:*

- In a solution, the particles are individual atoms, ions, or small molecules.
- In a colloid, the particles are typically either macromolecules or aggregations of small molecules that are not large enough to settle out.

As you'll see later in the chapter, these molecular-scale differences result in many observable differences.

IN THIS CHAPTER . . . We examine intermolecular forces between solute and solvent and their role in forming solutions. To predict solubility in different solvents, we focus on the dual polarity of simple organic compounds and then apply this idea to biological macromolecules and the cell membrane. We investigate why a substance dissolves in terms of the enthalpy of solution and the dispersal of matter that occurs during the solution process. To understand the second factor, the concept of entropy is introduced. We examine the equilibrium nature of solubility and see how temperature and pressure affect it. Various concentration units are discussed and interconverted. You'll see why the physical properties of solutions are different from those of pure substances and how we employ those differences. Then we investigate colloids and apply solution and colloid chemistry to the purification of water.

Concepts & Skills to Review

before you study this chapter

- classification and separation of mixtures (Section 2.9)
- calculations involving mass percent (Section 3.1) and molarity (Section 3.5)
- electrolytes; water as a solvent (Sections 4.1 and 12.5)
- mole fraction and Dalton's law of partial pressures (Section 5.4)
- types of intermolecular forces and the concept of polarizability (Section 12.3)
- distinction between monomer and polymer (Section 12.7)
- vapor pressure of liquids (Section 12.2)

13.1 TYPES OF SOLUTIONS: INTERMOLECULAR FORCES AND SOLUBILITY

We often describe solutions in terms of one substance dissolving in another: the **solute** dissolves in the **solvent.** Usually, *the solvent is the most abundant component* of a given solution. In some cases, however, the substances are **miscible,** that is, soluble in each other in any proportion; in such cases, it may not be meaningful to call one the solute and the other the solvent.

The **solubility** (*S*) of a solute is the maximum amount that dissolves in a fixed quantity of a particular solvent at a specified temperature, given that excess solute is present. Different solutes have different solubilities. For example, for sodium chloride (NaCl), S = 39.12 g/100. mL water at 100.°C, whereas for silver chloride (AgCl), S = 0.0021 g/100. mL water at 100.°C. Obviously, NaCl is much more soluble in water than AgCl is. (Solubility is also expressed in other units, as you'll see later.) Although solubility has a quantitative meaning, *dilute* and *concentrated* are qualitative terms that refer to the *relative amounts of solute:* a dilute solution contains much less dissolved solute than a concentrated one.

From everyday experience, you know that some solvents can dissolve a given solute, whereas others can't. For example, butter doesn't dissolve in water, but it does in cooking oil. A major factor determining whether a solution forms is the relative strength of the intermolecular forces within and between solute and solvent. Experience shows that *substances with similar types of intermolecular forces dissolve in each other.* This fact is summarized in the rule-of-thumb **like dissolves like.** From a knowledge of these forces, we can often predict which solutes will dissolve in which solvents.

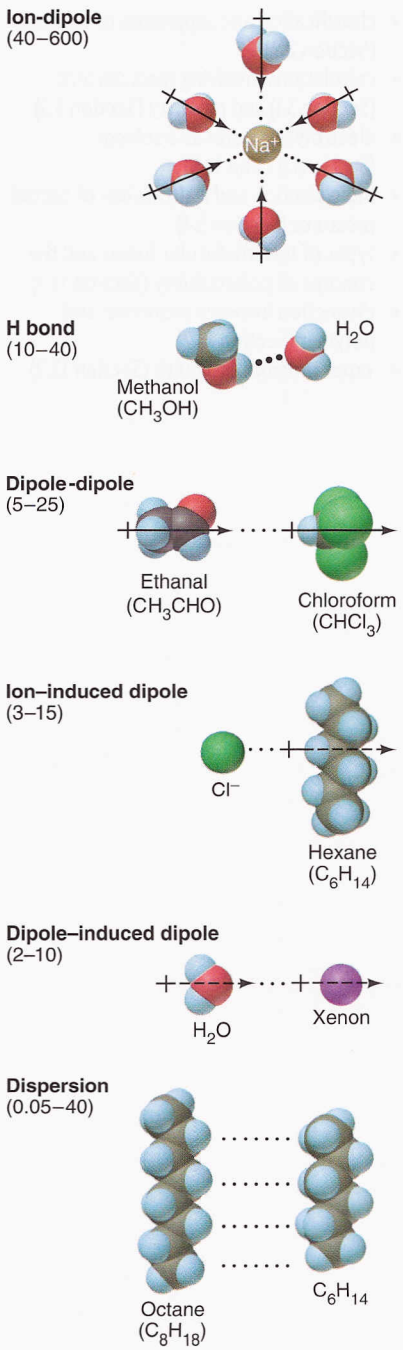


Figure 13.1 The major types of intermolecular forces in solutions. Forces are listed in decreasing order of strength (with values in kJ/mol), and an example of each is shown with space-filling models.

Intermolecular Forces in Solution

All the intermolecular forces we discussed in Section 12.3 for pure substances also occur between solute and solvent in solutions (Figure 13.1):

1. *Ion-dipole forces* are the principal force involved in the solubility of ionic compounds in water. When a salt dissolves, each ion on the crystal's surface attracts the oppositely charged end of the water dipole. These attractive forces overcome those between the ions and break down the crystal structure. As each ion becomes separated, more water molecules cluster around it in **hydration shells** (Figure 13.2). Recent evidence shows that water's normal H bonding is altered only among molecules in the closest hydration shell. These molecules are H bonded to others slightly farther away, which are in turn H bonded to other molecules in the bulk solvent. It's important to remember that this process does not lead to a jumble of ions and water molecules; rather, there is less freedom of motion for molecules in the closest hydration shell. For monatomic ions, the number of water molecules in the closest shell depends on the ion's size. Four water molecules can fit tetrahedrally around small ions, such as Li^+, while larger ions, such as Na^+ and F^-, have six water molecules surrounding them octahedrally.

2. *Hydrogen bonding* is especially important in aqueous solution. In fact, it is a primary factor in the solubility in water—and, thus, cell fluid—of many oxygen- and nitrogen-containing organic and biological compounds, such as alcohols, sugars, amines, and amino acids. (Recall that O and N are small and electronegative, so their bound H atoms are partially positive and can get very close to the O of H_2O.)

3. *Dipole-dipole forces,* in the absence of H bonding, account for the solubility of polar organic molecules, such as acetaldehyde (CH_3CHO), in polar, nonaqueous solvents like chloroform ($CHCl_3$).

4. **Ion–induced dipole forces** are one of two types of *charge-induced dipole forces*, which rely on the polarizability of the components. They result when an ion's charge distorts the electron cloud of a nearby nonpolar molecule. This type of force plays an essential biological role in the binding between the Fe^{2+} ion in

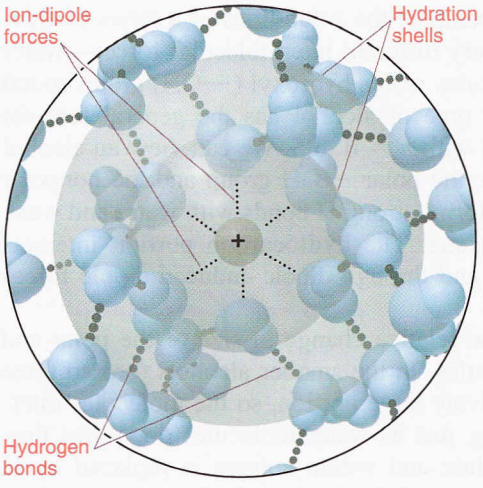

Figure 13.2 Hydration shells around an aqueous ion. When an ionic compound dissolves in water, ion-dipole forces orient water molecules around the separated ions to form hydration shells. The cation shown here is octahedrally surrounded by six water molecules, which form H bonds with water molecules in the next hydration shell, and those form H bonds with others farther away.

hemoglobin and an O_2 molecule in the bloodstream. Because an ion increases the magnitude of any nearby dipole, ion–induced dipole forces also contribute to the solubility of salts in less polar solvents, such as LiCl in ethanol.

5. **Dipole–induced dipole forces,** also based on polarizability, are weaker than the ion–induced dipole forces because the magnitude of the charge is smaller (Coulomb's law). They arise when a polar molecule distorts the electron cloud of a nearby nonpolar molecule. The solubility in water, limited though it is, of atmospheric O_2, N_2, and the noble gases is due in large part to these forces. Paint thinners and grease solvents also function through dipole–induced dipole forces.

6. *Dispersion forces* contribute to the solubility of all solutes in all solvents, but they are the *principal* type of intermolecular force in solutions of nonpolar substances, such as petroleum and gasoline.

As you'll see in Section 13.2, these intermolecular forces are also responsible for keeping cellular macromolecules in their biologically active shapes.

Liquid Solutions and the Role of Molecular Polarity

Solutions can be gaseous, liquid, or solid. In general, *the physical state of the solvent determines the physical state of the solution.* We focus on liquid solutions because they are by far the most common and important.

From cytoplasm to tree sap, gasoline to cleaning fluid, iced tea to urine, solutions in which the solvent is a liquid are familiar in everyday life. Water is the most prominent solvent because it is so common and dissolves so many ionic and polar substances. But there are many other liquid solvents, and their polarity ranges from very polar to nonpolar.

Liquid-Liquid and Solid-Liquid Solutions Many salts dissolve in water because the strong ion-dipole attractions that water molecules form with the ions are very similar to the strong attractions between the ions themselves and, therefore, can *substitute* for them. The same salts are insoluble in hexane (C_6H_{14}) because the weak ion–induced dipole forces their ions could form with the nonpolar molecules of this solvent *cannot* substitute for attractions between the ions. Similarly, oil does not dissolve in water because the weak dipole–induced dipole forces between oil and water molecules cannot substitute for the strong H bonds between water molecules. Oil *does* dissolve in hexane, however, because the dispersion forces in one substitute readily for the dispersion forces in the other. Thus, for a solution to form, "like dissolves like" means that the forces created between solute and solvent must be *comparable in strength* to the forces destroyed within both the solute and the solvent.

To examine this idea further, let's compare the solubilities of a series of alcohols in two solvents that act through very different intermolecular forces—water and hexane. Alcohols are organic molecules with a hydroxyl (—OH) group bound to a hydrocarbon group. The simplest type of alcohol has the general formula $CH_3(CH_2)_nOH$; we'll consider alcohols with $n = 0$ to 5. We can view an alcohol molecule as consisting of two portions: the polar —OH group and the nonpolar hydrocarbon chain. The —OH portion forms strong H bonds with water and weak dipole–induced dipole forces with hexane. The hydrocarbon portion interacts through dispersion forces with hexane and through dipole–induced dipole forces with water.

In Table 13.2, the models show the relative change in size of the polar and nonpolar portions of the alcohol molecules. In the smaller alcohols (one to three carbons), the hydroxyl group is a relatively large portion, so the molecules interact with each other through H bonding, just as water molecules do. When they mix with water, H bonding within solute and within solvent is replaced by H bonding *between* solute and solvent (Figure 13.3). As a result, these smaller alcohols are miscible with water.

Water solubility decreases dramatically for alcohols larger than three carbons, and those with chains longer than six carbons are insoluble in water. For these larger alcohols to dissolve, the nonpolar chains have to move between the water molecules, substituting their weak attractions with those water molecules for strong H bonds among the water molecules themselves. The —OH portion of the alcohol does form H bonds to water, but these don't outweigh the H bonds between water molecules that have to break to make room for the hydrocarbon portion.

Table 13.2 shows that the opposite trend occurs with hexane. Now the major solute-solvent *and* solvent-solvent interactions are dispersion forces. The weak

Table 13.2 Solubility* of a Series of Alcohols in Water and Hexane

Alcohol	Model	Solubility in Water	Solubility in Hexane
CH_3OH (methanol)		∞	1.2
CH_3CH_2OH (ethanol)		∞	∞
$CH_3(CH_2)_2OH$ (1-propanol)		∞	∞
$CH_3(CH_2)_3OH$ (1-butanol)		1.1	∞
$CH_3(CH_2)_4OH$ (1-pentanol)		0.30	∞
$CH_3(CH_2)_5OH$ (1-hexanol)		0.058	∞

*Expressed in mol alcohol/1000 g solvent at 20°C.

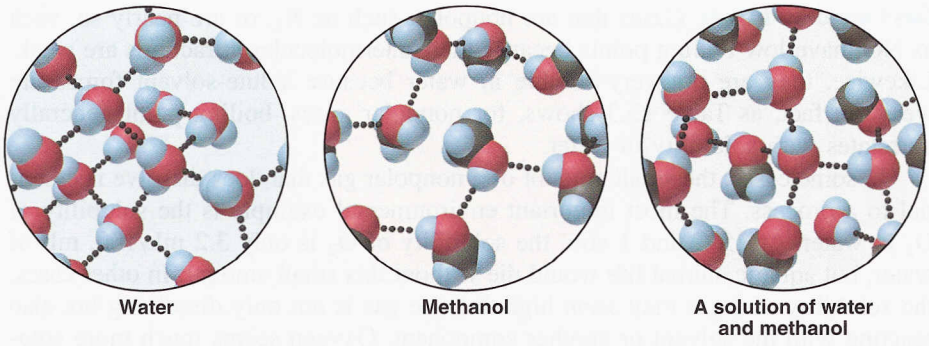

Figure 13.3 Like dissolves like: solubility of methanol in water. The H bonds in water and in methanol are similar in type and strength, so they can substitute for one another. Thus, methanol is soluble in water; in fact, the two substances are miscible.

forces between the —OH group of methanol (CH_3OH) and hexane cannot substitute for the strong H bonding among CH_3OH molecules, so the solubility of methanol in hexane is relatively low. In any larger alcohol, however, dispersion forces become increasingly more important, and these *can* substitute for dispersion forces in pure hexane; thus, solubility increases. With no strong solvent-solvent forces to be replaced by weak solute-solvent forces, even the two-carbon chain of ethanol has strong enough solute-solvent attractions to be miscible in hexane.

Many other organic molecules have polar and nonpolar portions, and the predominance of one portion or the other determines their solubility in different solvents. For example, carboxylic acids and amines behave very much like alcohols. Thus, methanoic acid (HCOOH, formic acid) and methanamine (CH_3NH_2) are miscible in water and much less soluble in hexane, whereas hexanoic acid [$CH_3(CH_2)_4COOH$] and 1-hexanamine [$CH_3(CH_2)_5NH_2$] are slightly soluble in water and very soluble in hexane.

A "Greener" Approach to Working with Organic Solvents Volatile organic solvents have many uses in paints and other coatings, in cleaning agents, and in propellants for hairspray, cooking oils, lubricants, and so forth. But they also play a role in smog formation and may have adverse health effects. These concerns have led to the development of "greener" processes, such as the use of nonvolatile organic solvents, nonaqueous ionic liquid solvents, supercritical fluids, and solvent-free and water-based methods. With the implementation of these approaches, atmospheric emissions and worker exposure are greatly reduced.

SAMPLE PROBLEM 13.1 Predicting Relative Solubilities of Substances

Problem Predict which solvent will dissolve more of the given solute:
(a) Sodium chloride in methanol (CH_3OH) or in 1-propanol ($CH_3CH_2CH_2OH$)
(b) Ethylene glycol ($HOCH_2CH_2OH$) in hexane ($CH_3CH_2CH_2CH_2CH_2CH_3$) or in water
(c) Diethyl ether ($CH_3CH_2OCH_2CH_3$) in water or in ethanol (CH_3CH_2OH)

Plan We examine the formulas of the solute and each solvent to determine the types of forces that could occur. A solute tends to be more soluble in a solvent whose intermolecular forces are similar to, and therefore can substitute for, its own.

Solution **(a)** Methanol. NaCl is an ionic solid that dissolves through ion-dipole forces. Both methanol and 1-propanol contain a polar —OH group, but 1-propanol's longer hydrocarbon chain can form only weak forces with the ions, so it is less effective at substituting for the ionic attractions in the solute.

(b) Water. Ethylene glycol molecules have two —OH groups, so the molecules interact with each other through H bonding. They are more soluble in H_2O, whose H bonds can substitute for their own H bonds better than the dispersion forces in hexane can.

(c) Ethanol. Diethyl ether molecules interact with each other through dipole-dipole and dispersion forces and can form H bonds to both H_2O and ethanol. The ether is more soluble in ethanol because that solvent can form H bonds *and* substitute for the ether's dispersion forces. Water, on the other hand, can form H bonds with the ether, but it lacks any hydrocarbon portion, so it forms much weaker dispersion forces with that solute.

FOLLOW-UP PROBLEM 13.1 Which solute is more soluble in the given solvent?
(a) 1-Butanol ($CH_3CH_2CH_2CH_2OH$) or 1,4-butanediol ($HOCH_2CH_2CH_2CH_2OH$) in water
(b) Chloroform ($CHCl_3$) or carbon tetrachloride (CCl_4) in water

Table 13.3 Correlation Between Boiling Point and Solubility in Water

Gas	Solubility (*M*)*	bp (K)
He	4.2×10^{-4}	4.2
Ne	6.6×10^{-4}	27.1
N_2	10.4×10^{-4}	77.4
CO	15.6×10^{-4}	81.6
O_2	21.8×10^{-4}	90.2
NO	32.7×10^{-4}	121.4

*At 273 K and 1 atm.

Gas-Liquid Solutions Gases that are nonpolar, such as N_2, or are nearly so, such as NO, have low boiling points because their intermolecular attractions are weak. Likewise, they are not very soluble in water because solute-solvent forces are weak. In fact, as Table 13.3 shows, for nonpolar gases, boiling point generally correlates with solubility in water.

In some cases, the small amount of a nonpolar gas that does dissolve is essential to a process. The most important environmental example is the solubility of O_2 in water. At 25°C and 1 atm, the solubility of O_2 is only 3.2 mL/100. mL of water, but aquatic animal life would die without this small amount. In other cases, the solubility of a gas may *seem* high, but the gas is not only dissolving but also reacting with the solvent or another component. Oxygen seems much more soluble in blood than in water because O_2 molecules are continually bonding with hemoglobin molecules in red blood cells. Similarly, carbon dioxide, which is essential for aquatic plants and coral-reef growth, seems very soluble in water (~81 mL of CO_2/100. mL of H_2O at 25°C and 1 atm) because it is reacting, in addition to simply dissolving:

$$CO_2(g) + H_2O(l) \longrightarrow H^+(aq) + HCO_3^-(aq)$$

Gas Solutions and Solid Solutions

Despite the central place of liquid solutions in chemistry, gaseous solutions and solid solutions also have vital importance and numerous applications.

Gas-Gas Solutions *All gases are infinitely soluble in one another.* Air is the classic example of a gaseous solution, consisting of about 18 gases in widely differing proportions. Anesthetic gas proportions are finely adjusted to the needs of the patient and the length of the surgical procedure. The ratios of components in many industrial gas mixtures, such as CO:H_2 in syngas production or N_2:H_2 in ammonia production, are controlled to optimize product yield under varying conditions of temperature and pressure.

Gas-Solid Solutions *When a gas dissolves in a solid, it occupies the spaces between the closely packed particles.* Hydrogen gas can be purified by passing an impure sample through a solid metal such as palladium. Only the H_2 molecules are small enough to enter the spaces between the Pd atoms, where they form Pd—H covalent bonds. Under high H_2 pressure, the H atoms are passed along the Pd crystal structure and emerge from the solid as H_2 molecules.

The ability of gases to penetrate a solid also has disadvantages. The electrical conductivity of copper, for example, is drastically reduced by the presence of O_2, which dissolves into the crystal structure and reacts to form copper(I) oxide. High-conductivity copper is prepared by melting and recasting the copper in an O_2-free atmosphere.

Solid-Solid Solutions Because solids diffuse so little, their mixtures are usually heterogeneous, as in gravel mixed with sand. Some solid-solid solutions can be formed by melting the solids and then mixing them and allowing them to freeze. Many **alloys,** mixtures of elements that have an overall metallic character, are examples of solid-solid solutions (although several common alloys have microscopic heterogeneous regions). In *substitutional* alloys, such as brass (Figure 13.4A) and sterling silver, atoms of another element substitute for some atoms of the main element in the structure. In *interstitial* alloys, atoms of another element (often a nonmetal) fill some of the spaces *(interstices)* between atoms of the main element. For example, some forms of carbon steel (Figure 13.4B) are interstitial alloys of iron with a small amount of carbon.

Waxes are another familiar type of solid-solid solution. Most waxes are amorphous solids that may contain small regions of crystalline regularity. A natural *wax* is a solid of biological origin that is insoluble in water but dissolves in non-

Figure 13.4 The arrangement of atoms in two types of alloys. A, Brass is a substitutional alloy in which zinc atoms substitute for copper atoms at many of copper's face-centered cubic packing sites. **B,** Some forms of carbon steel are interstitial alloys in which carbon atoms lie in the holes (interstices) of the body-centered cubic crystal structure of iron.

polar solvents. Many plants have waxy coatings on their leaves and fruit to prevent evaporation of interior water.

SECTION SUMMARY

Solutions are homogeneous mixtures consisting of a solute dissolved in a solvent through the action of intermolecular forces. The solubility of a solute in a given amount of solvent is the maximum amount, with excess solute present, that can dissolve at a specified temperature. (For gaseous solutes, the pressure must be specified also.) In addition to the intermolecular forces that exist in pure substances, ion-dipole, ion–induced dipole, and dipole–induced dipole forces occur in solution. If similar intermolecular forces occur in solute and solvent, a solution will likely form ("like dissolves like"). When ionic compounds dissolve in water, the ions become surrounded by hydration shells of H-bonded water molecules. Solubility of organic molecules in various solvents depends on their polarity and the extent of their polar and nonpolar portions. The solubility of nonpolar gases in water is low because of weak intermolecular forces. Gases are miscible with one another and dissolve in solids by fitting into spaces in the crystal structure. Solid-solid solutions, such as alloys and waxes, form when the components are mixed while molten.

Waxes for Home and Auto Beeswax, the remarkable structural material that bees secrete to build their combs, is a complex mixture of fatty acids, long-chain carboxylic acids, and hydrocarbons in which some of the molecules contain chains more than 40 carbon atoms long. Carnauba wax, from a South American palm, is a mixture of compounds, each consisting of a fatty acid bound to a long-chain alcohol. It is hard but forms a thick gel in nonpolar solvents, perfect for car waxes.

13.2 INTERMOLECULAR FORCES AND BIOLOGICAL MACROMOLECULES

The forces responsible for solutes dissolving in solvents also play a fundamental role in maintaining the complex three-dimensional shapes of cellular biopolymers: proteins, nucleic acids, and polysaccharides. The structures of these molecules, and that of the cell membrane itself, can be understood through two simple ideas involving intermolecular forces: (1) polar and ionic groups interact with the surrounding cellular water, while nonpolar groups do not, and (2) distant groups on a large molecule are often close enough to interact through intermolecular forces.

In this section, we'll see how these forces stabilize the three types of biological macromolecules and the cell membrane; in Chapter 15, we'll see the reactions that form these molecules and how their structure is crucial to their function.

The Structures of Proteins

Proteins are unbranched polymers formed from monomers called **amino acids,** organic compounds with amine ($—NH_2$) and carboxyl (—COOH) groups in the same molecule. Proteins range from about 50 amino acids ($\mathcal{M} \approx 5\times10^3$ g/mol) to several thousand ($\mathcal{M} \approx 5\times10^5$ g/mol). *Protein shapes are determined completely by the sequence of amino acids in the chain.* Some proteins have few amino acids

in repeating patterns, and thus, extended helical or sheetlike shapes. These function to give structure to hair, skin, and so forth. Others have many more types of amino acids and more complex, globular shapes. These function as antibodies that defend against infection, enzymes that speed metabolic reactions, membrane gates and pumps that control ion concentrations in the cell, and so forth. Let's see how the amino acid composition influences the shapes of globular proteins.

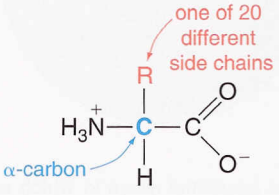

Figure 13.5 The physiological form of an amino acid. Under physiological conditions, amino acids have charged groups. There are about 20 different side chains.

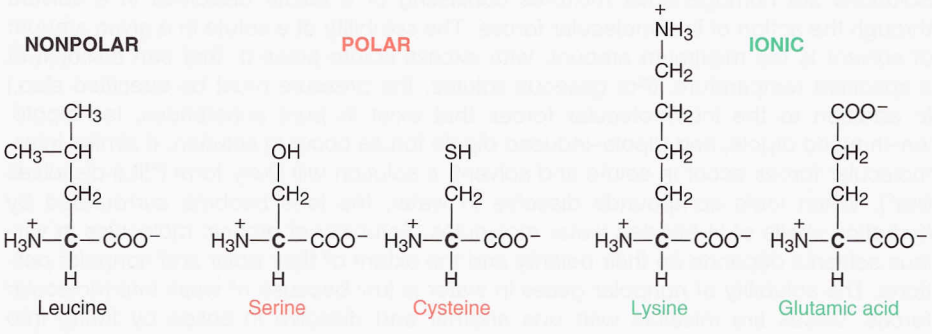
The Polarity of Amino-Acid Side Chains In the cell, an individual amino acid has four groups bonded to its α-carbon (Figure 13.5): charged carboxyl ($—COO^-$) and amine ($—NH_3^+$) groups, an H atom, and a *side chain*, which ranges from an H atom to a two-ringed C_9H_8N group. The *peptide* bond is the covalent linkage between amino acids in a protein and is formed between the carboxyl group of one amino acid and the amine group of the next. (We discuss amino acid structures and details of peptide bond formation in Chapter 15.)

In essence, then, the backbone of a protein consists of an α-*carbon bonded to a peptide bond, which is bonded to the next* α-*carbon bonded to the next peptide bond,* and so forth, with the various side chains dangling off the α-carbons on alternate sides of the chain (Figure 13.6). Globular proteins are made up of about 20 different types of amino acids, each characterized by its particular side chain. The simple classification of amino acids we use here focuses on their polarity and/or charge: nonpolar, polar, and ionic. A few examples are



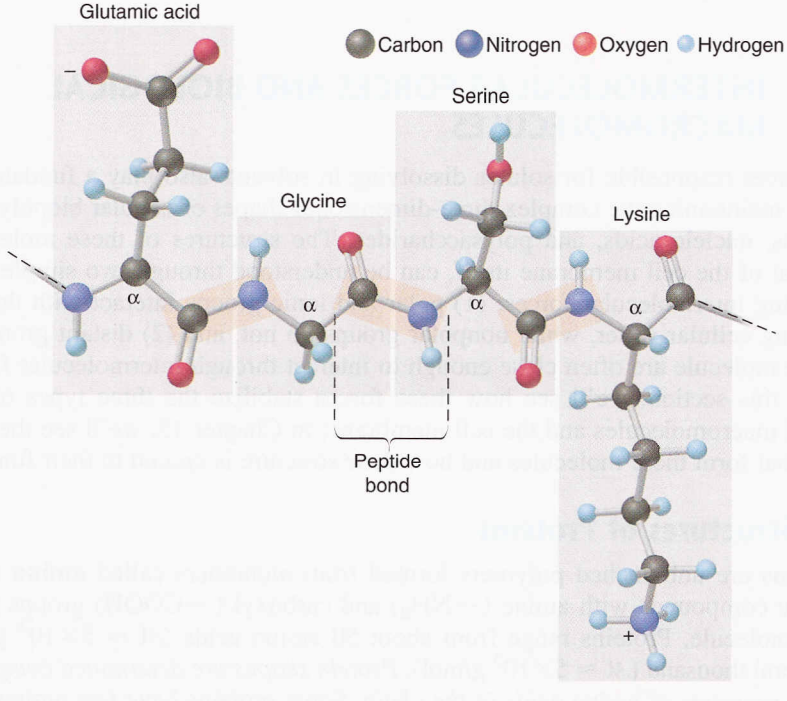


Figure 13.6 A portion of a polypeptide chain. The peptide bond holds the monomers together in a protein. Three peptide bonds (*orange screens*) joining four amino acids (*gray screens*) occur in this portion of a polypeptide chain. Note the repeating pattern of the chain: peptide bond—α-carbon—peptide bond—α-carbon—and so on. Also note that the side chains dangle off the main chain.

Intermolecular Forces and Protein Shape The forces responsible for protein shapes are *the same bonding and intermolecular forces that operate for all molecules*. A long protein chain has many bends, and distant groups of the same molecule end up near enough to interact.

Figure 13.7 depicts the forces operating in proteins dissolved in the aqueous cell medium. (Membrane-bound proteins have an important structural difference, as we'll see shortly.) The covalent peptide bonds create the chain. The —SH ends of two cysteine side chains often form an —S—S— bond, a covalent *disulfide bridge* that brings together distant parts of the chain. Polar and ionic side chains usually protrude into the surrounding cell fluid, interacting with water through ion-dipole forces and H bonds. But sometimes oppositely charged ends of ionic side chains lie near each other, and the $-COO^-$ and $-NH_3^+$ groups form an electrostatic *salt link* (or *ion pair*), which secures the chain's bends. Helical and sheetlike segments arise from *H bonds between the C=O of one peptide bond and the N—H of another.* Other H bonds involving atoms in peptide bonds or in side chains act to keep distant portions of the chain near each other. Nonpolar side chains interact through dispersion forces within the nonaqueous protein interior. Thus, through the influence of intermolecular forces among the protein's side chains, *soluble proteins have polar-ionic exteriors and nonpolar interiors.*

A protein's shape is so important because, as we emphasize in Chapter 15, *the amino acid sequence determines the protein's shape, and the shape determines its function.*

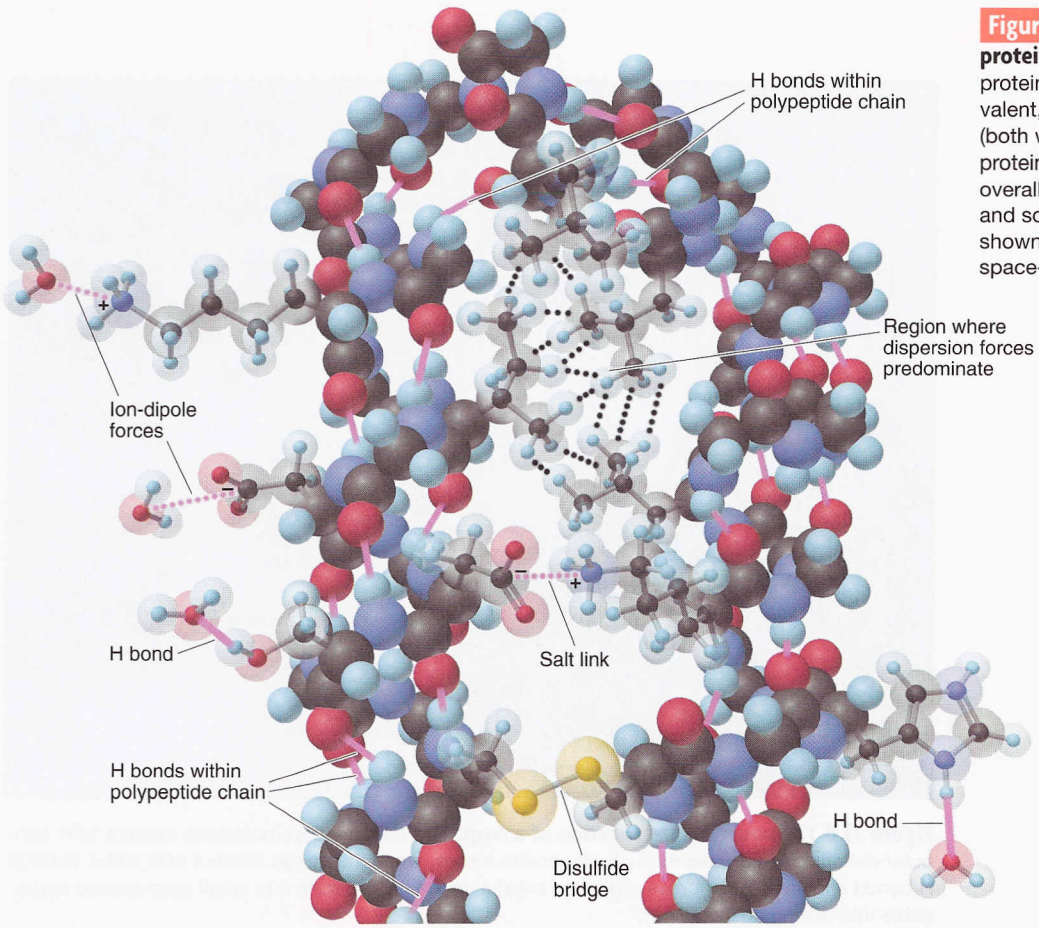

Figure 13.7 The forces that maintain protein structure. A portion of a general protein shows that a combination of covalent, ionic, and intermolecular forces (both within the protein and between the protein and water) is responsible for the overall protein shape. (Water molecules and some amino-acid side chains are shown as ball-and-stick models within a space-filling contour.)

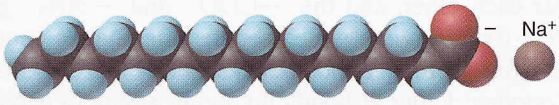
The Structure of the Cell Membrane

The dual polarity that we discussed earlier with reference to solubility can help us understand the function of systems as diverse as soaps, antibiotics, and cell membranes.

The Dual Polarity of Soaps and Detergents A **soap** is the salt of a strong base (metal hydroxide) and a *fatty acid*, a carboxylic acid with a long hydrocarbon chain. A typical soap molecule has an even number of carbon atoms, and is usually made up of a nonpolar "tail" 15–19 carbons long and a polar-ionic "head" consisting of the $—COO^-$ group and a cation. For example, sodium stearate, $CH_3(CH_2)_{16}COONa$, is a major component of many bar soaps:



Sodium stearate $C_{17}H_{35}COONa$

When grease on your hands or clothes is immersed in soapy water, the nonpolar tails of the soap molecules interact with the nonpolar grease molecules through dispersion forces, while the polar-ionic heads interact with the water through ion-dipole forces and H bonds. Agitation creates tiny aggregates of grease molecules with embedded soap molecules, whose polar-ionic heads stick into the water. These aggregates are flushed away by added water (Figure 13.8). Detergents have a similar structure of nonpolar tail and polar-ionic head, but they typically consist of an amine with four hydrocarbon groups, which give the N a positive charge, and an inorganic anion (see Figure 15.17, p. 642).

The Hardness and Softness of Soaps
The cation of a soap influences its properties greatly. Lithium soaps are hard and high melting and are used in car lubricants. Softer, more water-soluble sodium soaps are used as common bar soap. Potassium soaps are low melting and used as liquid soaps. The insolubility of calcium soaps explains why it is difficult to clean clothes in hard water, which typically contains Ca^{2+} ions (see Chemical Connections, p. 529).

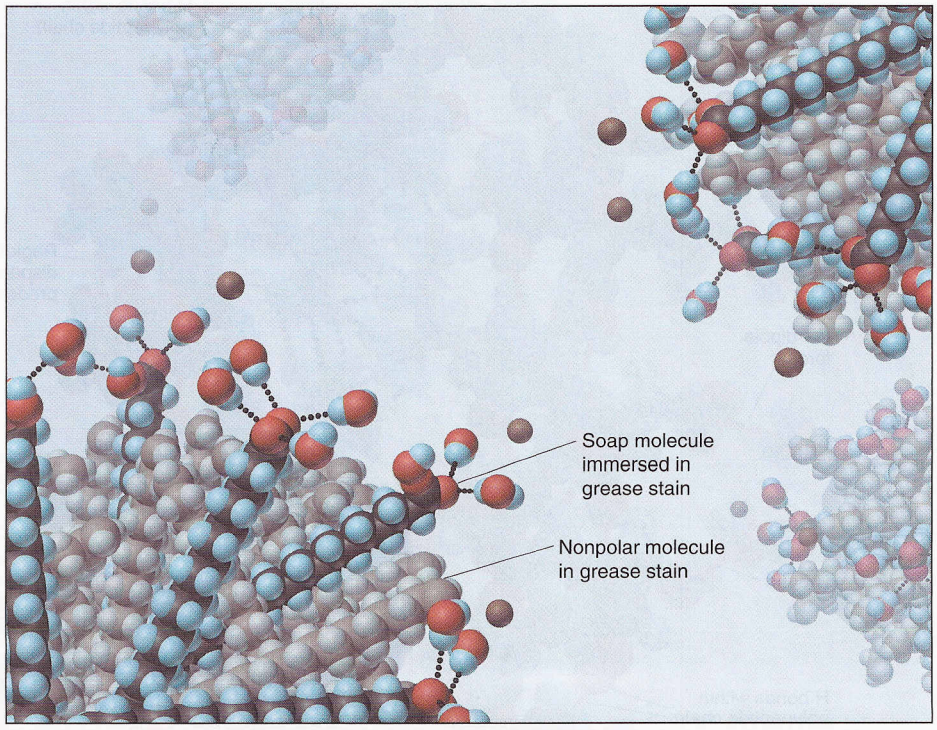


Figure 13.8 The structure and function of a soap. The tails of soap molecules interact with nonpolar molecules in grease through dispersion forces, while the heads interact with water through H bonds and ion-dipole forces. Agitation breaks up the grease stain into small soap-grease aggregates that rinsing flushes away.

The Lipid Bilayer The most abundant molecules in the cell membranes of most species are *phospholipids*. They consist of two long fatty acid chains and a charged organophosphate group all linked to glycerol, a three-carbon trialcohol. Thus, as Figure 13.9 shows, phospholipids, like soaps, have a polar-ionic head and a nonpolar tail.

In water, phospholipids undergo a remarkable self-assembly into an extended sheetlike double layer of molecules, called a **lipid bilayer.** On each surface of the bilayer, the charged heads face the water, and within the interior of the bilayer, the nonpolar tails face each other. So that the tails at the ends of the bilayer are not exposed to the aqueous surroundings, the bilayer tends to close on itself. In the laboratory, bilayers can be made to form spherical vesicles that trap water inside. The result is an energetically favorable structure that optimizes the various intermolecular forces: ion-dipole forces between polar heads and water inside and out, dispersion forces between nonpolar tails within the bilayer, and minimum contact between nonpolar tails and water. Experiments show that the lipid bilayer is impermeable to ions and most polar molecules, including water.

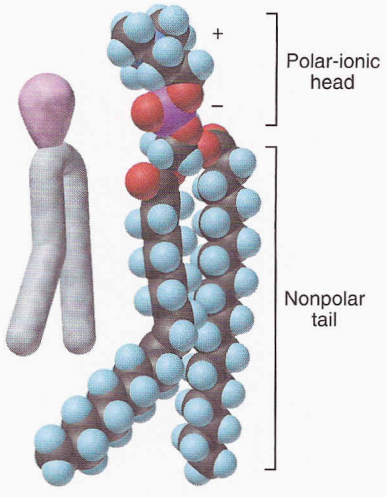

Figure 13.9 Membrane phospholipids. The phospholipids found in cell membranes all have similar shapes, with a polar-ionic head and a nonpolar tail; lecithin (phosphatidylcholine) is shown here. The purple-and-gray shape is a simplified representation of the structure.

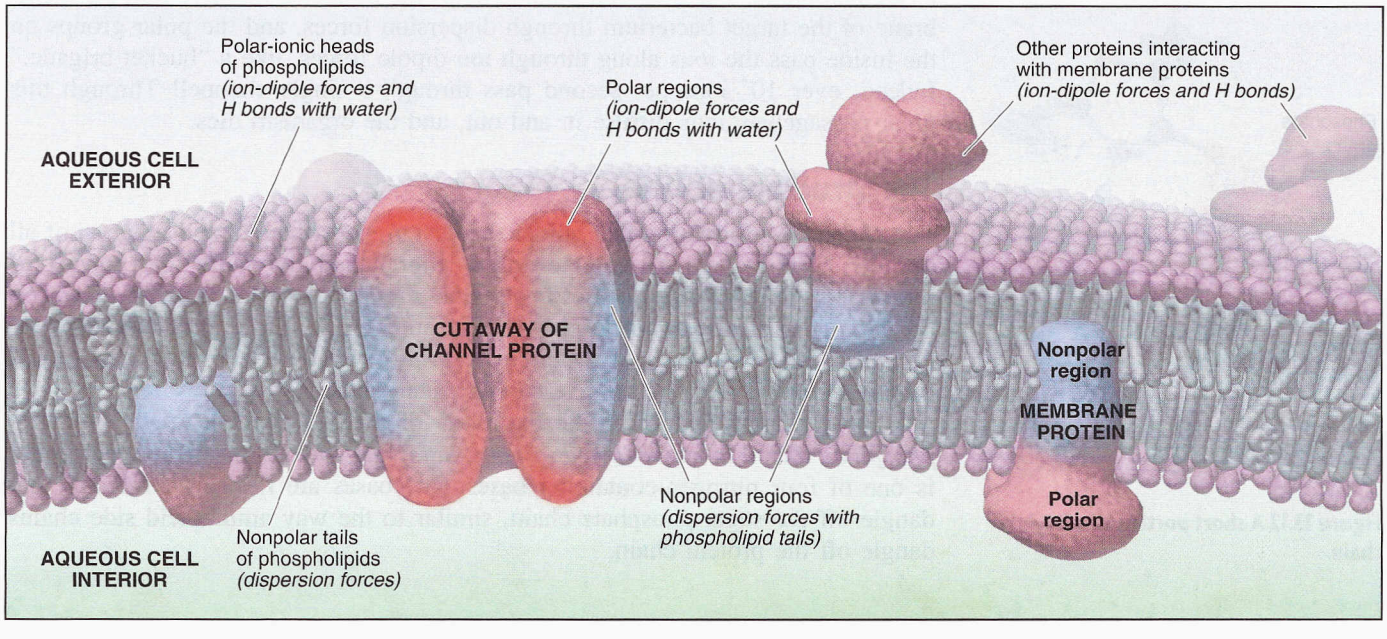
Structure of the Cell Membrane The cell membrane is a perfect example of the effect of intermolecular forces in a complex biological assembly. A typical animal cell membrane is about 8 nm thick and consists of the phospholipid bilayer embedded with various proteins that may comprise as much as 50% by mass of the membrane. Depending on the type of cell, membrane proteins function as pumps that actively move ions and specific molecules in or out, channels or gates that passively allow ions or molecules in or out, or receptors for small biomolecules (see Chemical Connections, pp. 390–391), or they may be involved in energy production or metabolic reactions.

The structures of membrane proteins differ in a fundamental way from those of the soluble proteins we discussed previously. In soluble proteins, in most cases, *polar groups are found on the exterior* and *nonpolar groups on the interior,* away from water. Studies in many systems, from red blood cells to photosynthetic bacteria, show that membrane proteins have this arrangement partly inverted: *the exterior of the protein region that lies within the lipid bilayer consists of nonpolar amino-acid side chains*. Dispersion forces between these groups and the hydrocarbon tails of the membrane lipids stabilize this orientation (Figure 13.10).

Figure 13.10 Intermolecular forces and membrane structure.



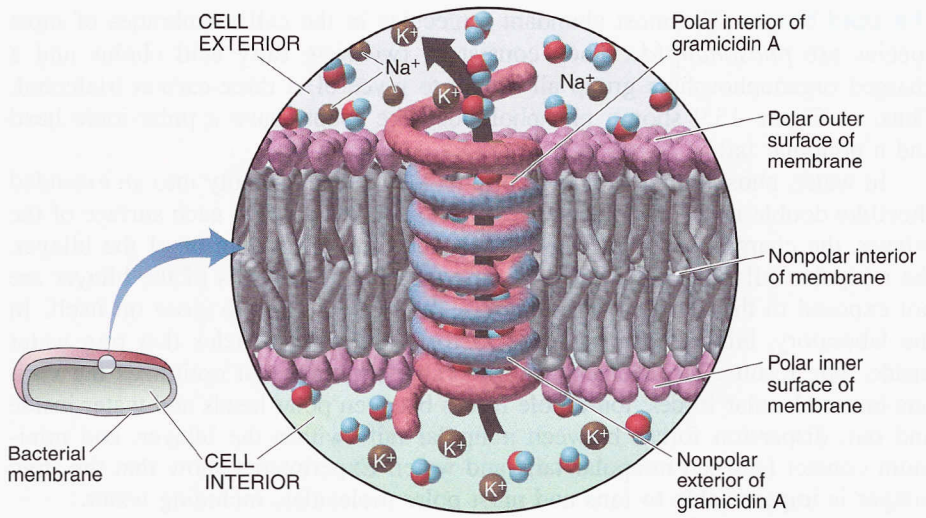


Figure 13.11 The mode of action of an antibiotic. Gramicidin A is a tubelike molecule, nonpolar on the outside and polar on the inside. After dissolving into the nonpolar interior of a bacterial cell membrane via dispersion forces, pairs of gramicidin molecules aligned end to end span the membrane's thickness. Ions diffuse through the polar interior of these molecules, which destroys the cell's ion balance and its segregation of Na^+ outside and K^+ inside.

The Dual Polarity of Antibiotics A clear example of how this orientation of molecules in the cell membrane functions is seen in channel-forming antibiotics. Antibiotics are produced by one microorganism to destroy another, and many have been adapted by medical science to fight bacterial infection.

One function of the membrane is to balance internal and external ion concentrations: Na^+ is excluded from the cell, and K^+ is kept inside. If this ionic segregation is disrupted, the organism dies. Gramicidin A and similar antibiotics disrupt the ion balance by forming a channel in the bacterial membrane through which ions can flow (Figure 13.11). Two helical gramicidin A molecules—with nonpolar groups outside and polar groups inside—lie end to end and span the bacterial membrane. The nonpolar outside helps the molecule dissolve into the membrane of the target bacterium through dispersion forces, and the polar groups on the inside pass the ions along through ion-dipole forces, like a "bucket brigade." Indeed, over 10^7 ions per second pass through a single channel! Through this polar passageway ions diffuse in and out, and the organism dies.

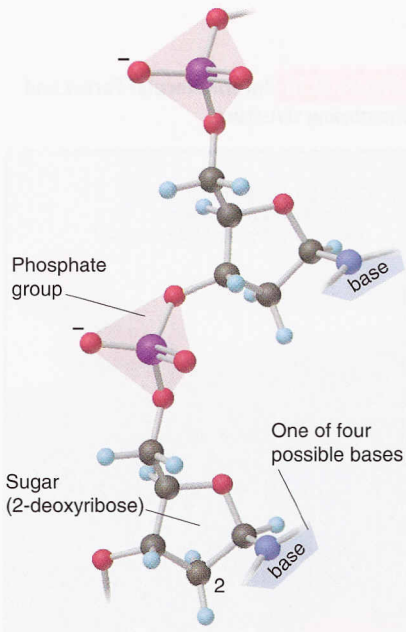

Figure 13.12 A short portion of a DNA chain.

The Structure of DNA

The chemical information that guides the design, construction, and function of all proteins is contained in **nucleic acids,** unbranched polymers that consist of monomers called **mononucleotides.** Each mononucleotide consists of an N-containing base, a sugar, and a phosphate group (Figure 13.12). In DNA (***d****eoxyri-****b****onucleic* ***a****cid*), the sugar is *2-deoxyribose,* in which —H substitutes for —OH on the second C atom of the five-carbon sugar ribose.

The repeating pattern of the backbone of a DNA chain is *sugar linked to phosphate linked to sugar linked to phosphate,* and so on. Attached to each sugar is one of four nitrogen-containing bases. The bases are flat ring structures that dangle off the sugar-phosphate chain, similar to the way amino-acid side chains dangle off the protein chain.

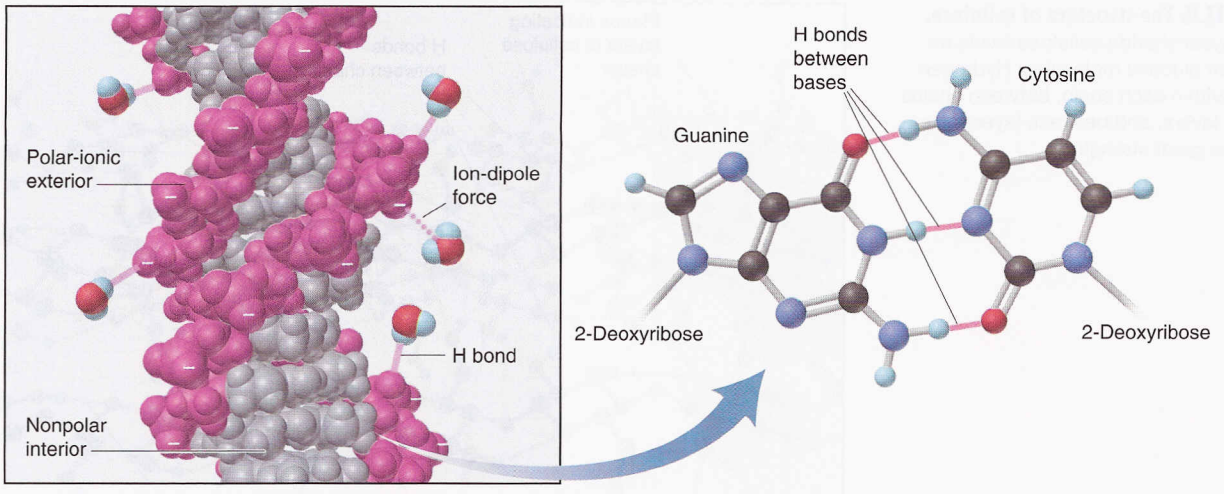

Figure 13.13 The double helix of DNA. In this space-filling segment of DNA (*left*), the polar, negatively charged, sugar-phosphate portion (*pink*) lies on the exterior of the structure and interacts with the aqueous cell fluid through ion-dipole forces and H bonds. Dispersion forces stabilize the stacked, nonpolar bases (*gray*) in the interior. Specific pairs (*right*) are attached by H bonds: a guanine-cytosine pair is shown.

Intermolecular Forces and the Double Helix In the cell nucleus, DNA exists as two chains wrapped around each other in a **double helix** (Figure 13.13). Intermolecular forces play a central role in stabilizing this structure. On the exterior, negatively charged sugar-phosphate chains form ion-dipole and H bonds with the aqueous surroundings. In the interior, the flat, nitrogen-containing bases stack above each other, which allows extensive interaction through dispersion forces. Most important, specific pairs of bases form interchain H bonds; that is, each base in one chain is always H bonded with the same partner base in the other chain. Thus, *the base sequence of one chain is the H-bonded complement of the base sequence of the other.*

A DNA molecule contains millions of H bonds linking bases in these prescribed pairs. The total energy of the H bonds keeps the chains together, but each H bond is weak enough (around 5% of a typical covalent single bond) that a few at a time can break as the chains separate during crucial cellular processes. Linear segments of DNA act as *genes,* chemical blueprints for synthesizing the organism's proteins. In Chapter 15, we'll see how base pairing through H bonding is essential to protein synthesis (the process by which the cell makes its proteins) and DNA replication (the process by which the genes copy themselves during cell division).

The Structure of Cellulose

Strength and energy storage are the two main functions of **polysaccharides,** polymers consisting of monomers called **monosaccharides,** or simple sugars. The three major natural polysaccharides—cellulose, starch, and glycogen—consist entirely of glucose units, but they differ in the way the units are linked and in the extent of crosslinking. In aqueous systems, glucose occurs as a polyhydroxy six-membered cyclic molecule (Figure 13.14).

The same intermolecular forces operate in all three of these polysaccharides, but we'll focus here on cellulose, the most abundant organic chemical on Earth. Cellulose is the only unbranched polysaccharide of the three and consists entirely of long chains of glucose monomers. Picture parallel chains of linked glucose

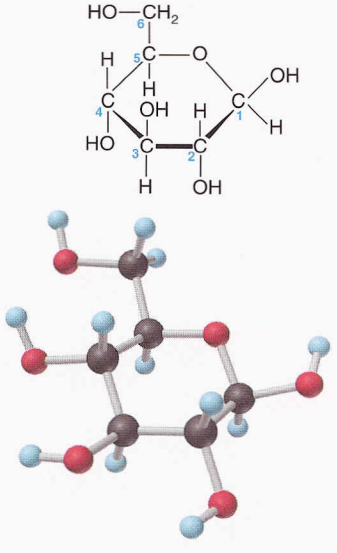

Figure 13.14 The cyclic structure of glucose in aqueous solution.

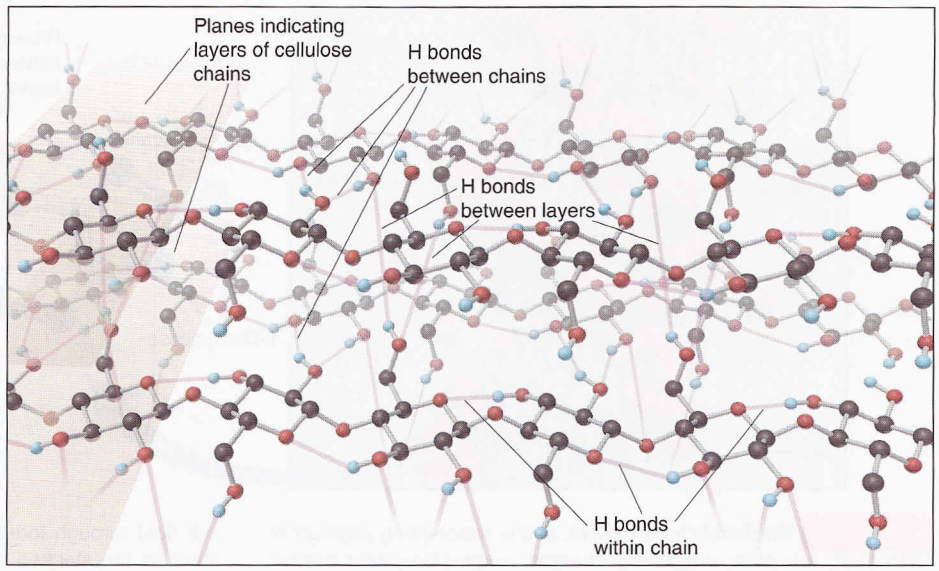

Figure 13.15 The structure of cellulose. The polysaccharide cellulose exists as chains of glucose molecules. Hydrogen bonds within each chain, between chains to form layers, and between layers give cellulose great strength.

units lying next to each other in three dimensions, their —OH groups everywhere (Figure 13.15). The opportunities for dispersion forces and extensive interchain H bonding are enormous. In fact, the great strength of wood is due largely to the countless H bonds among cellulose chains. (We compare the structures of the three polysaccharides in Chapter 15.)

SECTION SUMMARY

Intermolecular forces stabilize the structures of the three biological macromolecules—proteins, nucleic acids, and polysaccharides—and the cell membrane. In soluble proteins, polar and ionic amino-acid side chains face the water, while nonpolar side chains interact with each other in the molecular interior. Soaps have a polar-ionic head and a nonpolar tail that allow them to dissolve grease while interacting with water. Membranes consist of phospholipids that also have two polarities. They assemble in a self-sealing, water-impermeable lipid bilayer. In a cell membrane, the lipid bilayer has embedded proteins whose nonpolar side chains face the surrounding bilayer. Channel-forming antibiotics also have nonpolar exteriors and polar interiors. DNA forms a double helix with a sugar-phosphate, polar-ionic exterior. In the interior, bases H bond in specific pairs and stack through dispersion forces. Cellulose consists of long chains of linked glucose molecules, which interact through extensive H bonding.

13.3 WHY SUBSTANCES DISSOLVE: UNDERSTANDING THE SOLUTION PROCESS

As a qualitative predictive tool, "like dissolves like" is helpful in many cases. As you might expect, this handy *macroscopic* rule is based on the *molecular* interactions that occur between solute and solvent particles. To see *why* like dissolves like, let's break down the solution process conceptually into steps and examine them in terms of changes in *enthalpy* and *entropy* of the system. We discussed enthalpy in Chapter 6 and focus on it first here. The concept of entropy is introduced at the end of this section and treated quantitatively in Chapter 20.

Heats of Solution and Solution Cycles

Picture a general solute and solvent about to form a solution. Both consist of particles attracting each other. For one substance to dissolve in another, three events must occur: (1) solute particles must separate from each other, (2) some solvent

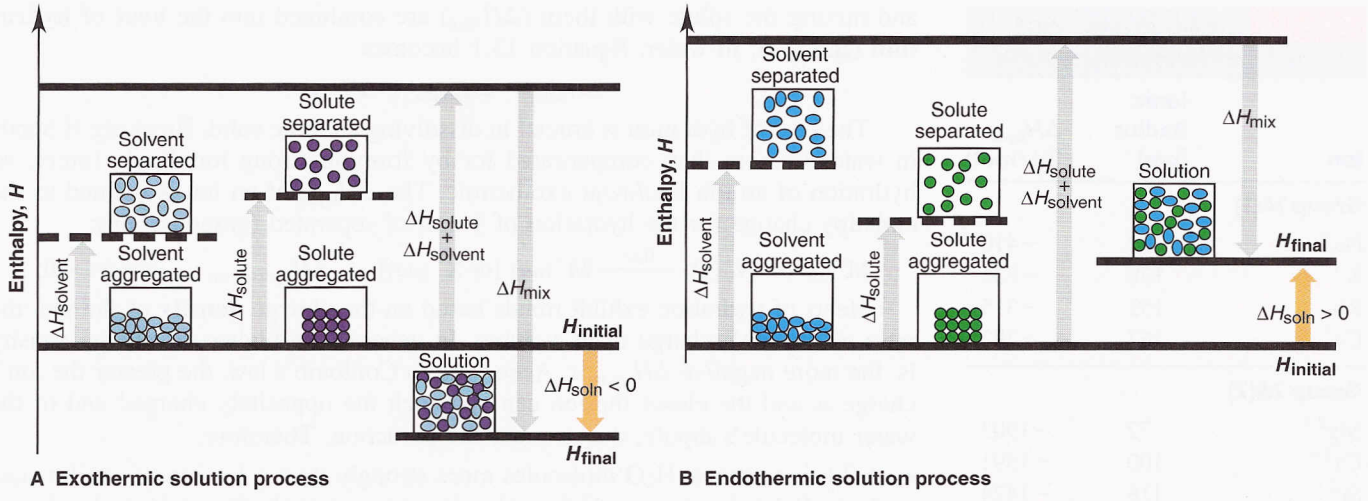

Figure 13.16 Solution cycles and the enthalpy components of the heat of solution. ΔH_{soln} can be thought of as the sum of three enthalpy changes: $\Delta H_{solvent}$ (separating the solvent; always >0), ΔH_{solute} (separating the solute; always >0), and ΔH_{mix} (mixing solute and solvent; always <0). **A,** ΔH_{mix} is larger than the sum of ΔH_{solute} and $\Delta H_{solvent}$, so ΔH_{soln} is negative (exothermic process). **B,** ΔH_{mix} is smaller than the sum of the others, so ΔH_{soln} is positive (endothermic process).

particles must separate to make room for the solute particles, and (3) solute and solvent particles must mix together. No matter what the nature of the attractions within the solute and within the solvent, some energy must be *absorbed* for particles to separate, and some energy is *released* when they mix and attract each other. As a result of these changes, the solution process is typically accompanied by a change in enthalpy. We can divide the process into these three steps, each with its own enthalpy term:

Step 1. Solute particles separate from each other. This step involves overcoming intermolecular attractions, so it is *endothermic:*

$$\text{Solute (aggregated)} + \textit{heat} \longrightarrow \text{solute (separated)} \qquad \Delta H_{solute} > 0$$

Step 2. Solvent particles separate from each other. This step also involves overcoming attractions, so it is *endothermic*, too:

$$\text{Solvent (aggregated)} + \textit{heat} \longrightarrow \text{solvent (separated)} \qquad \Delta H_{solvent} > 0$$

Step 3. Solute and solvent particles mix. The particles attract each other, so this step is *exothermic:*

$$\text{Solute (separated)} + \text{solvent (separated)} \longrightarrow \text{solution} + \textit{heat} \qquad \Delta H_{mix} < 0$$

The total enthalpy change that occurs when a solution forms from solute and solvent is the **heat of solution (ΔH_{soln}),** and we combine the three individual enthalpy changes to find it. The overall process is called a *thermochemical solution cycle* and is yet another application of Hess's law:

$$\Delta H_{soln} = \Delta H_{solute} + \Delta H_{solvent} + \Delta H_{mix} \qquad (13.1)$$

(In Section 9.2 we conceptually broke down the heat of formation of an ionic compound into component enthalpies in a similar way using a Born-Haber cycle.) If the sum of the endothermic terms ($\Delta H_{solute} + \Delta H_{solvent}$) is smaller than the exothermic term (ΔH_{mix}), ΔH_{soln} is negative; that is, the process is exothermic. Figure 13.16A is an enthalpy diagram for the formation of such a solution. If the sum of the endothermic terms is larger than the exothermic term, ΔH_{soln} is positive; that is, the process is endothermic (Figure 13.16B). However, if ΔH_{soln} is highly positive, the solute may not dissolve to any significant extent in that solvent.

Heats of Hydration: Ionic Solids in Water

We can simplify the solution cycle for aqueous systems. The $\Delta H_{solvent}$ and ΔH_{mix} components of the heat of solution are difficult to measure individually. Combined, these terms represent the enthalpy change during **solvation,** the process of surrounding a solute particle with solvent particles. Solvation in water is called **hydration.** Thus, enthalpy changes for separating the water molecules ($\Delta H_{solvent}$)

Table 13.4 Trends in Ionic Heats of Hydration

Ion	Ionic Radius (pm)	ΔH_{hydr} (kJ/mol)
Group 1A(1)		
Na^+	102	−410
K^+	138	−336
Rb^+	152	−315
Cs^+	167	−282
Group 2A(2)		
Mg^{2+}	72	−1903
Ca^{2+}	100	−1591
Sr^{2+}	118	−1424
Ba^{2+}	135	−1317
Group 7A(17)		
F^-	133	−431
Cl^-	181	−313
Br^-	196	−284
I^-	220	−247

and mixing the solute with them (ΔH_{mix}) are combined into the **heat of hydration (ΔH_{hydr}).** In water, Equation 13.1 becomes

$$\Delta H_{soln} = \Delta H_{solute} + \Delta H_{hydr}$$

The heat of hydration is crucial in dissolving an ionic solid. Breaking H bonds in water is more than compensated for by forming strong ion-dipole forces, so hydration of an ion is *always* exothermic. The ΔH_{hydr} of an ion is defined as the enthalpy change for the hydration of 1 mol of separated (gaseous) ions:

$$M^+(g)\ [\text{or } X^-(g)] \xrightarrow{H_2O} M^+(aq)\ [\text{or } X^-(aq)] \qquad \Delta H_{hydr \text{ of the ion}}\ (\text{always } <0)$$

Heats of hydration exhibit trends based on the **charge density** of the ion, the ratio of the ion's charge to its volume. In general, the higher the charge density is, the more negative ΔH_{hydr} is. According to Coulomb's law, the greater the ion's charge is and the closer the ion can approach the oppositely charged end of the water molecule's dipole, the stronger the attraction. Therefore,

- A 2+ ion attracts H_2O molecules more strongly than a 1+ ion of similar size.
- A small 1+ ion attracts H_2O molecules more strongly than a large 1+ ion.

Down a group of ions, for example, from Na^+ to Cs^+ in Group 1A(1), the charge stays the same and the size increases; thus, the charge densities decrease, as do the heats of hydration. Going across the periodic table from Group 1A(1) to Group 2A(2), the 2A ion has a smaller radius *and* a greater charge, so its charge density and ΔH_{hydr} are greater. Table 13.4 shows these relationships for some ions.

The energy required to separate an ionic solute (ΔH_{solute}) into gaseous ions is its lattice energy ($\Delta H_{lattice}$), so ΔH_{solute} is highly positive:

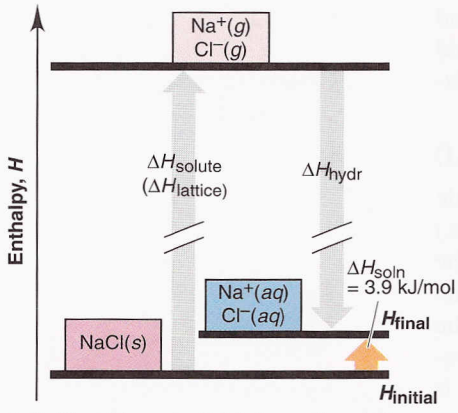
$$M^+X^-(s) \longrightarrow M^+(g) + X^-(g) \qquad \Delta H_{solute}\ (\text{always } >0) = \Delta H_{lattice}$$

Thus, the heat of solution for ionic compounds in water combines the lattice energy (always positive) and the combined heats of hydration of cation and anion (always negative),

$$\Delta H_{soln} = \Delta H_{lattice} + \Delta H_{hydr \text{ of the ions}} \qquad (13.2)$$

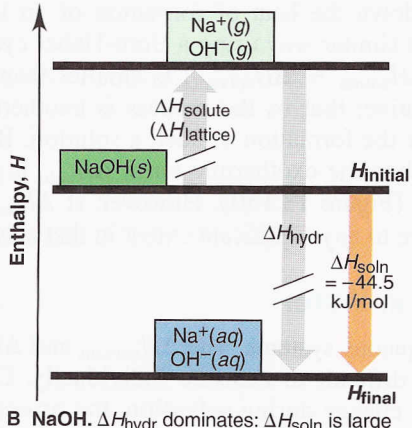
The sizes of the individual terms determine the sign of the heat of solution.

Figure 13.17 shows enthalpy diagrams for dissolving three ionic solutes in water. The first, NaCl, has a small positive heat of solution (ΔH_{soln} = 3.9 kJ/mol).

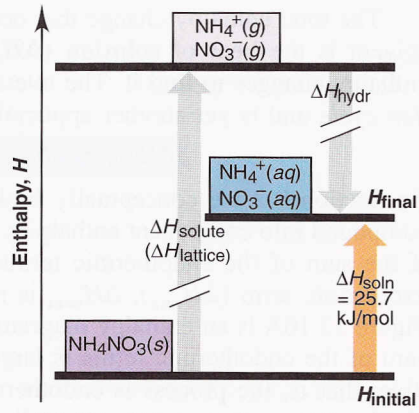


A NaCl. $\Delta H_{lattice}$ is slightly larger than ΔH_{hydr}: ΔH_{soln} is small and positive.

Figure 13.17 Dissolving ionic compounds in water. The enthalpy diagram for an ionic compound in water includes $\Delta H_{lattice}$ (ΔH_{solute}; always positive) and the combined ionic heats of hydration (ΔH_{hydr}; always negative).



B NaOH. ΔH_{hydr} dominates: ΔH_{soln} is large and negative.



C NH_4NO_3. $\Delta H_{lattice}$ dominates: ΔH_{soln} is large and positive.

Its lattice energy is only slightly greater than the combined ionic heats of hydration, so if you dissolve NaCl in water in a flask, you do not notice any temperature change. However, if you dissolve NaOH in water, the flask feels hot. The lattice energy for NaOH is much smaller than the combined ionic heats of hydration, so dissolving NaOH is highly exothermic ($\Delta H_{soln} = -44.5$ kJ/mol). Finally, if you dissolve NH_4NO_3 in water, the flask feels cold. In this case, the lattice energy is much larger than the combined ionic heats of hydration, so the process is quite endothermic ($\Delta H_{soln} = 25.7$ kJ/mol).

Hot Packs, Cold Packs, and Self-Heating Soup Strain a muscle or sprain a joint and you may obtain temporary relief by applying the appropriate heat of solution. Hot packs and cold packs consist of a thick outer pouch containing water and a thin inner pouch containing a salt. A squeeze on the outer pouch breaks the inner pouch, and the salt dissolves. Most hot packs use anhydrous $CaCl_2$ ($\Delta H_{soln} = -82.8$ kJ/mol), whereas cold packs use NH_4NO_3 ($\Delta H_{soln} = 25.7$ kJ/mol). The change in temperature can be large—a cold pack, for instance, can bring the solution from room temperature down to 0°C—but a pack's usable time is limited to around half an hour. In Japan, some cans of soup have double walls, with an ionic compound in a packet and water between the walls. When you open the can, the packet breaks, and the exothermic solution process, which can quickly reach about 90°C, warms the soup.

The Solution Process and the Change in Entropy

The heat of solution (ΔH_{soln}) is one of two factors that determine whether a solute dissolves in a solvent. The other factor concerns the natural tendency of a system to distribute, or disperse, its energy in as many ways as possible. A thermodynamic variable called **entropy** *(S)* is directly related to the number of ways that a system can distribute its energy, which in turn is closely related to the freedom of motion of the particles and the number of ways they can be arranged.

Let's see what it means for a system to "distribute its energy." We'll first compare the three physical states and then compare solute and solvent with solution. In a solid, the particles are relatively fixed in their positions, but in the liquid, they are free to move around each other. This greater freedom of motion means the particles can distribute their kinetic energy in more ways; thus, the liquid has higher entropy than the solid ($S_{liquid} > S_{solid}$). The gas, in turn, has higher entropy than the liquid because the particles have much more freedom of motion ($S_{gas} > S_{liquid}$). Another way to state this is that the change in entropy when the liquid vaporizes to a gas (ΔS_{vap}) is positive; that is, $\Delta S_{vap} > 0$.

Similarly, *a solution usually has higher entropy than the pure solute and pure solvent.* Here, the number of ways to distribute the energy and the freedom of motion of the particles is related to the number of different interactions between the molecules, and there are far more interactions possible when solute and solvent are mixed than when they are separate; thus, $S_{soln} > (S_{solute} + S_{solvent})$, or $\Delta S_{soln} > 0$.

From everyday experience, we know that solutions form naturally, whereas pure solutes and solvents do not. We'll see in Chapter 20 that energy must be expended to reverse this tendency of systems to distribute their energy in more ways—to get "mixed up." Water treatment facilities, oil refineries, metal foundries, and many other industrial processes expend enormous quantities of energy in order to reverse this natural tendency and separate mixtures into pure components.

The solution process involves the interplay of two factors—the change in enthalpy and the change in entropy. *Systems tend toward a state of lower enthalpy and higher entropy.* In many cases, the relative magnitudes of ΔH_{soln} and ΔS_{soln} determine whether a solution forms.

To see this interplay of enthalpy and entropy, let's consider three solute-solvent pairs in which different influences dominate. In our first example, sodium chloride does not dissolve in hexane (C_6H_{14}), as you would predict from the dissimilar intermolecular forces. As Figure 13.18A on the next page shows, separating the solvent is easy because of the relatively weak dispersion forces, but separating the ionic solute requires supplying $\Delta H_{lattice}$. Mixing releases very little heat because the ion–induced dipole attractions between Na^+ (or Cl^-) ions and hexane molecules are weak. The sum of the endothermic terms is much larger than the exothermic term, so ΔH_{soln} is highly positive. In this case, *a solution does not form because the entropy increase that would accompany the mixing of solute and solvent is much smaller than the enthalpy increase required to separate the ions.*

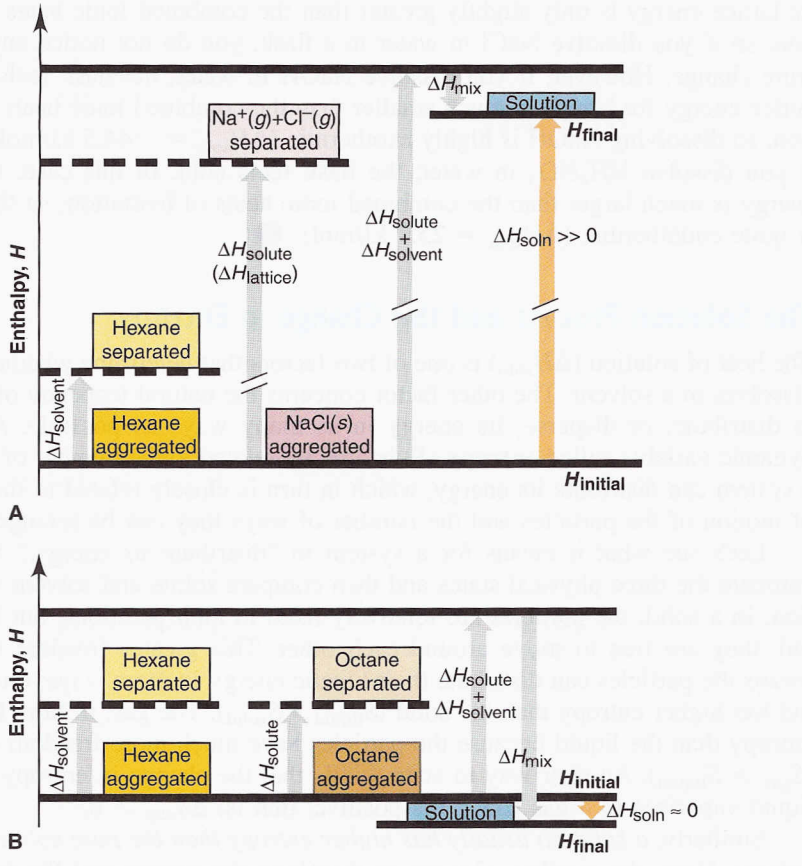


Figure 13.18 Enthalpy diagrams for dissolving NaCl and octane in hexane. **A,** Because attractions between Na^+ (or Cl^-) ions and hexane molecules are weak, ΔH_{mix} is *much* smaller than ΔH_{solute}. Thus, ΔH_{soln} is so positive that NaCl does *not* dissolve in hexane. **B,** Intermolecular forces in octane and in hexane are so similar that ΔH_{soln} is very small. Octane dissolves in hexane because the solution has greater entropy than the pure components.

The second solute-solvent pair is octane (C_8H_{18}) and hexane. Both consist of nonpolar molecules held together by dispersion forces of comparable strength. We therefore predict that octane is soluble in hexane; in fact, they are infinitely soluble (miscible). But this does not necessarily mean that a great deal of heat is released; in fact, ΔH_{soln} is around zero (Figure 13.18B). *With no enthalpy change driving the process, octane dissolves in hexane because the entropy increases greatly when the pure substances mix.* Thus, the large increase in entropy drives formation of this solution.

In some cases, a large enough increase in entropy can cause a solution to form even when the enthalpy increases significantly ($\Delta H_{soln} > 0$). As Figure 13.17C showed, when ammonium nitrate (NH_4NO_3) dissolves in water the process is very endothermic. Nevertheless, in that case, *the increase in entropy that occurs when the crystal breaks down and the ions mix with water molecules more than compensates for the increase in enthalpy.* The enthalpy/entropy interplay in physical and chemical systems is covered in depth in Chapter 20.

SECTION SUMMARY

An overall heat of solution can be obtained from a thermochemical solution cycle as the sum of two endothermic steps (solute separation and solvent separation) and one exothermic step (solute-solvent mixing). In aqueous solutions, the combination of solvent separation and mixing is called *hydration.* Ionic heats of hydration are always negative because of strong ion-dipole forces. Most systems have a natural tendency to increase their entropy (distribute their energy in more ways), and a solution has greater entropy than the pure solute and solvent. The combination of enthalpy and entropy changes determines whether a solution forms. A substance with a positive ΔH_{soln} dissolves *only* if the entropy increase is large enough to outweigh it.

13.4 SOLUBILITY AS AN EQUILIBRIUM PROCESS

When an ionic solid dissolves, ions leave the solid and become dispersed in the solvent. Some dissolved ions collide occasionally with the undissolved solute and recrystallize. As long as the rate of dissolving is greater than the rate of recrystallizing, the concentration of ions rises. Eventually, ions from the solid are dissolving at the same rate as ions in the solution are recrystallizing (Figure 13.19).

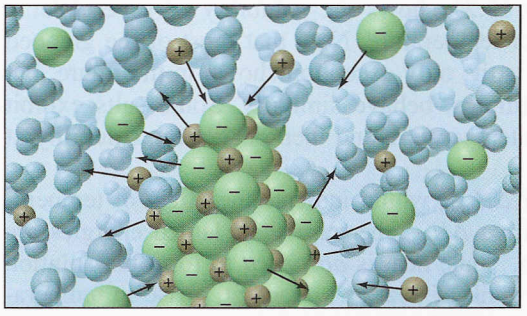

Figure 13.19 Equilibrium in a saturated solution. In a saturated solution, equilibrium exists between excess solid solute and dissolved solute. At a particular temperature, the number of solute particles dissolving per unit time equals the number recrystallizing.

At this point, even though dissolving and recrystallizing continue, there is no further change in the concentration with time. The system has reached equilibrium; that is, *excess undissolved solute is in equilibrium with the dissolved solute:*

$$\text{Solute (undissolved)} \rightleftharpoons \text{solute (dissolved)}$$

This solution is called **saturated:** it contains the maximum amount of dissolved solute at a given temperature in the presence of undissolved solute. Filter off the saturated solution and add more solute to it, and the added solute will not dissolve. A solution that contains less than this amount of dissolved solute is called **unsaturated:** add more solute, and more will dissolve until the solution becomes saturated.

In some cases, we can prepare a solution that contains more than the equilibrium amount of dissolved solute. Such a solution is called **supersaturated.** It is unstable relative to the saturated solution: if you add a "seed" crystal of solute, or just tap the container, the excess solute crystallizes immediately, leaving a saturated solution (Figure 13.20). You can often prepare a supersaturated solution of a solute if it has greater solubility at a higher temperature. While warming the contents of the flask, you dissolve more than the amount of solute required to prepare a saturated solution at some lower temperature and then slowly cool the solution. If the excess solute remains dissolved, the solution is supersaturated.

A Saturated Solution Is Like a Pure Liquid and Its Vapor Equilibrium processes in a saturated solution are analogous to those for a pure liquid and its vapor in a closed flask (Section 12.2). For the liquid, rates of vaporizing and condensing are equal; in the solution, rates of dissolving and recrystallizing are equal. In the liquid-vapor system, particles leave the liquid to enter the vapor, and their concentration (pressure) increases until, at equilibrium, the available space above the liquid is "saturated" with vapor at a given temperature. In the solution, solute particles leave the crystal to enter the solvent, and their concentration increases until, at equilibrium, the available solvent is saturated with solute at a given temperature.

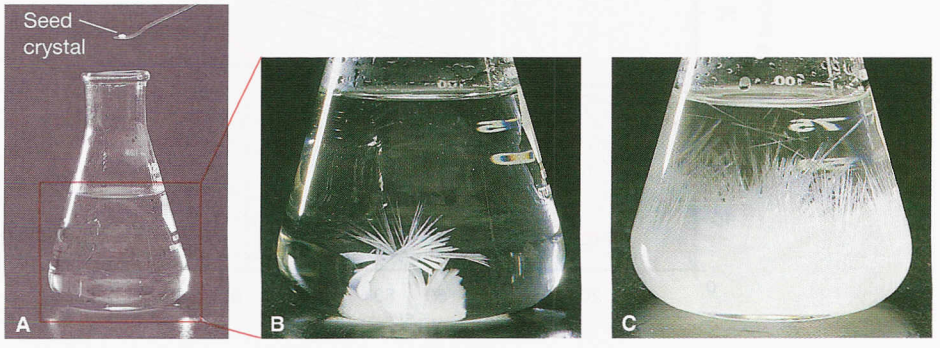

Figure 13.20 Sodium acetate crystallizing from a supersaturated solution. When a seed crystal of sodium acetate is added to a supersaturated solution of the compound (**A**), solute begins to crystallize out of solution (**B**) and continues to do so until the remaining solution is saturated (**C**).

Effect of Temperature on Solubility

Temperature affects the solubility of most substances. You may have noticed, for example, that not only does sugar dissolve more quickly in hot tea than in iced tea, but *more* sugar dissolves; in other words, the solubility of sugar in tea is greater at higher temperatures. Let's examine the effects of temperature on the solubility of solids and of gases.

Temperature and the Solubility of Solids Like sugar, *most solids are more soluble at higher temperatures*. Figure 13.21 shows the solubility of several ionic compounds in water as a function of temperature. Note that most of the graphed lines curve upward. Cerium sulfate is the only exception shown in the figure, but several other salts, mostly other sulfates, behave similarly. Some salts exhibit increasing solubility up to a certain temperature and then decreasing solubility at still higher temperatures.

We might think that the sign of ΔH_{soln} would indicate the effect of temperature. Most ionic solids have a positive ΔH_{soln} because their lattice energies are greater than their heats of hydration. Thus, heat is *absorbed* to form the solution from solute and solvent, and if we think of heat as a reactant, a rise in temperature should increase the rate of the forward process:

$$\text{Solute} + \text{solvent} + \textit{heat} \rightleftharpoons \text{saturated solution}$$

Tabulated ΔH_{soln} values refer to the enthalpy change for a solution to reach the standard state of 1 M, but in order to understand the effect of temperature, we need to know the sign of the enthalpy change very close to the point of saturation, which may not be the same. To use earlier examples, tabulated values give a negative ΔH_{soln} for NaOH and a positive one for NH_4NO_3, yet both compounds are more soluble at higher temperatures. The point is that solubility is a complex behavior, and, although the effect of temperature ultimately reflects the equilibrium nature of solubility, no single measure can help us predict the effect for a given solute.

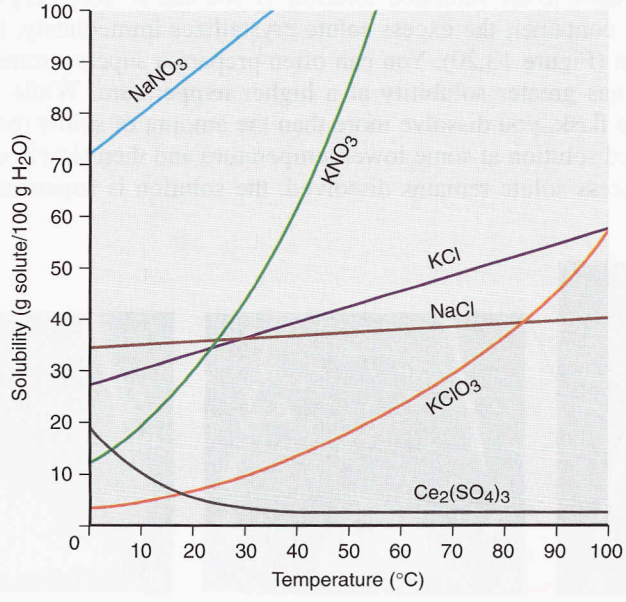

Figure 13.21 The relation between solubility and temperature for several ionic compounds. Most ionic compounds have higher solubilities at higher temperatures. Cerium sulfate is one of several exceptions.

Temperature and Gas Solubility in Water The effect of temperature on gas solubility is much more predictable. When a solid dissolves in a liquid, the solute particles must separate, so energy must be added; thus, for a solid, $\Delta H_{solute} > 0$. In contrast, gas particles are already separated, so $\Delta H_{solute} \approx 0$. Because the hydration step is exothermic ($\Delta H_{hydr} < 0$), the sum of these two terms must be negative. Thus, for all gases in water, $\Delta H_{soln} < 0$:

$$\text{Solute}(g) + \text{water}(l) \rightleftharpoons \text{saturated solution}(aq) + \text{heat}$$

This equation means that *gas solubility in water* ***decreases*** *with rising temperature*. Gases have weak intermolecular forces, so there are relatively weak intermolecular forces between a gas and water. When the temperature rises, the average kinetic energy of the particles in solution increases, allowing the gas particles to easily overcome these weak forces and re-enter the gas phase.

This behavior can lead to an environmental problem known as *thermal pollution*. During many industrial processes, large amounts of water are taken from a nearby river or lake, pumped through the system to cool liquids, gases, and equipment, and then returned to the body of water at a higher temperature. The metabolic rates of fish and other aquatic animals increase in the warmer water released near the plant outlet; thus, their need for O_2 increases, but the concentration of dissolved O_2 is lower at the higher temperature. This oxygen depletion can harm these aquatic populations. Moreover, the warmer water is less dense, so it floats on the cooler water below and prevents O_2 from reaching it. Thus, creatures living at lower levels become oxygen deprived as well. Farther from the plant, the water temperature returns to ambient levels, the O_2 solubility increases, and the temperature layering disappears. One way to lessen the problem is with cooling towers, which cool the water before it exits the plant (Figure 13.22).

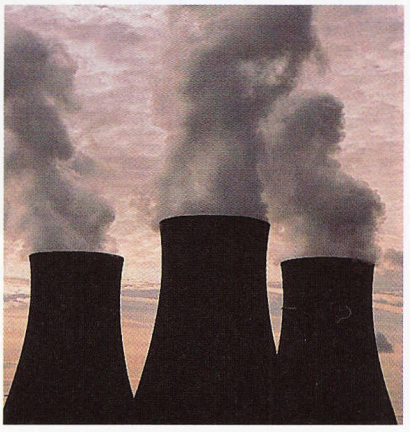

Figure 13.22 Fighting thermal pollution. Steam billowing from cooling towers is common at large electric power plants. Hot water resulting from the cooling of gases and equipment enters near the top of the tower and cools in contact with air. The cooler water is then released back into the water source.

Effect of Pressure on Solubility

Because liquids and solids are almost incompressible, pressure has little effect on their solubility, but it has a major effect on gas solubility. Consider the piston-cylinder assembly in Figure 13.23, with a gas above a saturated aqueous solution of the gas. At a given pressure, the same number of gas molecules enter and leave the solution per unit time; that is, the system is at equilibrium:

$$\text{Gas} + \text{solvent} \rightleftharpoons \text{saturated solution}$$

If you push down on the piston, the gas volume decreases, its pressure increases, and gas particles collide with the liquid surface more often. Thus, more gas particles enter than leave the solution per unit time. Higher gas pressure disturbs the

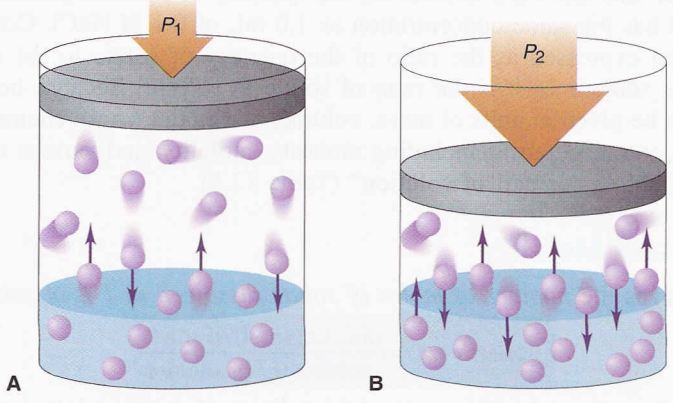

Figure 13.23 The effect of pressure on gas solubility. A, A saturated solution of a gas is in equilibrium at pressure P_1. **B,** If the pressure is increased to P_2, the volume of the gas decreases. As a result, the frequency of collisions with the surface increases, and more gas is in solution when equilibrium is re-established.

Scuba Diving and Soda Pop Although N_2 is barely soluble in water or blood at sea level, high external pressures significantly increase its solubility. Scuba divers who breathe compressed air and dive below about 50 ft have much more N_2 dissolved in their blood. If they ascend quickly to lower pressures, they may be afflicted with decompression sickness (the "bends"), as the dissolved N_2 bubbles out of their blood and causes painful, sometimes fatal, blockage of capillaries. This condition can be avoided by using less soluble gases, such as He, in the breathing mixtures. In principle, the same thing happens when you open a can of a carbonated drink. In the closed can, dissolved CO_2 is at equilibrium with 4 atm of CO_2 gas in the space above it. In the open can, the dissolved CO_2 is under 1 atm of air ($P_{CO_2} = 3\times10^{-4}$ atm), so CO_2 bubbles out of solution. With time, the system reaches equilibrium with the P_{CO_2} in air: the drink goes "flat."

balance at equilibrium, so more gas dissolves to reduce this disturbance (a shift to the right in the preceding equation) until the system re-establishes equilibrium.

Henry's law expresses the quantitative relationship between gas pressure and solubility: *the solubility of a gas (S_{gas}) is directly proportional to the partial pressure of the gas (P_{gas}) above the solution:*

$$S_{gas} = k_H \times P_{gas} \qquad (13.3)$$

where k_H is the Henry's law constant and is specific for a given gas-solvent combination at a given temperature. With S_{gas} in mol/L and P_{gas} in atm, the units of k_H are mol/L·atm.

SAMPLE PROBLEM 13.2 Using Henry's Law to Calculate Gas Solubility

Problem The partial pressure of carbon dioxide gas inside a bottle of cola is 4 atm at 25°C. What is the solubility of CO_2? The Henry's law constant for CO_2 dissolved in water is 3.3×10^{-2} mol/L·atm at 25°C.

Plan We know P_{CO_2} (4 atm) and the value of k_H (3.3×10^{-2} mol/L·atm), so we substitute them into Equation 13.3 to find S_{CO_2}.

Solution $S_{CO_2} = k_H \times P_{CO_2} = (3.3\times10^{-2}\ \text{mol/L·atm})(4\ \text{atm}) = 0.1\ \text{mol/L}$

Check The units are correct for solubility. We rounded the answer to one significant figure because there is only one in the pressure value.

FOLLOW-UP PROBLEM 13.2 If air contains 78% N_2 by volume, what is the solubility of N_2 in water at 25°C and 1 atm (k_H for N_2 in H_2O at 25°C = 7×10^{-4} mol/L·atm)?

SECTION SUMMARY

A solution that contains the maximum amount of dissolved solute in the presence of excess solute is saturated. A state of equilibrium exists when a saturated solution is in contact with excess solute, because solute particles are entering and leaving the solution at the same rate. Most solids are more soluble at higher temperatures. All gases have a negative ΔH_{soln} in water, so heating lowers gas solubility in water. Henry's law says that the solubility of a gas is directly proportional to its partial pressure above the solution.

13.5 QUANTITATIVE WAYS OF EXPRESSING CONCENTRATION

Concentration is the *proportion* of a substance in a mixture, so it is an intensive property, one that does not depend on the quantity of mixture present: 1.0 L of 0.1 *M* NaCl has the same concentration as 1.0 mL of 0.1 *M* NaCl. Concentration is most often expressed as the ratio of the quantity of solute to the quantity of *solution,* but sometimes it is the ratio of solute to *solvent.* Because both parts of the ratio can be given in units of mass, volume, or amount (mol), chemists employ several concentration terms, including molarity, molality, and various expressions of "parts of solute per part of solution" (Table 13.5).

Molarity and Molality

Molarity (*M*) is the *number of moles of solute dissolved in 1 L of solution:*

$$\text{Molarity } (M) = \frac{\text{amount (mol) of solute}}{\text{volume (L) of solution}} \qquad (13.4)$$

In Chapter 3, you used molarity to convert liters of solution into moles of dissolved solute. Expressing concentration in terms of molarity may have drawbacks, however. Because volume is affected by temperature, so is molarity. A solution expands when heated, so a unit volume of hot solution contains slightly less solute than a unit volume of cold solution. This can be a source of error in very precise

Table 13.5 Concentration Definitions

Concentration Term	Ratio
Molarity (M)	$\frac{\text{amount (mol) of solute}}{\text{volume (L) of solution}}$
Molality (m)	$\frac{\text{amount (mol) of solute}}{\text{mass (kg) of solvent}}$
Parts by mass	$\frac{\text{mass of solute}}{\text{mass of solution}}$
Parts by volume	$\frac{\text{volume of solute}}{\text{volume of solution}}$
Mole fraction (X)	$\frac{\text{amount (mol) of solute}}{\text{amount (mol) of solute + amount (mol) of solvent}}$

work. More importantly, because of solute-solvent interactions that are difficult to predict, *solution volumes may not be additive;* that is, adding 500. mL of one solution to 500. mL of another may not give 1000. mL. Therefore, in precise work, a solution with a desired molarity may not be easy to prepare.

A concentration term that does not contain volume in its ratio is **molality (*m*),** *the number of moles of solute dissolved in 1000 g (1 kg) of solvent:*

$$\text{Molality } (m) = \frac{\text{amount (mol) of solute}}{\text{mass (kg) of solvent}} \tag{13.5}$$

Note that molality includes the quantity of *solvent,* not solution. Molal solutions are prepared by measuring *masses* of solute and solvent, not solvent or solution volume. Mass does not change with temperature, so neither does molality. Moreover, unlike volumes, masses *are* additive: adding 500. g of one solution to 500. g of another *does* give 1000. g of final solution. For these reasons, molality is a preferred unit when temperature, and hence density, may change, as in the examination of solutions' physical properties. It's important to realize that, because 1 L of water has a mass of 1 kg, *molality and molarity are nearly the same for dilute aqueous solutions.*

SAMPLE PROBLEM 13.3 Calculating Molality

Problem What is the molality of a solution prepared by dissolving 32.0 g of $CaCl_2$ in 271 g of water?

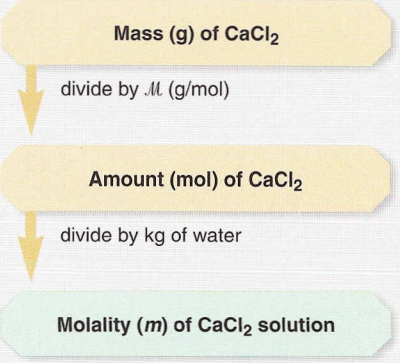
Plan To use Equation 13.5, we convert mass of $CaCl_2$ (32.0 g) to amount (mol) with the molar mass (g/mol) and then divide by the mass of water (271 g), being sure to convert from grams to kilograms.

Solution Converting from grams of solute to moles:

$$\text{Moles of } CaCl_2 = 32.0 \text{ g } CaCl_2 \times \frac{1 \text{ mol } CaCl_2}{110.98 \text{ g } CaCl_2} = 0.288 \text{ mol } CaCl_2$$

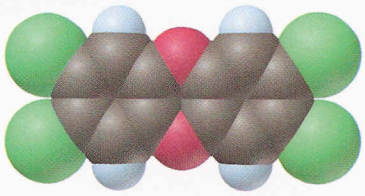
Finding molality:

$$\text{Molality} = \frac{\text{mol solute}}{\text{kg solvent}} = \frac{0.288 \text{ mol } CaCl_2}{271 \text{ g} \times \frac{1 \text{ kg}}{10^3 \text{ g}}} = 1.06 \ m \ CaCl_2$$



Check The answer seems reasonable: the given numbers of moles of $CaCl_2$ and kilograms of H_2O are about the same, so their ratio is about 1.

FOLLOW-UP PROBLEM 13.3 How many grams of glucose ($C_6H_{12}O_6$) must be dissolved in 563 g of ethanol (C_2H_5OH) to prepare a 2.40×10^{-2} *m* solution?



Unhealthy Ultralow Concentrations Environmental toxicologists often measure extremely low concentrations of pollutants. The Centers for Disease Control and Prevention considers TCDD (*t*etra*c*hloro*d*ibenzo*d*ioxin, *above*) one of the most toxic substances known. It is a member of the dioxin family of chlorinated hydrocarbons, a by-product of bleaching paper. TCDD is considered unsafe at soil levels above 1 ppb. From contact with air, water, and soil, most North Americans have an average of 0.01 ppb TCDD in their fatty tissues. The Environmental Protection Agency has assessed TCDD as unsafe at *all* levels measured.

Parts of Solute by Parts of Solution

Several concentration terms are based on the number of solute (or solvent) parts present in a specific number of *solution* parts. The solution parts can be expressed in terms of mass, volume, or amount (mol).

Parts by Mass The most common of the parts-by-mass terms is **mass percent,** which you encountered in Chapter 3. The word *percent* means "per hundred," so mass percent of solute means the mass of solute dissolved in every 100. parts by mass of solution, or the mass fraction times 100:

$$\text{Mass percent} = \frac{\text{mass of solute}}{\text{mass of solute} + \text{mass of solvent}} \times 100 = \frac{\text{mass of solute}}{\text{mass of solution}} \times 100 \qquad (13.6)$$

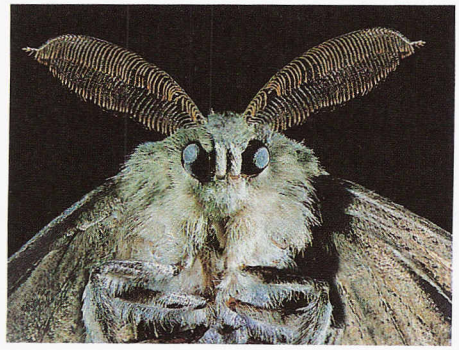
Sometimes mass percent is symbolized as **% (w/w),** indicating that the percentage is a ratio of weights (more accurately, masses). You may have seen mass percent values on jars of solid chemicals to indicate the amounts of impurities present. Two very similar terms are parts per million (ppm) by mass and parts per billion (ppb) by mass: grams of solute per million or per billion grams of solution. For these quantities, in Equation 13.6 you multiply by 10^6 or by 10^9, respectively, instead of by 100.

Parts by Volume The most common of the parts-by-volume terms is **volume percent,** the volume of solute in 100. volumes of solution:

$$\text{Volume percent} = \frac{\text{volume of solute}}{\text{volume of solution}} \times 100 \qquad (13.7)$$

A common symbol for volume percent is **% (v/v).** Commercial rubbing alcohol, for example, is an aqueous solution of isopropyl alcohol (a three-carbon alcohol) that contains 70 volumes of isopropyl alcohol per 100. volumes of solution, and the label indicates this as "70% (v/v)." Parts-by-volume concentrations are most often used for liquids and gases. Minor atmospheric components occur in parts per million by volume (ppmv). For example, there are about 0.05 ppmv of the toxic gas carbon monoxide (CO) in clean air, 1000 times as much (about 50 ppmv of CO) in air over urban traffic, and 10,000 times as much (about 500 ppmv of CO) in the smoke of one cigarette. Some extremely tiny concentrations are found in nature. *Pheromones* are organic compounds secreted by one member of a species to signal other members about food, danger, sexual readiness, and so forth. Many organisms, including dogs and monkeys, release pheromones, and researchers suspect that humans do as well. Some insect pheromones are active at only a few hundred molecules per milliliter of air, about 100 parts per quadrillion by volume (Figure 13.24).

A measure of concentration frequently used for aqueous solutions is % (w/v), a ratio of solute *weight* (actually mass) to solution *volume*. Thus, a 1.5% (w/v)



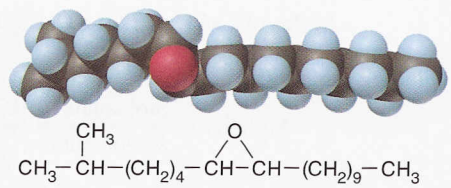


Figure 13.24 The sex attractant of the gypsy moth. The pheromone secreted by the female gypsy moth (called *disparlure*) can attract a male over 0.5 mi away. Chemists synthesize pheromones for insect pest control.

NaCl solution contains 1.5 g of NaCl per 100. mL of *solution*. This way of expressing concentrations is particularly common in medical labs and other health-related facilities.

Mole Fraction The **mole fraction** (X) of a solute is the ratio of number of solute moles to the total number of moles (solute plus solvent), that is, parts by mole. The *mole percent* is the mole fraction expressed as a percentage:

$$\text{Mole fraction } (X) = \frac{\text{amount (mol) of solute}}{\text{amount (mol) of solute} + \text{amount (mol) of solvent}} \qquad (13.8)$$

$$\text{Mole percent (mol \%)} = \text{mole fraction} \times 100$$

We discussed these terms in Chapter 5 in relation to Dalton's law of partial pressures for mixtures of gases, but they apply to liquids and solids as well. Concentrations given as mole fractions provide the clearest picture of the actual proportion of solute (or solvent) particles among all the particles in the solution.

SAMPLE PROBLEM 13.4 Expressing Concentrations in Parts by Mass, Parts by Volume, and Mole Fraction

Problem **(a)** Find the concentration of calcium (in ppm) in a 3.50-g pill that contains 40.5 mg of Ca.

(b) The label on a 0.750-L bottle of Italian chianti indicates "11.5% alcohol by volume." How many liters of alcohol does the wine contain?

(c) A sample of rubbing alcohol contains 142 g of isopropyl alcohol (C_3H_7OH) and 58.0 g of water. What are the mole fractions of alcohol and water?

Plan **(a)** We are given the masses of Ca (40.5 mg) and the pill (3.50 g). We convert the mass of Ca from mg to g, find the ratio of mass of Ca to mass of pill, and multiply by 10^6 to obtain ppm. **(b)** We know the volume % (11.5%, or 11.5 parts by volume of alcohol to 100 parts of chianti) and the total volume (0.750 mL), so we use Equation 13.7 to find the volume of alcohol. **(c)** We know the mass and formula of each component, so we convert masses to amounts (mol) and apply Equation 13.8 to find the mole fractions.

Solution **(a)** Finding parts per million by mass of Ca. Combining the steps, we have

$$\text{ppm Ca} = \frac{\text{mass of Ca}}{\text{mass of pill}} \times 10^6 = \frac{40.5 \text{ mg Ca} \times \dfrac{1 \text{ g}}{10^3 \text{ mg}}}{3.50 \text{ g}} \times 10^6 = 1.16 \times 10^4 \text{ ppm Ca}$$

(b) Finding volume (L) of alcohol:

$$\text{Volume (L) of alcohol} = 0.750 \text{ L chianti} \times \frac{11.5 \text{ L alcohol}}{100. \text{ L chianti}} = 0.0862 \text{ L}$$

(c) Finding mole fractions. Converting from grams to moles:

$$\text{Moles of } C_3H_7OH = 142 \text{ g } C_3H_7OH \times \frac{1 \text{ mol } C_3H_7OH}{60.09 \text{ g } C_3H_7OH} = 2.36 \text{ mol } C_3H_7OH$$

$$\text{Moles of } H_2O = 58.0 \text{ g } H_2O \times \frac{1 \text{ mol } H_2O}{18.02 \text{ g } H_2O} = 3.22 \text{ mol } H_2O$$

Calculating mole fractions:

$$X_{C_3H_7OH} = \frac{\text{moles of } C_3H_7OH}{\text{total moles}} = \frac{2.36 \text{ mol}}{2.36 \text{ mol} + 3.22 \text{ mol}} = 0.423$$

$$X_{H_2O} = \frac{\text{moles of } H_2O}{\text{total moles}} = \frac{3.22 \text{ mol}}{2.36 \text{ mol} + 3.22 \text{ mol}} = 0.577$$

Check **(a)** The mass ratio is about 0.04 g/4 g = 10^{-2}, and $10^{-2} \times 10^6 = 10^4$ ppm, so it seems correct. **(b)** The volume % is a bit more than 10%, so the volume of alcohol should be a bit more than 75 mL (0.075 L). **(c)** Always check that the *mole fractions add up to 1*: 0.423 + 0.577 = 1.000.

FOLLOW-UP PROBLEM 13.4 An alcohol solution contains 35.0 g of 1-propanol (C_3H_7OH) and 150. g of ethanol (C_2H_5OH). Calculate the mass percent and the mole fraction of each alcohol.

Interconverting Concentration Terms

All the terms we just discussed represent different ways of expressing concentration, so they are interconvertible. Keep these points in mind:

- To convert a term based on amount (mol) to one based on mass, you need the molar mass. These conversions are similar to the mass-mole conversions you've done earlier.
- To convert a term based on mass to one based on volume, you need the solution *density*. Given the mass of a solution, the density (mass/volume) gives you the volume, or vice versa.
- Molality involves quantity of *solvent*, whereas the other concentration terms involve quantity of *solution*.

SAMPLE PROBLEM 13.5 Converting Concentration Terms

Problem Hydrogen peroxide is a powerful oxidizing agent used in concentrated solution in rocket fuels and in dilute solution as a hair bleach. An aqueous solution of H_2O_2 is 30.0% by mass and has a density of 1.11 g/mL. Calculate its

(a) Molality

(b) Mole fraction of H_2O_2

(c) Molarity

Plan We know the mass % (30.0) and the density (1.11 g/mL). **(a)** For molality, we need the amount (mol) of solute and the mass (kg) of *solvent*. Assuming 100.0 g of H_2O_2 solution allows us to express the mass % directly as grams of substance. We subtract the grams of H_2O_2 to obtain the grams of solvent. To find molality, we convert grams of H_2O_2 to moles and divide by mass of solvent (converting g to kg). **(b)** To find the mole fraction, we use the number of moles of H_2O_2 [from part (a)] and convert the grams of H_2O to moles. Then we divide the moles of H_2O_2 by the total moles. **(c)** To find molarity, we assume 100.0 g of solution and use the given solution density to find the volume. Then we divide the amount (mol) of H_2O_2 [from part (a)] by *solution* volume (in L).

Solution **(a)** From mass % to molality. Finding mass of solvent (assuming 100.0 g of solution):

$$\text{Mass (g) of } H_2O = 100.0 \text{ g solution} - 30.0 \text{ g } H_2O_2 = 70.0 \text{ g } H_2O$$

Converting from grams of H_2O_2 to moles:

$$\text{Moles of } H_2O_2 = 30.0 \text{ g } H_2O_2 \times \frac{1 \text{ mol } H_2O_2}{34.02 \text{ g } H_2O_2} = 0.882 \text{ mol } H_2O_2$$

Calculating molality:

$$\text{Molality of } H_2O_2 = \frac{0.882 \text{ mol } H_2O_2}{70.0 \text{ g} \times \dfrac{1 \text{ kg}}{10^3 \text{ g}}} = 12.6\ m\ H_2O_2$$

(b) From mass % to mole fraction:

$$\text{Moles of } H_2O_2 = 0.882 \text{ mol } H_2O_2 \text{ [from part (a)]}$$

$$\text{Moles of } H_2O = 70.0 \text{ g } H_2O \times \frac{1 \text{ mol } H_2O}{18.02 \text{ g } H_2O} = 3.88 \text{ mol } H_2O$$

$$X_{H_2O_2} = \frac{0.882 \text{ mol}}{0.882 \text{ mol} + 3.88 \text{ mol}} = 0.185$$

(c) From mass % and density to molarity. Converting from solution mass to volume:

$$\text{Volume (mL) of solution} = 100.0 \text{ g} \times \frac{1 \text{ mL}}{1.11 \text{ g}} = 90.1 \text{ mL}$$

Calculating molarity:

$$\text{Molarity} = \frac{\text{mol } H_2O_2}{\text{L soln}} = \frac{0.882 \text{ mol } H_2O_2}{90.1 \text{ mL} \times \dfrac{1 \text{ L soln}}{10^3 \text{ mL}}} = 9.79\ M\ H_2O_2$$

Check Rounding shows the answers seem reasonable: **(a)** The ratio of ~0.9 mol/0.07 kg is greater than 10. **(b)** ~0.9 mol H_2O_2/(1 mol + 4 mol) ≈ 0.2. **(c)** The ratio of moles to liters (0.9/0.09) is around 10.

FOLLOW-UP PROBLEM 13.5 A sample of commercial concentrated hydrochloric acid is 11.8 *M* HCl and has a density of 1.190 g/mL. Calculate the mass %, molality, and mole fraction of HCl.

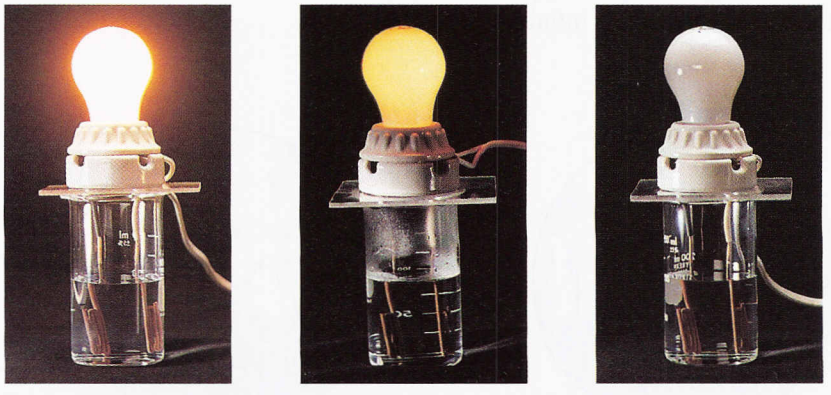
SECTION SUMMARY

The concentration of a solution is independent of the amount of solution and can be expressed as molarity (mol solute/L solution), molality (mol solute/kg solvent), parts by mass (mass solute/mass solution), parts by volume (volume solute/volume solution), or mole fraction [mol solute/(mol solute + mol solvent)]. The choice of units depends on convenience or the nature of the solution. If, in addition to the quantities of solute and solution, the solution density is also known, all ways of expressing concentration are interconvertible.

13.6 COLLIGATIVE PROPERTIES OF SOLUTIONS

We might expect the presence of solute particles to make the physical properties of a solution different from those of the pure solvent. However, what we might *not* expect is that, in the case of four important solution properties, the *number* of solute particles makes the difference, not their chemical identity. These properties, known as **colligative properties** (*colligative* means "collective"), are vapor pressure lowering, boiling point elevation, freezing point depression, and osmotic pressure. Even though most of these effects are small, they have many practical applications, including some that are vital to biological systems.

Historically, colligative properties were measured to explore the nature of a solute in aqueous solution and its extent of dissociation into ions. In Chapter 4, we classified solutes by their ability to conduct an electric current, which requires moving ions to be present. Recall that an aqueous solution of an **electrolyte** conducts a current because the solute separates into ions as it dissolves. Soluble salts, strong acids, and strong bases dissociate completely. Their solutions conduct a large current, so these solutes are *strong electrolytes*. Weak acids and weak bases dissociate very little. They are *weak electrolytes* because their solutions conduct little current. Many compounds, such as sugar and alcohol, do not dissociate into ions at all. They are **nonelectrolytes** because their solutions do not conduct a current. Figure 13.25 shows these behaviors.



A Strong electrolyte B Weak electrolyte C Nonelectrolyte

Figure 13.25 The three types of electrolytes. A, Strong electrolytes conduct a large current because they dissociate completely into ions. **B,** Weak electrolytes conduct a small current because they dissociate very little. **C,** Nonelectrolytes do not conduct a current because they do not dissociate.

To predict the magnitude of a colligative property, we refer to the solute formula to find the number of particles in solution. Each mole of nonelectrolyte yields 1 mol of particles in the solution. For example, 0.35 *M* glucose contains 0.35 mol of solute particles per liter. In principle, each mole of strong electrolyte dissociates into the number of moles of ions in the formula unit: 0.4 *M* Na_2SO_4 contains 0.8 mol of Na^+ ions and 0.4 mol of SO_4^{2-} ions, or 1.2 mol of particles, per liter (see Sample Problem 4.1, p. 137). (We examine the equilibrium nature of the dissociation of weak electrolytes in Chapters 18 and 19.)

Colligative Properties of Nonvolatile Nonelectrolyte Solutions

In this section, we focus most of our attention on the simplest case, the colligative properties of solutes that do not dissociate into ions and have negligible vapor pressure even at the boiling point of the solvent. Such solutes are called *nonvolatile nonelectrolytes;* sucrose (table sugar) is an example. Later, we briefly explore the properties of volatile nonelectrolytes and of strong electrolytes.

Vapor Pressure Lowering The vapor pressure of a solution of a nonvolatile nonelectrolyte is always *lower* than the vapor pressure of the pure solvent. We can understand this **vapor pressure lowering (ΔP)** in terms of opposing rates and in terms of changes in entropy. Consider a pure solvent and the opposing rates of vaporization (molecules leaving the liquid) and of condensation (molecules reentering the liquid). At equilibrium, the two rates are equal. When we add some nonvolatile solute, the number of solvent molecules on the surface is lower, so fewer vaporize per unit time. To maintain equilibrium, fewer gas molecules can enter the liquid, which occurs only if the concentration of gas, that is, the vapor pressure, is lowered. In terms of the entropy change, recall that natural processes occur in a direction of increasing entropy. A pure solvent vaporizes because the vapor has a greater entropy than the liquid. However, the solvent in a solution already has a greater entropy than it does as pure solvent, so it has less tendency to vaporize in order to gain entropy. Thus, by either argument, equilibrium is reached at a lower vapor pressure for the solution. Figure 13.26 illustrates this point.

In quantitative terms, we find that the vapor pressure of solvent above the solution ($P_{solvent}$) equals the mole fraction of solvent in the solution ($X_{solvent}$) times the vapor pressure of the pure solvent ($P^0_{solvent}$). This relationship is expressed by **Raoult's law:**

$$P_{solvent} = X_{solvent} \times P^0_{solvent} \qquad (13.9)$$

In a solution, $X_{solvent}$ is always less than 1, so $P_{solvent}$ is always less than $P^0_{solvent}$. An **ideal solution** is one that follows Raoult's law at any concentration. However, just as most gases deviate from ideality, so do most solutions. In practice, Raoult's law gives a good approximation of the behavior of *dilute* solutions only, and it becomes exact at infinite dilution.

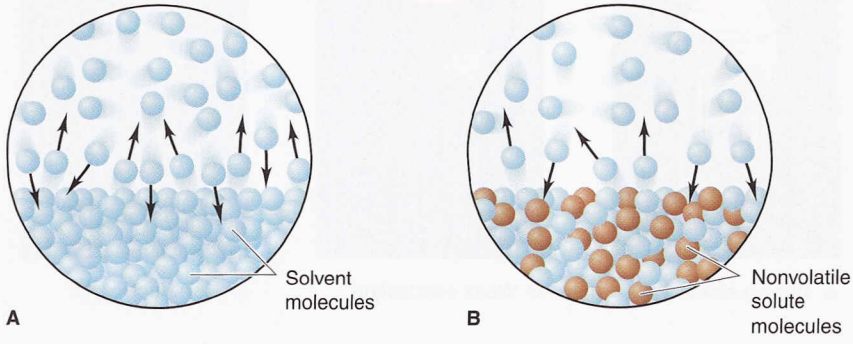


Figure 13.26 The effect of the solute on the vapor pressure of a solution. Vaporization occurs because of the tendency of a system to increase its entropy. **A,** Equilibrium is established between a pure liquid and its vapor when the numbers of molecules vaporizing and condensing in a given time are equal. **B,** The presence of a dissolved solute decreases the number of solvent molecules at the surface and increases the entropy of the system, so fewer solvent molecules vaporize in a given time. Therefore, fewer molecules need to condense to balance them, and equilibrium is established at a lower vapor pressure.

How does the *amount* of solute affect the *magnitude* of the vapor pressure lowering, ΔP? The solution consists of solvent and solute, so the sum of their mole fractions equals 1:

$$X_{solvent} + X_{solute} = 1; \quad \text{thus,} \quad X_{solvent} = 1 - X_{solute}$$

From Raoult's law, we have

$$P_{solvent} = X_{solvent} \times P^0_{solvent} = (1 - X_{solute}) \times P^0_{solvent}$$

Multiplying through on the right side gives

$$P_{solvent} = P^0_{solvent} - (X_{solute} \times P^0_{solvent})$$

Rearranging and introducing ΔP gives

$$P^0_{solvent} - P_{solvent} = \Delta P = X_{solute} \times P^0_{solvent} \qquad (13.10)$$

Thus, the *magnitude* of ΔP equals the mole fraction of solute times the vapor pressure of the pure solvent—a relationship applied in the next sample problem.

SAMPLE PROBLEM 13.6 Using Raoult's Law to Find Vapor Pressure Lowering

Problem Calculate the vapor pressure lowering, ΔP, when 10.0 mL of glycerol ($C_3H_8O_3$) is added to 500. mL of water at 50.°C. At this temperature, the vapor pressure of pure water is 92.5 torr and its density is 0.988 g/mL. The density of glycerol is 1.26 g/mL.

Plan To calculate ΔP, we use Equation 13.10. We are given the vapor pressure of pure water ($P^0_{H_2O} = 92.5$ torr), so we just need the mole fraction of glycerol, $X_{glycerol}$. We convert the given volume of glycerol (10.0 mL) to mass using the given density (1.26 g/L), find the molar mass from the formula, and convert mass (g) to amount (mol). The same procedure gives amount of H_2O. From these, we find $X_{glycerol}$ and ΔP.

Solution Calculating the amount (mol) of glycerol and of water:

$$\text{Moles of glycerol} = 10.0 \text{ mL glycerol} \times \frac{1.26 \text{ g glycerol}}{1 \text{ mL glycerol}} \times \frac{1 \text{ mol glycerol}}{92.09 \text{ g glycerol}}$$

$$= 0.137 \text{ mol glycerol}$$

$$\text{Moles of } H_2O = 500. \text{ mL } H_2O \times \frac{0.988 \text{ g } H_2O}{1 \text{ mL } H_2O} \times \frac{1 \text{ mol } H_2O}{18.02 \text{ g } H_2O} = 27.4 \text{ mol } H_2O$$

Calculating the mole fraction of glycerol:

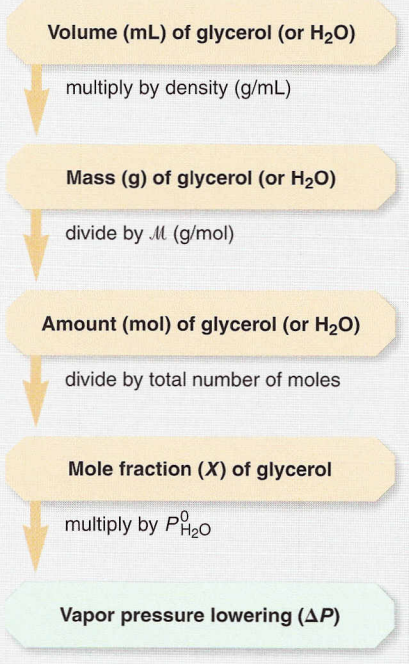
$$X_{glycerol} = \frac{0.137 \text{ mol}}{0.137 \text{ mol} + 27.4 \text{ mol}} = 0.00498$$

Finding the vapor pressure lowering:

$$\Delta P = X_{glycerol} \times P^0_{H_2O} = 0.00498 \times 92.5 \text{ torr} = 0.461 \text{ torr}$$

Check The amount of each component seems correct: for glycerol, ~10 mL × 1.25 g/mL ÷ 100 g/mol = 0.125 mol; for H_2O, ~500 mL × 1 g/mL ÷ 20 g/mol = 25 mol. The small ΔP is reasonable because the mole fraction of solute is small.

Comment The calculation assumes that glycerol is nonvolatile. At 1 atm, glycerol boils at 290.0°C, so the vapor pressure of glycerol at 50°C is so low it can be neglected.



FOLLOW-UP PROBLEM 13.6 Calculate the vapor pressure lowering of a solution of 2.00 g of aspirin ($\mathcal{M} = 180.15$ g/mol) in 50.0 g of methanol (CH_3OH) at 21.2°C. Pure methanol has a vapor pressure of 101 torr at this temperature.

Boiling Point Elevation *A solution boils at a higher temperature than the pure solvent.* Let's see why. The boiling point (boiling temperature, T_b) of a liquid is the temperature at which its vapor pressure equals the external pressure. The vapor pressure of a solution is lower than the external pressure at the solvent's boiling point because the vapor pressure of a solution is lower than that of the pure solvent at any temperature. Therefore, the solution does not yet boil. A higher temperature is needed to raise the solution's vapor pressure to equal the external pressure. We can see this **boiling point elevation (ΔT_b)** by superimposing a phase diagram for the solution on a phase diagram for the pure solvent, as shown in

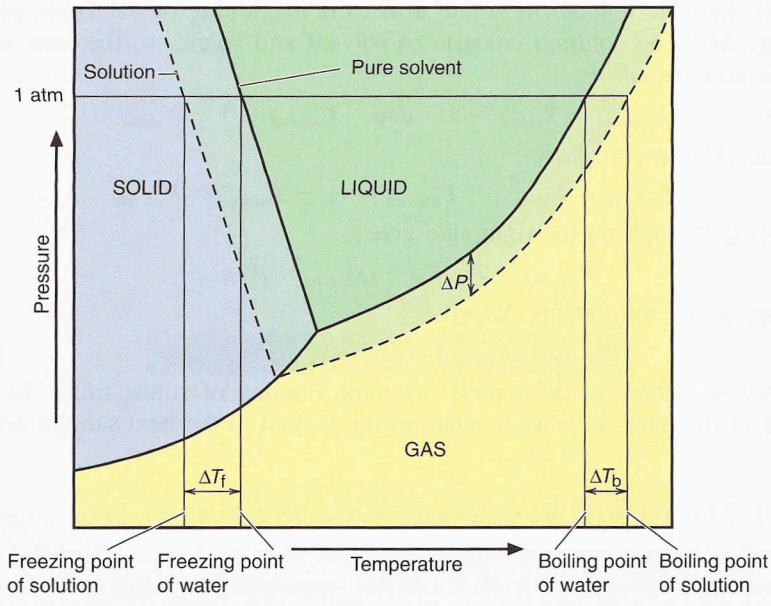


Figure 13.27 Phase diagrams of solvent and solution. Phase diagrams of an aqueous solution (*dashed lines*) and of pure water (*solid lines*) show that, by lowering the vapor pressure (ΔP), a dissolved solute elevates the boiling point (ΔT_b) and depresses the freezing point (ΔT_f).

Figure 13.27. Note that the gas-liquid line for the solution lies *below* that for the pure solvent at any temperature and to the right of it at any pressure.

Like the vapor pressure lowering, the magnitude of the boiling point elevation is proportional to the concentration of solute particles:

$$\Delta T_b \propto m \quad \text{or} \quad \Delta T_b = K_b m \tag{13.11}$$

where m is the solution molality, K_b is the *molal boiling point elevation constant,* and ΔT_b is the boiling point elevation. We typically speak of ΔT_b as a positive value, so we subtract the lower temperature from the higher; that is, we subtract the solvent T_b from the solution T_b:

$$\Delta T_b = T_{b(\text{solution})} - T_{b(\text{solvent})}$$

Molality is the concentration term used because it is related to mole fraction and thus to particles of solute. It also involves mass rather than volume of solvent, so it is not affected by temperature changes. The constant K_b has units of degrees Celsius per molal unit (°C/m) and is specific for a given solvent (Table 13.6).

Notice that the K_b for water is only 0.512°C/m, so the changes in boiling point are quite small: if you dissolved 1.00 mol of glucose (180. g; 1.00 mol of particles) in 1.00 kg of water, or 0.500 mol of NaCl (29.2 g; a strong electrolyte, so also 1.00 mol of particles) in 1.00 kg of water, the boiling points of the resulting solutions at 1 atm would be only 100.512°C instead of 100.000°C.

Table 13.6 Molal Boiling Point Elevation and Freezing Point Depression Constants of Several Solvents

Solvent	Boiling Point (°C)*	K_b (°C/m)	Melting Point (°C)	K_f (°C/m)
Acetic acid	117.9	3.07	16.6	3.90
Benzene	80.1	2.53	5.5	4.90
Carbon disulfide	46.2	2.34	−111.5	3.83
Carbon tetrachloride	76.5	5.03	−23	30.
Chloroform	61.7	3.63	−63.5	4.70
Diethyl ether	34.5	2.02	−116.2	1.79
Ethanol	78.5	1.22	−117.3	1.99
Water	100.0	0.512	0.0	1.86

*At 1 atm.

Freezing Point Depression As you just saw, only solvent molecules can vaporize from the solution, so molecules of the nonvolatile solute are left behind. Similarly, in many cases, *only solvent molecules can solidify,* again leaving solute molecules behind to form a slightly more concentrated solution. The freezing point of a solution is that temperature at which its vapor pressure equals that of the pure solvent. At this temperature, the two phases—solid solvent and liquid solution—are in equilibrium. Because the vapor pressure of the solution is lower than that of the solvent at any temperature, the solution freezes at a lower temperature than the solvent. In other words, the numbers of solvent particles leaving and entering the solid per unit time become equal at a lower temperature. The **freezing point depression (ΔT_f)** is shown in Figure 13.27; note that the solid-liquid line for the solution lies to the left of that for the pure solvent at any pressure.

Like ΔT_b, the freezing point depression has a magnitude proportional to the molal concentration of solute:

$$\Delta T_f \propto m \quad \text{or} \quad \Delta T_f = K_f m \tag{13.12}$$

where K_f is the *molal freezing point depression constant,* which also has units of °C/*m* (see Table 13.6). Also like ΔT_b, ΔT_f is considered a positive value, so we subtract the lower temperature from the higher; in this case, however, it is the solution T_f from the solvent T_f:

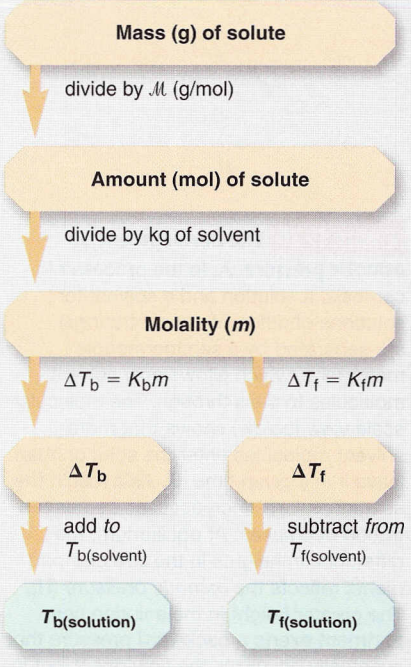
$$\Delta T_f = T_{f(\text{solvent})} - T_{f(\text{solution})}$$

Here, too, the overall effect in aqueous solution is quite small because the K_f value for water is small—only 1.86°C/*m*. Thus, 1 *m* glucose, 0.5 *m* NaCl, and 0.33 *m* K_2SO_4, all solutions with 1 mol of particles per kilogram of water, freeze at −1.86°C at 1 atm instead of at 0.00°C.

SAMPLE PROBLEM 13.7 Determining the Boiling Point Elevation and Freezing Point Depression of a Solution

Problem You add 1.00 kg of ethylene glycol ($C_2H_6O_2$) antifreeze to your car radiator, which contains 4450 g of water. What are the boiling and freezing points of the solution?

Plan To find the boiling and freezing points of the solution, we first find the molality by converting the given mass of solute (1.00 kg) to amount (mol) and dividing by mass of solvent (4450 g). Then we calculate ΔT_b and ΔT_f from Equations 13.11 and 13.12 (using constants from Table 13.6). We add ΔT_b to the solvent boiling point and subtract ΔT_f from the solvent freezing point. The roadmap shows the steps.



Solution Calculating the molality:

$$\text{Moles of } C_2H_6O_2 = 1.00 \text{ kg } C_2H_6O_2 \times \frac{10^3 \text{ g}}{1 \text{ kg}} \times \frac{1 \text{ mol } C_2H_6O_2}{62.07 \text{ g } C_2H_6O_2} = 16.1 \text{ mol } C_2H_6O_2$$

$$\text{Molality} = \frac{\text{mol solute}}{\text{kg solvent}} = \frac{16.1 \text{ mol } C_2H_6O_2}{4450 \text{ g } H_2O \times \dfrac{1 \text{ kg}}{10^3 \text{ g}}} = 3.62 \, m \, C_2H_6O_2$$

Finding the boiling point elevation and $T_{b(solution)}$, with $K_b = 0.512°C/m$:

$$\Delta T_b = \frac{0.512°C}{m} \times 3.62 \, m = 1.85°C$$

$$T_{b(solution)} = T_{b(solvent)} + \Delta T_b = 100.00°C + 1.85°C = 101.85°C$$

Finding the freezing point depression and $T_{f(solution)}$, with $K_f = 1.86°C/m$:

$$\Delta T_f = \frac{1.86°C}{m} \times 3.62 \, m = 6.73°C$$

$$T_{f(solution)} = T_{f(solvent)} - \Delta T_f = 0.00°C - 6.73°C = -6.73°C$$

Check The changes in boiling and freezing points should be in the same proportion as the constants used. That is, $\Delta T_b/\Delta T_f$ should equal K_b/K_f: 1.85/6.73 = 0.275 = 0.512/1.86.

Comment These answers are only approximate because the concentration far exceeds that of a *dilute* solution, for which Raoult's law is most useful.

FOLLOW-UP PROBLEM 13.7 What is the minimum concentration (molality) of ethylene glycol solution that will protect the car's cooling system from freezing at 0.00°F? (Assume the solution is ideal.)

Osmotic Pressure The fourth colligative property appears when two solutions of different concentrations are separated by a **semipermeable membrane,** one that allows solvent, but *not* solute, molecules to pass through. This process is called **osmosis.** Many organisms have semipermeable membranes that regulate internal concentrations by osmosis, and synthetic polymers are studied by osmosis.

Consider a simple apparatus in which a semipermeable membrane lies at the curve of a U tube and separates an aqueous sugar solution from pure water. The membrane allows water molecules to pass in *either* direction, but not the larger sugar molecules. Because the solute molecules are present, fewer water molecules touch the membrane on the solution side, so fewer of them leave the solution in a given time than enter it (Figure 13.28A). This *net flow of water into the solution* increases the volume of the solution and thus decreases its concentration.

As the height of the solution rises and that of the solvent falls, the resulting pressure difference pushes some water molecules *from* the solution back through the membrane. At equilibrium, water is pushed out of the solution at the same rate it enters (Figure 13.28B). The pressure difference at equilibrium is the **osmotic pressure (Π),** which is defined as the applied pressure required to *prevent* the net movement of water from solvent to solution (Figure 13.28C).

The osmotic pressure is proportional to the number of solute particles in a given *volume* of solution, that is, to the molarity (M):

$$\Pi \propto \frac{n_{\text{solute}}}{V_{\text{soln}}} \qquad \text{or} \qquad \Pi \propto M$$

The proportionality constant is R times the absolute temperature T. Thus,

$$\Pi = \frac{n_{\text{solute}}}{V_{\text{soln}}} RT = MRT \tag{13.13}$$

The similarity of Equation 13.13 to the ideal gas law ($P = nRT/V$) is not surprising, because both relate the pressure of a system to its concentration and temperature. The Gallery shows some important applications of colligative properties.

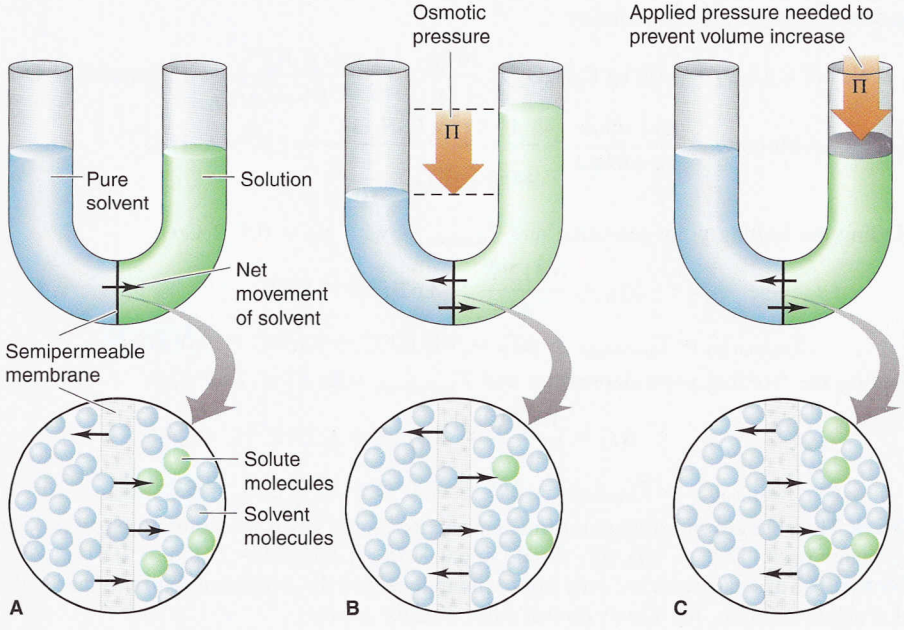


Figure 13.28 The development of osmotic pressure. A, In the process of osmosis, a solution and a solvent (or solutions of different concentrations) are separated by a semipermeable membrane, which allows only solvent molecules to pass through. The molecular-scale view (*below*) shows that more solvent molecules enter the solution than leave it in a given time. **B,** As a result, the solution volume increases, so its concentration decreases. At equilibrium, the difference in heights in the two compartments reflects the *osmotic pressure* (Π). The greater height in the solution compartment exerts a backward pressure that eventually equalizes the flow of solvent in both directions. **C,** Osmotic pressure is defined as the applied pressure required to *prevent* this volume change.

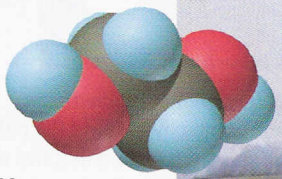
Colligative Properties in Industry and Biology

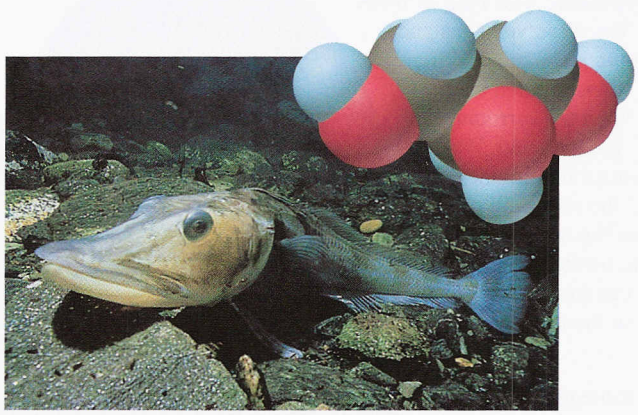
GALLERY

Colligative properties—especially freezing point depression and osmotic pressure—have much practical relevance to everyday life. Some common applications of freezing point depression make life safer during cold winter months. Others are essential to the electronics industry. Applications of osmotic pressure are found throughout nature and in the health and biological sciences—without question, the most important semipermeable membranes surround living cells.

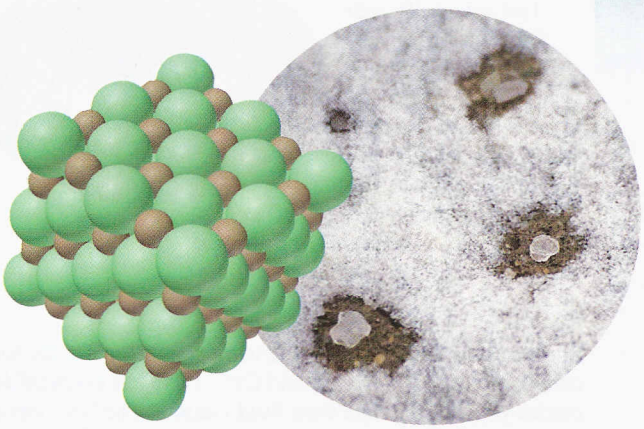
Applications of Freezing Point Depression



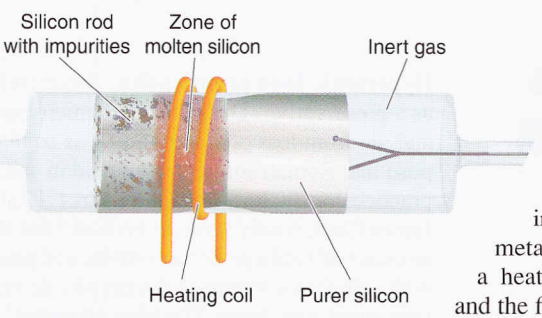
Plane de-icing and car antifreezing Ethylene glycol ($C_2H_6O_2$) is miscible with water through extensive hydrogen bonding and has a high enough boiling point for it to be essentially nonvolatile at 100°C. It is the major ingredient in airplane "de-icers." In "year-round" automobile antifreeze, it lowers the freezing point of water in the radiator in the winter and raises its boiling point in the summer.



Biological antifreeze To survive in the Arctic and in northern winters, many fish and insects, including the common housefly, produce large amounts of glycerol ($C_3H_8O_3$)—a substance with a structure very similar to that of ethylene glycol and also miscible with water—which lowers the freezing point of their blood.



Salts for slippery streets Highway crews use salts, such as mixtures of NaCl and $CaCl_2$, to melt ice on streets. A small amount of salt dissolves in the ice by lowering its freezing point and melting it. More salt dissolves, more ice melts, and so forth. An advantage of $CaCl_2$ is that it has a highly negative ΔH_{soln}, so heat is released when it dissolves, which melts more ice.

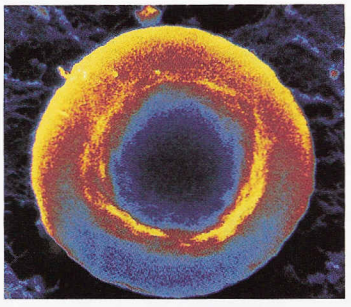


Zone refining Manufacturing computer chips requires extremely pure starting materials. In the process of *zone refining*, a rod of impure silicon (or other metal or metalloid) is passed slowly through a heating coil in an inert atmosphere, and the first narrow zone of impure solid melts. As the next zone melts, the dissolved impurities from the first zone lower the freezing point of the solution, while the purer solvent refreezes. The process continues, zone by zone, throughout the entire rod. After several passes through the coil, in which each zone's impurities move into the adjacent zone, the refrozen silicon at the end of the rod becomes extremely pure—more than 99.999999%. The ultrapure silicon is then sliced into wafers for the production of computer chips (Section 12.7).

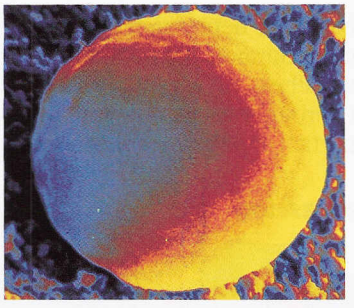
(continued)

GALLERY

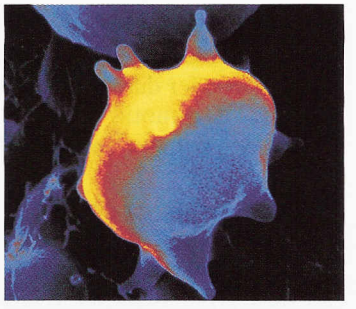
Applications of Osmotic Pressure



Controlling cell shape The word *tonicity* refers to the tone, or firmness, of a biological cell. An *isotonic* solution has the same concentration of particles as in the cell fluid, so water enters the cell at the same rate that it leaves, thereby maintaining the cell's normal shape.



To study cell contents, biochemists rupture membranes by placing the cell in a *hypotonic* solution, one that has a lower concentration of solute particles than the cell fluid. As a result, water enters the cell faster than it leaves, causing the cell to expand and burst.

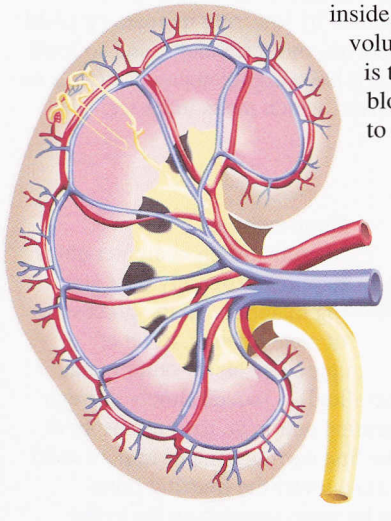


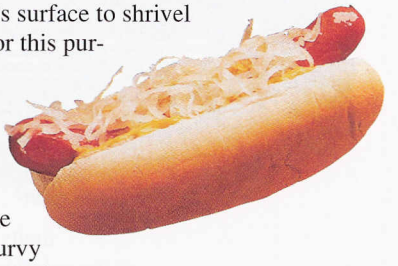
In a *hypertonic* solution, one that contains a higher concentration of solute particles than the cell fluid, the cell shrinks from the net outward flow of water.

Isotonic daily care Contact-lens rinses consist of isotonic saline (0.15 *M* NaCl) to prevent any changes in the volume of corneal cells. Solutions for the intravenous delivery of nutrients or drugs are always isotonic.

Hypotonic watering of trees The dissolved substances in tree sap create a more concentrated solution than the surrounding groundwater. Water enters membranes in the roots and rises into the tree, creating an osmotic pressure that can exceed 20 atm in the tallest trees!

Sodium ion: the extracellular osmoregulator Of the four major biological cations—Na^+, K^+, Mg^{2+}, and Ca^{2+}—Na^+ is essential for all animals (which includes you!) to regulate their fluid volume. The Na^+ ion accounts for more than 90 mol % of all cations *outside* a cell. A high Na^+ concentration draws water out of the cell by osmosis; a low Na^+ concentration leaves more inside. The primary role of Na^+ is to regulate the water volume of the body, and the primary role of the kidneys is to regulate the concentration of Na^+. Changes in blood pressure (volume) activate nerves and hormones to adjust blood flow and alter kidney function.





Hypertonic food preservation Before refrigeration was common, salt was used as a preservative. The salt causes microbes on the food's surface to shrivel and die from loss of water. (Salt was so highly prized for this purpose that Roman soldiers were paid in salt, from which practice comes the word *salary*.) In 1772, Captain James Cook wisely brought on board his ship large amounts of cabbage as food stores and preserved it with salt, thus converting the perishable vegetable into long-lived sauerkraut. The high vitamin-C content of the pickled cabbage prevented the debilitating effects of scurvy and allowed Cook's crew to continue explorations and partake in experiments that would revolutionize longitude measurements and, thus, oceangoing navigation.

The Underlying Theme of Colligative Properties A common thread runs through our explanations of the four colligative properties of nonvolatile solutes. Each property rests on the inability of solute particles to cross between two phases. Solute particles cannot enter the gas phase, which leads to vapor pressure lowering and boiling point elevation. They cannot enter the solid phase, which leads to freezing point depression. They cannot cross a semipermeable membrane, which leads to the development of osmotic pressure. The presence of solute decreases the mole fraction of solvent, which lowers the number of solvent particles leaving the solution per unit time; this lowering requires an adjustment to reach equilibrium again. This adjustment to reach the new balance in numbers of particles crossing between two phases per unit time results in the measured colligative property.

Using Colligative Properties to Find Solute Molar Mass

Each colligative property relates concentration to some measurable quantity—the number of degrees the freezing point is lowered, the magnitude of osmotic pressure created, and so forth. From these measurements, we can determine the amount (mol) of solute particles and, for a known mass of solute, the molar mass of the solute as well.

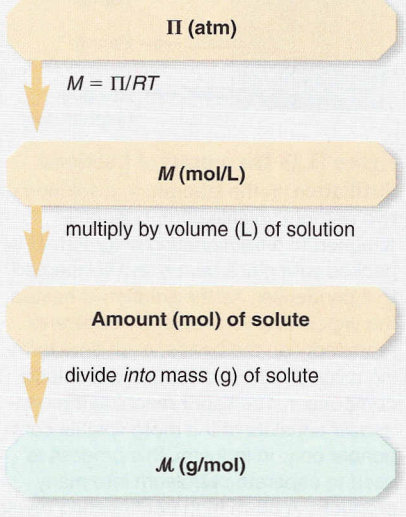
In principle, any of the colligative properties can be used to find the solute's molar mass, but in practice, some systems provide more accurate data than others. For example, to determine the molar mass of an unknown solute by freezing point depression, you would select a solvent with as large a molal freezing point depression constant as possible (see Table 13.6). If the solute is soluble in acetic acid, for instance, a 1 *m* concentration of it depresses the freezing point of acetic acid by 3.90°C, more than twice the change in water (1.86°C).

Of the four colligative properties, osmotic pressure creates the largest changes and therefore the most precise measurements. Biological and polymer chemists estimate molar masses as great as 10^5 g/mol by measuring osmotic pressure. Because only a tiny fraction of a mole of a macromolecular solute dissolves, it would create too small a change in the other colligative properties.

SAMPLE PROBLEM 13.8 Determining Molar Mass from Osmotic Pressure

Problem Biochemists have discovered more than 400 mutant varieties of hemoglobin, the blood protein that carries oxygen throughout the body. A physician studying a variety associated with a fatal disease first finds its molar mass ($\mathcal{M}$). She dissolves 21.5 mg of the protein in water at 5.0°C to make 1.50 mL of solution and measures an osmotic pressure of 3.61 torr. What is the molar mass of this variety of hemoglobin?

Plan We know the osmotic pressure (Π = 3.61 torr), R, and T (5.0°C). We convert Π from torr to atm, and T from °C to K, and then use Equation 13.13 to solve for molarity (M). Then we calculate the amount (mol) of hemoglobin from the known volume (1.50 mL) and use the known mass (21.5 mg) to find $\mathcal{M}$.



Solution Combining unit conversion steps and solving for molarity from Equation 13.13:

$$M = \frac{\Pi}{RT} = \frac{\dfrac{3.61 \text{ torr}}{760 \text{ torr}/1 \text{ atm}}}{\left(0.0821 \dfrac{\text{atm·L}}{\text{mol·K}}\right)(273.15 \text{ K} + 5.0)} = 2.08\times10^{-4}\, M$$

Finding amount (mol) of solute (after changing mL to L):

$$\text{Moles of solute} = M \times V = \frac{2.08\times10^{-4} \text{ mol}}{1 \text{ L soln}} \times 0.00150 \text{ L soln} = 3.12\times10^{-7} \text{ mol}$$

Calculating molar mass of hemoglobin (after changing mg to g):

$$\mathcal{M} = \frac{0.0215\ \text{g}}{3.12\times10^{-7}\ \text{mol}} = 6.89\times10^{4}\ \text{g/mol}$$

Check The answers seem reasonable: The small osmotic pressure implies a very low molarity. Hemoglobin is a protein, a biological macromolecule, so we expect a small number of moles [$(\sim2\times10^{-4}$ mol/L) $(1.5\times10^{-3}$ L) $= 3\times10^{-7}$ mol] and a high molar mass ($\sim21\times10^{-3}$ g/3×10^{-7} mol $= 7\times10^{4}$ g/mol).

FOLLOW-UP PROBLEM 13.8 A 0.30 *M* solution of sucrose that is at 37°C has approximately the same osmotic pressure as blood does. What is the osmotic pressure of blood?

Colligative Properties of Volatile Nonelectrolyte Solutions

What is the effect on vapor pressure when the solute *is* volatile, that is, when the vapor consists of solute *and* solvent molecules? From Raoult's law (Equation 13.9), we know that

$$P_{\text{solvent}} = X_{\text{solvent}} \times P^0_{\text{solvent}} \quad \text{and} \quad P_{\text{solute}} = X_{\text{solute}} \times P^0_{\text{solute}}$$

where X_{solvent} and X_{solute} refer to the mole fractions in the liquid phase. According to Dalton's law of partial pressures, the total vapor pressure is the sum of the partial vapor pressures:

$$P_{\text{total}} = P_{\text{solvent}} + P_{\text{solute}} = (X_{\text{solvent}} \times P^0_{\text{solvent}}) + (X_{\text{solute}} \times P^0_{\text{solute}})$$

Just as a nonvolatile solute lowers the vapor pressure of the solvent by making the mole fraction of the solvent less than 1, *the presence of each volatile component lowers the vapor pressure of the other* by making each mole fraction less than 1.

Let's examine this effect in a solution that contains equal amounts (mol) of benzene (C_6H_6) and toluene (C_7H_8): $X_{\text{ben}} = X_{\text{tol}} = 0.500$. At 25°C, the vapor pressure of pure benzene (P^0_{ben}) is 95.1 torr and that of pure toluene (P^0_{tol}) is 28.4 torr; note that benzene is more volatile than toluene. We find the partial pressures from Raoult's law:

$$P_{\text{ben}} = X_{\text{ben}} \times P^0_{\text{ben}} = 0.500 \times 95.1\ \text{torr} = 47.6\ \text{torr}$$

$$P_{\text{tol}} = X_{\text{tol}} \times P^0_{\text{tol}} = 0.500 \times 28.4\ \text{torr} = 14.2\ \text{torr}$$

As you can see, the presence of benzene lowers the vapor pressure of toluene, and vice versa.

Does the composition of the vapor differ from that of the solution? To see, let's calculate the mole fraction of each substance *in the vapor* by applying Dalton's law. Recall from Section 5.4 that $X_A = P_A/P_{\text{total}}$. Therefore, for benzene and toluene in the vapor,

$$X_{\text{ben}} = \frac{P_{\text{ben}}}{P_{\text{total}}} = \frac{47.6\ \text{torr}}{47.6\ \text{torr} + 14.2\ \text{torr}} = 0.770$$

$$X_{\text{tol}} = \frac{P_{\text{tol}}}{P_{\text{total}}} = \frac{14.2\ \text{torr}}{47.6\ \text{torr} + 14.2\ \text{torr}} = 0.230$$

The vapor composition is very different from the solution composition. The essential point to notice is that *the vapor has a higher mole fraction of the* ***more*** *volatile solution component*. The 50:50 ratio of benzene:toluene in the liquid created a 77:23 ratio of benzene:toluene in the vapor. Condense this vapor into a separate container, and that new *solution* would have this 77:23 composition, and the new *vapor* above it would be enriched still further in benzene.

In the process of **fractional distillation,** this phenomenon is used to separate a mixture of volatile components. Numerous vaporization-condensation steps continually enrich the vapor, until the vapor reaching the top of the fractionating column consists solely of the most volatile component. Figure 13.29 shows how

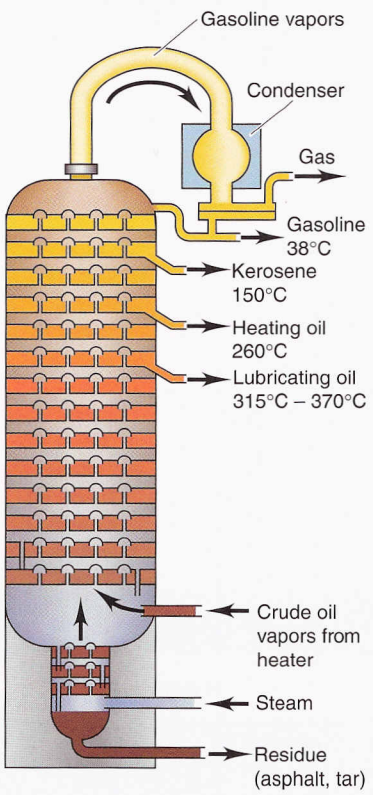


Figure 13.29 The process of fractional distillation. In the laboratory, a solution of two or more volatile components is attached to a *fractionating column* that is packed with glass beads and connected to a condenser. As the solution is heated, the vapor mixture rises and condenses repeatedly on the beads, each time forming a liquid enriched in the more volatile component. The vapor reaching the condenser consists of the more volatile component only. In industry, this process is used to separate petroleum into many products. A 30-m high fractionating tower can separate components that differ by a few tenths of a degree in their boiling points. (The illustration is a simplified version of a multipart process.)

fractional distillation is used in the industrial process of petroleum refining to separate the hundreds of individual compounds in crude oil into a small number of "fractions" based on boiling point range.

Colligative Properties of Strong Electrolyte Solutions

When we consider colligative properties of strong electrolyte solutions, the solute formula tells us the number of particles. For instance, the boiling point elevation (ΔT_b) of 0.050 *m* NaCl should be twice that of 0.050 *m* glucose ($C_6H_{12}O_6$), because NaCl dissociates into two particles per formula unit. Thus, we include a multiplying factor in the equations for the colligative properties of electrolyte solutions. The *van't Hoff factor (i),* named after the Dutch chemist Jacobus van't Hoff (1852–1911), is the ratio of the *measured* value of the colligative property in the electrolyte solution to the *expected* value for a nonelectrolyte solution:

$$i = \frac{\text{measured value for electrolyte solution}}{\text{expected value for nonelectrolyte solution}}$$

To calculate the colligative properties of strong electrolyte solutions, we incorporate the van't Hoff factor into the equation:

For vapor pressure lowering: $\Delta P = i(X_{solute} \times P^0_{solvent})$

For boiling point elevation: $\Delta T_b = i(K_b m)$

For freezing point depression: $\Delta T_f = i(K_f m)$

For osmotic pressure: $\Pi = i(MRT)$

If strong electrolyte solutions behaved ideally, the factor *i* would be the amount (mol) of particles in solution divided by the amount (mol) of dissolved solute; that is, *i* would be 2 for NaCl, 3 for $Mg(NO_3)_2$, and so forth. Careful experiment shows, however, that *most strong electrolyte solutions are* ***not*** *ideal.* For example, comparing the boiling point elevation for 0.050 *m* NaCl solution with that for 0.050 *m* glucose solution gives a factor *i* of 1.9, not 2.0:

$$i = \frac{\Delta T_b \text{ of } 0.050\ m \text{ NaCl}}{\Delta T_b \text{ of } 0.050\ m \text{ glucose}} = \frac{0.049°C}{0.026°C} = 1.9$$

The measured value of the van't Hoff factor is typically *lower* than that expected from the formula. This deviation implies that the ions are not behaving as independent particles. However, we know from other evidence that soluble salts dissociate completely into ions. The fact that the deviation is greater with divalent and trivalent ions is a strong indication that the ionic charge is somehow involved (Figure 13.30).

To explain this nonideal behavior, we picture ions as separate but near each other. Clustered near a positive ion are, on average, more negative ions, and vice versa. Figure 13.31 shows each ion surrounded by an **ionic atmosphere** of net opposite charge. Through these electrostatic associations, each type of ion behaves as if it were "tied up," so its concentration seems *lower* than it actually is. Thus, we often speak of an *effective* concentration, obtained by multiplying *i* by the *stoichiometric* concentration based on the formula. The greater the charge, the stronger the electrostatic associations, so the deviation from ideal behavior is greater for compounds that dissociate into multivalent ions.

At ordinary conditions and concentrations, nonideal behavior of solutions is much more common (and the deviations much larger) than nonideal behavior of gases, because the particles in solutions are so much closer together. Nevertheless, the two systems exhibit some interesting similarities. Gases display nearly ideal behavior at low pressures because the distances between particles are large. Similarly, van't Hoff factors (*i*) approach their ideal values as the solution becomes more dilute, that is, as the distance between ions increases. In gases, attractions between particles cause deviations from the expected pressure. In solutions,

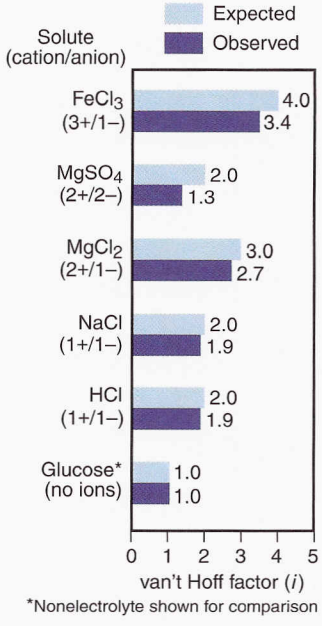

Figure 13.30 Nonideal behavior of strong electrolyte solutions. The van't Hoff factors *(i)* for various ionic solutes in dilute (0.05 *m*) aqueous solution show that the observed value (*dark blue*) is always *lower* than the expected value (*light blue*). This deviation is due to ionic interactions that, in effect, reduce the number of free ions in solution. The deviation is greatest for multivalent ions.

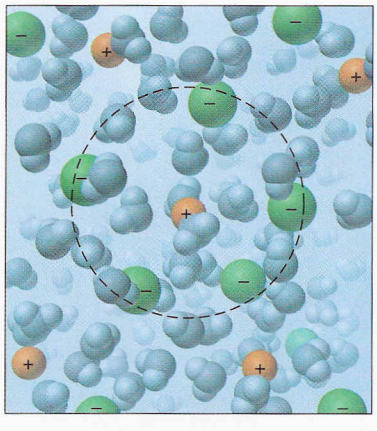

Figure 13.31 An ionic atmosphere model for nonideal behavior of electrolyte solutions. Hydrated anions cluster near cations, and vice versa, to form ionic atmospheres of net opposite charge. Because the ions do not act independently, their concentrations are effectively *less* than expected. Such interactions cause deviations from ideal behavior.

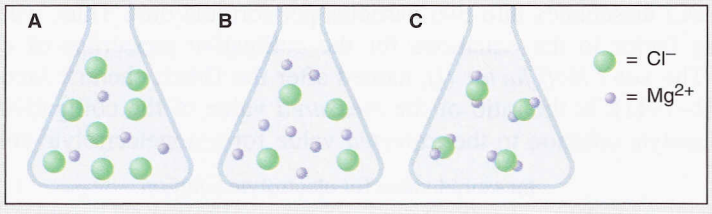
attractions between particles cause deviations from the expected size of a colligative property. Finally, for both real gases and real solutions, we use empirically determined numbers (van der Waals constants or van't Hoff factors) to transform theories (the ideal gas law or Raoult's law) into more useful relations.

SAMPLE PROBLEM 13.9 Depicting a Solution to Find Its Colligative Properties

Problem A 0.952-g sample of magnesium chloride is dissolved in 100. g of water in a flask.
(a) Which scene depicts the solution best?



(b) What is the amount (mol) represented by each green sphere?
(c) Assuming the solution is ideal, what is its freezing point (at 1 atm)?

Plan **(a)** From the name, we recognize an ionic compound, so we determine the formula to find the numbers of cations and anions per formula unit and compare this result with the three scenes: there is 1 magnesium ion for every 2 chloride ions. **(b)** From the given mass of solute, we find the amount (mol); from part (a), there are twice as many moles of chloride ions (green spheres). Dividing by the total number of green spheres gives the moles/sphere. **(c)** From the moles of solute and the given mass (kg) of water, we find the molality (m). We use K_f for water from Table 13.6 and multiply by m to get ΔT_f, and then subtract that from 0.000°C to get the solution freezing point.

Solution **(a)** The formula is $MgCl_2$; only scene A has 1 Mg^{2+} for every 2 Cl^-.

(b) $$\text{Moles of } MgCl_2 = \frac{0.952 \text{ g } MgCl_2}{95.21 \text{ g/mol } MgCl_2} = 0.0100 \text{ mol } MgCl_2$$

Therefore, $$\text{Moles of } Cl^- = 0.0100 \text{ mol } MgCl_2 \times \frac{2\ Cl^-}{1\ MgCl_2} = 0.0200 \text{ mol } Cl^-$$

$$\text{Moles/sphere} = \frac{0.0200 \text{ mol } Cl^-}{8 \text{ spheres}} = 2.50\times10^{-3} \text{ mol/sphere}$$

(c) $$\text{Molality } (m) = \frac{\text{mol of solute}}{\text{kg of solvent}} = \frac{0.0100 \text{ mol } MgCl_2}{100.\text{ g} \times \frac{1 \text{ kg}}{1000 \text{ g}}} = 0.100\ m\ MgCl_2$$

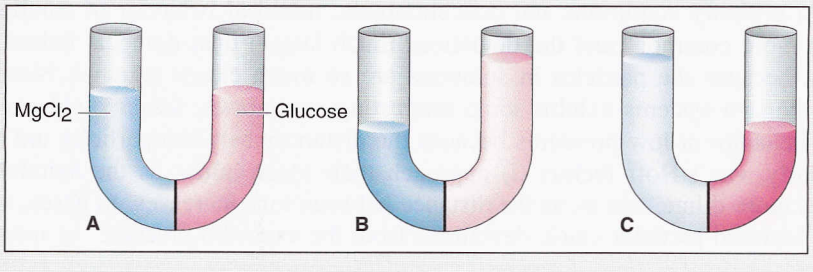
Assuming an ideal solution, the van't Hoff factor, i, is 3 for $MgCl_2$ because there are 3 ions per formula unit, so we have

$$\Delta T_f = i(K_f m) = 3(1.86°C/m \times 0.100\ m) = 0.558°C$$

And $$T_f = 0.000°C - 0.558°C = -0.558°C$$

Check Let's quickly check part (c): We have 0.01 mol dissolved in 0.1 kg, which gives 0.1 m. Then, rounding K_f, we have about $3(2°C/m \times 0.1\ m) = 0.6°C$.

FOLLOW-UP PROBLEM 13.9 The $MgCl_2$ solution in the sample problem has a density of 1.006 g/mL at 20.0°C. **(a)** What is the osmotic pressure of the solution? **(b)** A U-tube fitted with a semipermeable membrane is filled with this $MgCl_2$ solution in the left arm and a glucose solution of equal concentration in the right arm. After time, which scene depicts the U-tube best?



SECTION SUMMARY

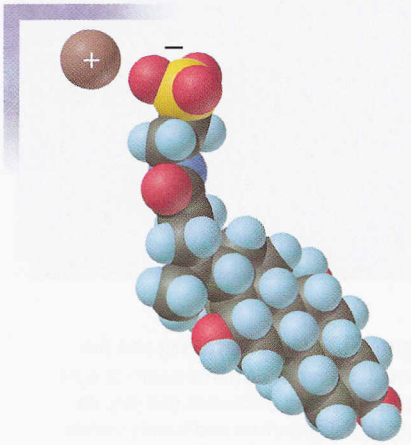
Colligative properties are related to the number of dissolved solute particles, not their chemical nature. Compared with the pure solvent, a solution of a nonvolatile nonelectrolyte has a lower vapor pressure (Raoult's law), an elevated boiling point, a depressed freezing point, and an osmotic pressure. Colligative properties can be used to determine the solute molar mass. When solute *and* solvent are volatile, the vapor pressure of each is lowered by the presence of the other. The vapor pressure of the more volatile component is always higher. Electrolyte solutions exhibit nonideal behavior because ionic interactions reduce the effective concentration of the ions.

13.7 THE STRUCTURE AND PROPERTIES OF COLLOIDS

Stir a handful of fine sand into a glass of water, and you'll see the sand particles are suspended at first but gradually settle to the bottom. Sand in water is a **suspension,** a *heterogeneous* mixture containing particles large enough to be seen by the naked eye and clearly distinct from the surrounding fluid. In contrast, stirring sugar into water forms a solution, a *homogeneous* mixture in which the particles are individual molecules distributed evenly throughout the surrounding fluid.

Between the extremes of suspensions and solutions is a large group of mixtures called *colloidal dispersions,* or **colloids,** in which a dispersed (solute-like) substance is distributed throughout a dispersing (solvent-like) substance. Colloidal particles are larger than simple molecules but small enough to remain distributed and not settle out. They range in diameter from 1 to 1000 nm (10^{-9} to 10^{-6} m). A colloidal particle may consist of a single macromolecule (such as a protein or synthetic polymer) or an aggregate of many atoms, ions, or molecules. Whatever their composition, colloidal particles have an enormous total surface area as a result of their small size. A cube with 1-cm sides has a total surface area of 6 cm^2. If it's divided equally into 10^{12} cubes, the cubes are the size of large colloidal particles and have a total surface area of 60,000 cm^2, or 6 m^2. This enormous surface area allows many more interactions to exert a great total adhesive force, which attracts other particles and leads to the practical uses of colloids.

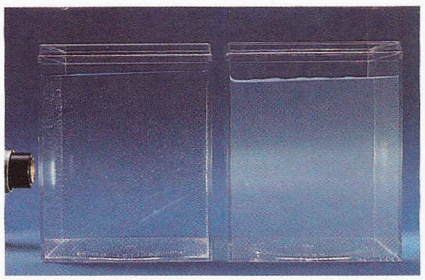
Colloids are classified in Table 13.7 according to whether the dispersed and dispersing substances are gases, liquids, or solids. Many familiar commercial products and natural objects are colloids. Whipped cream is a *foam,* a gas dispersed in a liquid. Firefighting foams are liquid mixtures of proteins in water that are made frothy with fine jets of air. Most biological fluids are aqueous *sols,* solids dispersed in water. Within a typical cell, proteins and nucleic acids are colloidal-size particles dispersed in an aqueous solution of ions and small molecules. The action of soaps and detergents occurs by the formation of an *emulsion,* a liquid (soap dissolved in grease) dispersed in another liquid (water).



"Soaps" in Your Small Intestine In the small intestine, fats are digested by *bile salts,* which are soaplike molecules with smaller polar-ionic and larger nonpolar portions. Secreted by the liver, stored in the gallbladder, and released in the intestine, bile salts emulsify fats just as soap emulsifies grease: fatty aggregates are broken down into particles of colloidal size and dispersed in the watery fluid. The fats are then broken down further and transported into the blood for cellular metabolism.

Table 13.7 Types of Colloids

Colloid Type	Dispersed Substance	Dispersing Medium	Example(s)
Aerosol	Liquid	Gas	Fog
Aerosol	Solid	Gas	Smoke
Foam	Gas	Liquid	Whipped cream
Solid foam	Gas	Solid	Marshmallow
Emulsion	Liquid	Liquid	Milk
Solid emulsion	Liquid	Solid	Butter
Sol	Solid	Liquid	Paint, cell fluid
Solid sol	Solid	Solid	Opal



A

B

Figure 13.32 Light scattering and the Tyndall effect. A, When a beam of light passes through a solution (*left jar*), its path remains narrow and barely visible. When it passes through a colloid (*right jar*), it is scattered and broadened by the particles and thus easily visible. **B,** Sunlight is scattered as it shines through misty air in a forest.

Most colloids are cloudy or opaque, but some are transparent to the naked eye. When light passes through a colloid, it is scattered randomly by the dispersed particles because their sizes are similar to the wavelengths of visible light (400 to 750 nm). Viewed from the side, the scattered light beam is visibly broader than one passing through a solution. This light-scattering phenomenon is called the **Tyndall effect** (Figure 13.32). Dust in air displays this effect when sunlight shines through it, as does mist pierced by headlights at night.

Under low magnification, you can see colloidal particles exhibit *Brownian motion,* a characteristic movement in which the particles change speed and direction erratically. This motion results because the colloidal particles are being pushed this way and that by molecules of the dispersing medium. These collisions are primarily responsible for keeping colloidal particles from settling out. (Einstein's explanation of Brownian motion in 1905 was a principal factor in the acceptance of the molecular nature of matter.)

When colloidal particles collide, why don't they aggregate into larger particles and settle out? Interparticle forces provide the explanation. Water-dispersed colloidal particles remain dispersed because they have charged surfaces that interact strongly with the water molecules through ion-dipole forces. Soap molecules form spherical *micelles,* with the charged heads forming the micelle exterior and the nonpolar tails interacting via dispersion forces in the interior. Aqueous proteins are typically spherical and mimic this micellar arrangement, with charged amino acid groups facing the water and uncharged groups buried within the molecule. Nonpolar oily particles can be dispersed in water by introducing ions, which are adsorbed onto their surfaces by dispersion forces. Charge repulsions between the adsorbed ions prevent the particles from aggregating.

Despite these forces, various methods can coagulate the particles and "destroy" the colloid. Heating a colloid makes the particles move faster and collide more often and with enough force to coalesce into heavier particles that settle out. Adding an electrolyte solution introduces oppositely charged ions that neutralize the particles' surface charges, which allows the particles to coagulate and settle. Uncharged colloidal particles in smokestack gases are removed by creating ions that become adsorbed on the particles, which are then attracted to the charged plates of a Cottrell precipitator. Such precipitators are installed in the smokestacks of coal-burning power plants (Figure 13.33) and collect about 90% of colloidal smoke particulates, thus preventing their release into the air.

The upcoming Chemical Connections essay applies solution and colloid chemistry to the purification of water for residential and industrial use.

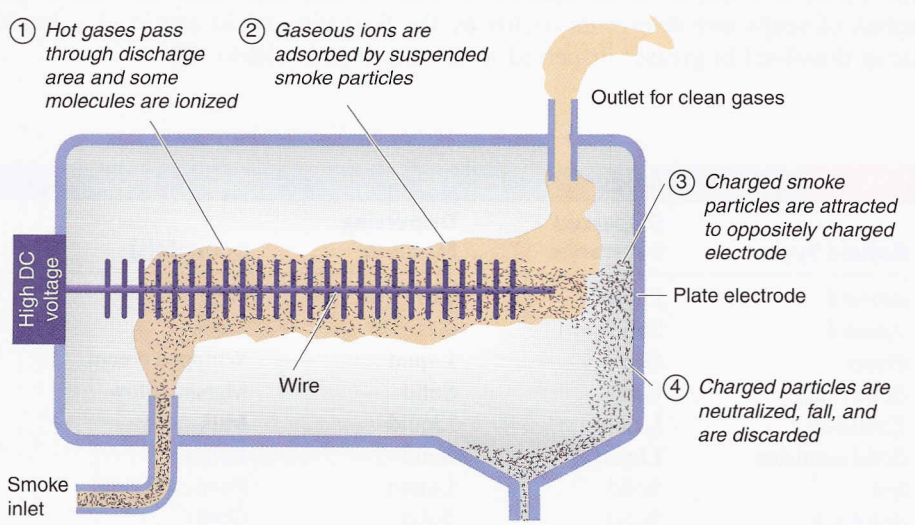


Figure 13.33 A Cottrell precipitator for removing particulates from industrial smokestack gases.

CHEMICAL CONNECTIONS to Sanitary Engineering

Solutions and Colloids in Water Purification

Clean water is a priceless and limited resource that we've begun to treasure only recently, after decades of pollution and waste. Because of the natural tendency of pure solutes and solvents to form solutions and colloids, it requires energy to remove dissolved, dispersed, and suspended particles from water to make it clean enough for humans to use.

Most water destined for human use comes from lakes, rivers, or reservoirs that may serve also as the final sink after the water is used. Many mineral ions, such as NO_3^- and Fe^{3+}, may be present in high concentrations. Dissolved organic compounds, some of which are toxic, may be present as well. Fine clay particles and a whole spectrum of microorganisms are dispersed in colloidal form. Larger particles and debris of every variety may be present in suspension.

Water Treatment Plants

As a sample of water moves from the natural source into a water treatment facility, the largest particles are physically removed at the intake site by screens (Figure B13.1, step 1). Finer particles, including microorganisms, are removed in large settling tanks by treatment with lime (CaO) and cake alum [$Al_2(SO_4)_3$] (step 2), which react to form a fluffy, gel-like mass of $Al(OH)_3$:

$$3CaO(s) + 3H_2O(l) + Al_2(SO_4)_3(s) \longrightarrow 2Al(OH)_3(\textit{colloidal gel}) + 3CaSO_4(aq)$$

The fine particles are trapped within or adsorbed onto the enormous surface area of the gel, which coagulates, settles out, and is filtered through a sand bed (step 3).

With suspended and colloidal particles removed, the water is aerated in large sprayers to saturate it with oxygen, which speeds the oxidation of dissolved organic compounds (step 4). The water is then disinfected, usually by treatment with Cl_2 gas and/or aqueous solutions of hypochlorite ion, ClO^- (step 5), which may give the water an unpleasant odor. Chlorine can also form toxic chlorinated hydrocarbons, but these can be removed by adsorption onto activated charcoal particles. These steps within the water treatment plant dispose of debris and grit, colloidal clay, microorganisms, and much of the oxidizable organic matter, but dissolved ions remain. Many of these can be removed by water softening and reverse osmosis.

Water Softening via Ion Exchange

Water that contains large amounts of divalent cations, such as Ca^{2+}, Mg^{2+}, and Fe^{2+}, is called **hard water.** These cations cause several problems. During cleaning, they combine with the anions of fatty acids in soaps to produce insoluble deposits on clothes, washing machine parts, and sinks:

$$Ca^{2+}(aq) + \underset{\text{soap}}{2C_{17}H_{35}COONa(aq)} \longrightarrow \underset{\text{insoluble deposit}}{(C_{17}H_{35}COO)_2Ca(s)} + 2Na^+(aq)$$

When a large amount of bicarbonate ion (HCO_3^-) is present in the water, the hard-water cations cause a buildup of *scale*, insoluble carbonate deposits within boilers and hot-water pipes that interfere with the transfer of heat and damage plumbing:

$$Ca^{2+}(aq) + 2HCO_3^-(aq) \xrightarrow{\Delta} CaCO_3(s) + CO_2(g) + H_2O(l)$$

The removal of hard-water ions, called **water softening,** solves these problems. It is accomplished by exchanging "soft-water" Na^+ ions for the hard-water cations. A typical domestic system for **ion exchange** contains an *ion-exchange resin,* an insoluble polymer that has covalently bonded anion groups, such as $-SO_3^-$ or $-COO^-$, to which Na^+ ions are attached to balance

(continued)

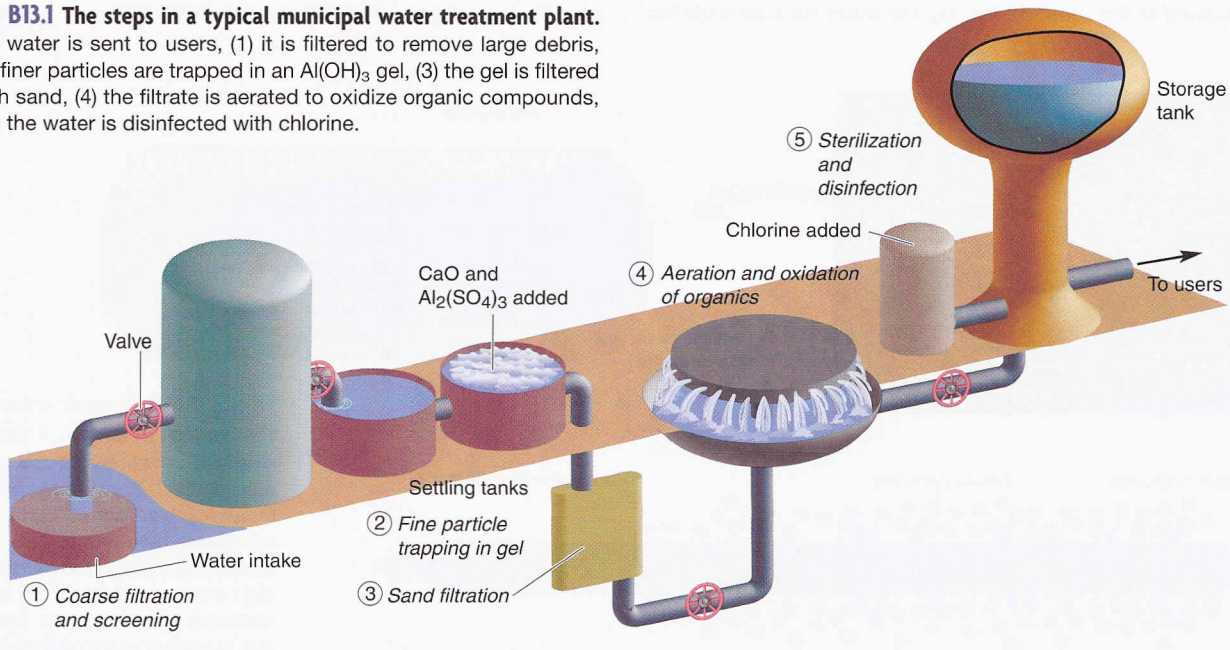

Figure B13.1 The steps in a typical municipal water treatment plant. Before water is sent to users, (1) it is filtered to remove large debris, (2) the finer particles are trapped in an $Al(OH)_3$ gel, (3) the gel is filtered through sand, (4) the filtrate is aerated to oxidize organic compounds, and (5) the water is disinfected with chlorine.

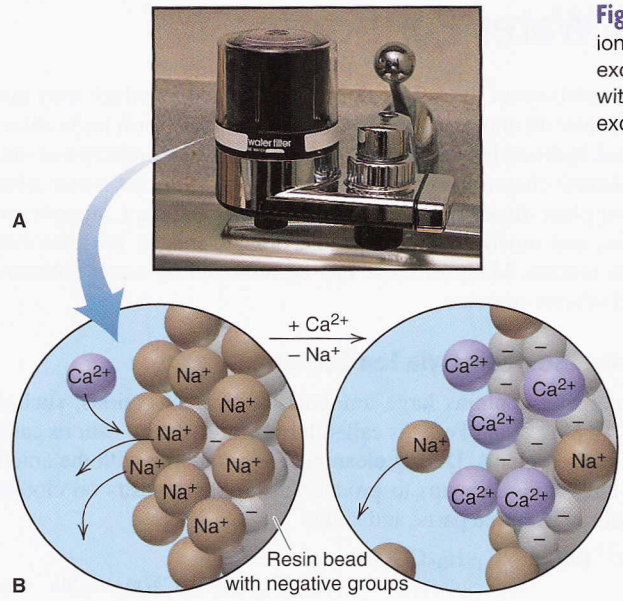

Figure B13.2 Ion exchange for removal of hard-water cations. A, A commercial ion-exchange column is installed in a household water system. **B,** In a typical ion-exchange resin, negatively charged groups are covalently bonded to resin beads, with Na^+ ions present to neutralize the charges. Hard-water ions, such as Ca^{2+}, exchange with the Na^+ ions, which are displaced into the flowing water.

the charges (Figure B13.2). The divalent cations in hard water are attracted to the resin's anionic groups and displace the Na^+ ions into the water: one type of ion is exchanged for another. The resin is replaced when all the resin sites are occupied, or it can be "regenerated" by treating it with a very concentrated Na^+ solution, which exchanges Na^+ ions for the bound Ca^{2+}.

Reverse Osmosis

Another way to remove ions and other dissolved substances from water is by **reverse osmosis.** In osmosis, water moves from a dilute to a concentrated solution through a semipermeable membrane. The resulting difference in water volumes creates an osmotic pressure. In reverse osmosis, water moves out of the concentrated solution when a pressure *greater* than the osmotic pressure is *applied* to the solution, forcing the water back through the membrane and leaving the ions behind—in a sense, filtering out the ions at the molecular level.

In domestic water systems, reverse osmosis is used to remove toxic ions, such as the *heavy-metal ions* Pb^{2+}, Cd^{2+}, and Hg^{2+}, present at concentrations too low for removal by ion exchange. On a much larger scale, reverse osmosis is used in **desalination** plants, which remove large amounts of ions from seawater (Figure B13.3). Reverse-osmosis plants are common in arid regions, such as the Middle East. Seawater is pumped under high pressure into tubes containing millions of hollow fibrous membranes, each the thickness of a human hair. Water molecules, but not ions, pass through the membranes into the fiber. Seawater containing about 40,000 ppm of dissolved solids can be purified to a level around 400 ppm (suitable for drinking) in one pass through such a system.

Water Treatment after Use

Used water is called **wastewater,** or *sewage,* and it must be treated before being returned to the groundwater, river, or lake. Sewage treatment is especially important for industrial wastewater, which may contain toxic components. In *primary* sewage treatment, wastewater undergoes the same steps as are used to treat water coming into the system. Most municipalities also include *secondary* sewage treatment. In this stage, bacteria biologically degrade the organic compounds and some microorganisms still present in solution or in the solids from the settling tanks. Secondary treatment is sometimes supplemented by *tertiary* treatment in a process tailored to the specific pollutant involved. Heavy-metal ions, for instance, can be eliminated by a precipitation step before primary and secondary treatment. Tertiary methods also exist for phosphates, nitrate, and toxic organic substances.

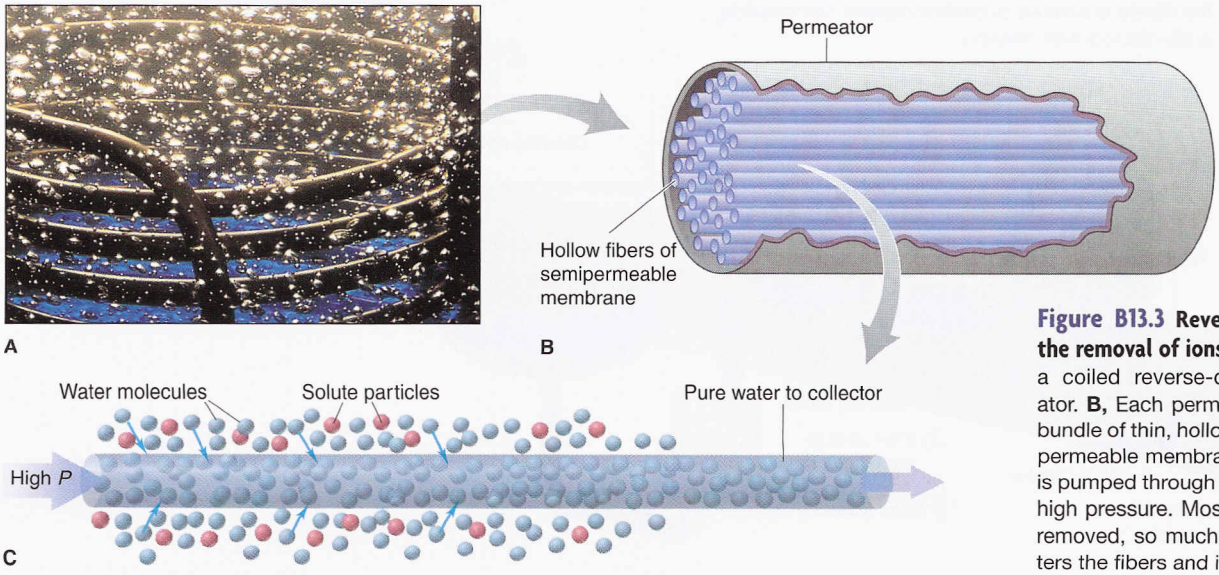

Figure B13.3 Reverse osmosis for the removal of ions. A, A section of a coiled reverse-osmosis permeator. **B,** Each permeator contains a bundle of thin, hollow fibers of semipermeable membrane. **C,** Seawater is pumped through the permeator at high pressure. Most of the ions are removed, so much purer water enters the fibers and is collected.

SECTION SUMMARY

Colloidal particles are smaller than those in a suspension and larger than those in a solution. Colloids are classified by the physical states of the dispersed and dispersing substances and are formed from many combinations of gas, liquid, and solid. Colloids have extremely large surface areas, scatter incoming light (Tyndall effect), and exhibit random (Brownian) motion. Colloidal particles in water have charged surfaces that keep them dispersed, but they can be coagulated by heating or by the addition of ions.

Chapter Perspective

In Chapter 12, you saw how pure liquids and solids behave, and here you've seen how their behaviors change when they are mixed together. Two features of these systems reappear in later chapters: their equilibrium nature in Chapters 17 to 19 and the importance of entropy in Chapter 20.

This chapter completes our general discussion of atomic and molecular properties and their influence on the properties of matter. Immediately following is an Interchapter feature that reviews these properties in a pictorial format and helps preview their application in the next two chapters. In Chapter 14, we travel through the main groups of the periodic table, applying the ideas you've learned so far to the chemical and physical behavior of the elements. Then, in Chapter 15, we apply them to carbon and its nearest neighbors to see how their properties are responsible for the fascinating world of organic substances, including synthetic polymers and biomolecules.

From Colloid to Civilization At times, civilizations have been born where colloids were being coagulated by electrolyte solutions. At the mouths of rivers, where salt concentrations increase near an ocean or sea, the clay particles dispersed in the river water come together to form muddy deltas, such as those of the Nile (*reddish area in photo*) and the Mississippi. The ancient Egyptian empire and the city of New Orleans are the results of this global colloid chemistry.

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. The quantitative meaning of solubility (13.1)
2. The major types of intermolecular forces in solution and their relative strengths (13.1)
3. How the like-dissolves-like rule depends on intermolecular forces (13.1)
4. Why gases have relatively low solubilities in water (13.1)
5. General characteristics of solutions formed by various combinations of gases, liquids, and solids (13.1)
6. How intermolecular forces stabilize the structures of proteins, the cell membrane, DNA, and cellulose (13.2)
7. The enthalpy components of a solution cycle and their effect on ΔH_{soln} (13.3)
8. The dependence of ΔH_{hydr} on ionic charge density and the factors that determine whether ionic solution processes are exothermic or endothermic (13.3)
9. The meaning of entropy and how the balance between the change in enthalpy and the change in entropy governs the solution process (13.3)
10. The distinctions among saturated, unsaturated, and supersaturated solutions, and the equilibrium nature of a saturated solution (13.4)
11. The relation between temperature and the solubility of solids (13.4)
12. Why the solubility of gases in water decreases with a rise in temperature (13.4)
13. The effect of gas pressure on solubility and its quantitative expression as Henry's law (13.4)
14. The meaning of molarity, molality, mole fraction, and parts by mass or by volume of a solution, and how to convert among them (13.5)
15. The distinction between electrolytes and nonelectrolytes in solution (13.6)
16. The four colligative properties and their dependence on number of dissolved particles (13.6)
17. Ideal solutions and the importance of Raoult's law (13.6)
18. How the phase diagram of a solution differs from that of the pure solvent (13.6)
19. Why the vapor over a solution of volatile nonelectrolyte is richer in the more volatile component (13.6)
20. Why electrolyte solutions are not ideal and the meanings of the van't Hoff factor and ionic atmosphere (13.6)
21. How particle size distinguishes suspensions, colloids, and solutions (13.7)
22. How colloidal behavior is demonstrated by the Tyndall effect and Brownian motion (13.7)

Learning Objectives *(continued)*

Master These Skills

1. Predicting relative solubilities from intermolecular forces (SP 13.1)
2. Using Henry's law to calculate the solubility of a gas (SP 13.2)
3. Expressing concentration in terms of molality, parts by mass, parts by volume, and mole fraction (SPs 13.3 and 13.4)
4. Interconverting among the various terms for expressing concentration (SP 13.5)
5. Using Raoult's law to calculate the vapor pressure lowering of a solution (SP 13.6)
6. Determining boiling point elevation and freezing point depression of a solution (SP 13.7)
7. Using a colligative property to calculate the molar mass of a solute (SP 13.8)
8. Using a solution depiction to determine colligative properties (SP 13.9)
9. Calculating the composition of vapor over a solution of volatile nonelectrolyte (13.6)
10. Calculating the van't Hoff factor i from the magnitude of a colligative property (13.6)

Key Terms

Section 13.1
solute (490)
solvent (490)
miscible (490)
solubility (S) (490)
like-dissolves-like rule (490)
hydration shell (490)
ion–induced dipole force (490)
dipole–induced dipole force (491)
alloy (494)

Section 13.2
protein (495)
amino acid (495)
soap (498)
lipid bilayer (499)
nucleic acid (500)
mononucleotide (500)
double helix (501)
polysaccharide (501)
monosaccharide (501)

Section 13.3
heat of solution (ΔH_{soln}) (503)
solvation (503)
hydration (503)
heat of hydration (ΔH_{hydr}) (504)
charge density (504)
entropy (S) (505)

Section 13.4
saturated solution (507)
unsaturated solution (507)
supersaturated solution (507)
Henry's law (510)

Section 13.5
molality (m) (511)
mass percent [% (w/w)] (512)
volume percent [% (v/v)] (512)
mole fraction (X) (513)

Section 13.6
colligative property (515)
electrolyte (515)
nonelectrolyte (515)
vapor pressure lowering (ΔP) (516)
Raoult's law (516)
ideal solution (516)
boiling point elevation (ΔT_b) (517)
freezing point depression (ΔT_f) (519)
semipermeable membrane (520)
osmosis (520)
osmotic pressure (Π) (520)
fractional distillation (524)
ionic atmosphere (525)

Section 13.7
suspension (527)
colloid (527)
Tyndall effect (528)
hard water (529)
water softening (529)
ion exchange (529)
reverse osmosis (530)
desalination (530)
wastewater (530)

Key Equations and Relationships

13.1 Dividing the general heat of solution into component enthalpies (503):

$$\Delta H_{soln} = \Delta H_{solute} + \Delta H_{solvent} + \Delta H_{mix}$$

13.2 Dividing the heat of solution of an ionic compound in water into component enthalpies (504):

$$\Delta H_{soln} = \Delta H_{lattice} + \Delta H_{hydr\ of\ the\ ions}$$

13.3 Relating gas solubility to its partial pressure (Henry's law) (510):

$$S_{gas} = k_H \times P_{gas}$$

13.4 Defining concentration in terms of molarity (510):

$$\text{Molarity } (M) = \frac{\text{amount (mol) of solute}}{\text{volume (L) of solution}}$$

13.5 Defining concentration in terms of molality (511):

$$\text{Molality } (m) = \frac{\text{amount (mol) of solute}}{\text{mass (kg) of solvent}}$$

13.6 Defining concentration in terms of mass percent (512):

$$\text{Mass percent [\% (w/w)]} = \frac{\text{mass of solute}}{\text{mass of solution}} \times 100$$

13.7 Defining concentration in terms of volume percent (512):

$$\text{Volume percent [\% (v/v)]} = \frac{\text{volume of solute}}{\text{volume of solution}} \times 100$$

13.8 Defining concentration in terms of mole fraction (513):

$$\text{Mole fraction (X)} = \frac{\text{amount (mol) of solute}}{\text{amount (mol) of solute + amount (mol) of solvent}}$$

13.9 Expressing the relationship between the vapor pressure of solvent above a solution and its mole fraction in the solution (Raoult's law) (516):

$$P_{solvent} = X_{solvent} \times P^0_{solvent}$$

13.10 Calculating the vapor pressure lowering due to solute (517):

$$\Delta P = X_{solute} \times P^0_{solvent}$$

13.11 Calculating the boiling point elevation of a solution (518):

$$\Delta T_b = K_b m$$

13.12 Calculating the freezing point depression of a solution (519):

$$\Delta T_f = K_f m$$

13.13 Calculating the osmotic pressure of a solution (520):

$$\Pi = \frac{n_{solute}}{V_{soln}} RT = MRT$$

Highlighted Figures and Tables

These figures (F) and tables (T) provide a review of key ideas.

F13.1 Major types of intermolecular forces in solutions (490)
F13.2 Hydration shells around an aqueous ion (491)

F13.30 Nonideal behavior of strong electrolyte solutions (525)
T13.7 Types of colloids (527)

Brief Solutions to Follow-up Problems

13.1 (a) 1,4-Butanediol is more soluble in water because it can form more H bonds.
(b) Chloroform is more soluble in water because of dipole-dipole forces.

13.2 $S_{N_2} = (7\times10^{-4}\ \text{mol/L·atm})\ (0.78\ \text{atm})$
$= 5\times10^{-4}\ \text{mol/L}$

13.3 Mass (g) of glucose = 563 g ethanol
$\times \dfrac{1\ \text{kg}}{10^3\ \text{g}} \times \dfrac{2.40\times10^{-2}\ \text{mol glucose}}{1\ \text{kg ethanol}}$
$\times \dfrac{180.16\ \text{g glucose}}{1\ \text{mol glucose}}$
$= 2.43\ \text{g glucose}$

13.4 Mass % $C_3H_7OH = \dfrac{35.0\ \text{g}}{35.0\ \text{g} + 150.\ \text{g}} \times 100 = 18.9$ mass %
Mass % $C_2H_5OH = 100.0 - 18.9 = 81.1$ mass %

$$X_{C_3H_7OH} = \frac{35.0\ \text{g}\ C_3H_7OH \times \dfrac{1\ \text{mol}\ C_3H_7OH}{60.09\ \text{g}\ C_3H_7OH}}{\left(35.0\ \text{g}\ C_3H_7OH \times \dfrac{1\ \text{mol}\ C_3H_7OH}{60.09\ \text{g}\ C_3H_7OH}\right)+\left(150.\ \text{g}\ C_2H_5OH \times \dfrac{1\ \text{mol}\ C_2H_5OH}{46.07\ \text{g}\ C_2H_5OH}\right)} = 0.152$$

$X_{C_2H_5OH} = 1.000 - 0.152 = 0.848$

13.5 Mass % HCl $= \dfrac{\text{mass of HCl}}{\text{mass of soln}} \times 100$
$= \dfrac{\dfrac{11.8\ \text{mol HCl}}{1\ \text{L soln}} \times \dfrac{36.46\ \text{g HCl}}{1\ \text{mol HCl}}}{\dfrac{1.190\ \text{g}}{1\ \text{mL soln}} \times \dfrac{10^3\ \text{mL}}{1\ \text{L}}} \times 100$
$= 36.2$ mass % HCl

Mass (kg) of soln $= 1\ \text{L soln} \times \dfrac{1.190\times10^{-3}\ \text{kg soln}}{1\times10^{-3}\ \text{L soln}}$
$= 1.190\ \text{kg soln}$

Mass (kg) of HCl $= 11.8\ \text{mol HCl} \times \dfrac{36.46\ \text{g HCl}}{1\ \text{mol HCl}} \times \dfrac{1\ \text{kg}}{10^3\ \text{g}}$
$= 0.430\ \text{kg HCl}$

Molality of HCl $= \dfrac{\text{mol HCl}}{\text{kg water}} = \dfrac{\text{mol HCl}}{\text{kg soln} - \text{kg HCl}}$
$= \dfrac{11.8\ \text{mol HCl}}{0.760\ \text{kg}\ H_2O} = 15.5\ m\ \text{HCl}$

$$X_{HCl} = \frac{\text{mol HCl}}{\text{mol HCl} + \text{mol}\ H_2O} = \frac{11.8\ \text{mol}}{11.8\ \text{mol} + \left(760\ \text{g}\ H_2O \times \dfrac{1\ \text{mol}}{18.02\ \text{g}\ H_2O}\right)} = 0.219$$

13.6 $\Delta P = X_{aspirin} \times P^0_{methanol}$
$= \dfrac{\dfrac{2.00\ \text{g}}{180.15\ \text{g/mol}}}{\dfrac{2.00\ \text{g}}{180.15\ \text{g/mol}} + \dfrac{50.0\ \text{g}}{32.04\ \text{g/mol}}} \times 101\ \text{torr}$
$= 0.713\ \text{torr}$

13.7 Molality of $C_2H_6O_2 = \dfrac{(0.00°\text{F} - 32°\text{F})\left(\dfrac{5°\text{C}}{9°\text{F}}\right)}{1.86°\text{C}/m} = 9.56\ m$

13.8 $\Pi = MRT = (0.30\ \text{mol/L})\left(0.0821\ \dfrac{\text{atm·L}}{\text{mol·K}}\right)(37°\text{C} + 273.15)$
$= 7.6\ \text{atm}$

13.9 (a) Mass of 0.100 m solution = 1 kg water + 0.100 mol $MgCl_2$
$= 1000\ \text{g} + 9.52\ \text{g} = 1009.52\ \text{g}$

Volume of solution $= 1009.52\ \text{g} \times \dfrac{1\ \text{mL}}{1.006\ \text{g}} = 1003\ \text{mL}$

Molarity $= \dfrac{9.52\ \text{g}\ MgCl_2}{1003\ \text{mL soln}} \times \dfrac{1\ \text{mol}}{9.52\ \text{g}\ MgCl_2} \times \dfrac{10^3\ \text{mL}}{1\ \text{L}}$
$= 9.97\times10^{-2}\ M$

Osmotic pressure (Π)
$= i(MRT)$
$= 3(9.97\times10^{-2}\ \text{mol/L})\left(0.0821\ \dfrac{\text{atm·L}}{\text{mol·K}}\right)(293\text{K})$
$= 7.19\ \text{atm}$

(b) Scene C

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

Types of Solutions: Intermolecular Forces and Predicting Solubility

(Sample Problem 13.1)

Concept Review Questions

13.1 Describe how properties of seawater illustrate the two characteristics that define mixtures.

13.2 What types of intermolecular forces give rise to hydration shells in an aqueous solution of sodium chloride?

13.3 Acetic acid is miscible with water. Would you expect carboxylic acids, general formula $CH_3(CH_2)_nCOOH$, to become more or less water soluble as n increases? Explain.

13.4 Which would you expect to be more effective as a soap, sodium acetate or sodium stearate? Explain.

13.5 Hexane and methanol are miscible as gases but only slightly soluble in each other as liquids. Explain.

13.6 Hydrogen chloride (HCl) gas is much more soluble than propane gas (C_3H_8) in water, even though HCl has a lower boiling point. Explain.

Skill-Building Exercises *(grouped in similar pairs)*

13.7 Which gives the more concentrated solution, (a) KNO_3 in H_2O or (b) KNO_3 in carbon tetrachloride (CCl_4)? Explain.

13.8 Which gives the more concentrated solution, stearic acid [$CH_3(CH_2)_{16}COOH$] in (a) H_2O or (b) CCl_4? Explain.

13.9 What is the strongest type of intermolecular force between solute and solvent in each solution?

(a) $CsCl(s)$ in $H_2O(l)$ (b) $CH_3\overset{\overset{O}{\|}}{C}CH_3(l)$ in $H_2O(l)$

(c) $CH_3OH(l)$ in $CCl_4(l)$

13.10 What is the strongest type of intermolecular force between solute and solvent in each solution?

(a) $Cu(s)$ in $Ag(s)$ (b) $CH_3Cl(g)$ in $CH_3OCH_3(g)$

(c) $CH_3CH_3(g)$ in $CH_3CH_2CH_2NH_2(l)$

13.11 What is the strongest type of intermolecular force between solute and solvent in each solution?

(a) $CH_3OCH_3(g)$ in $H_2O(l)$ (b) $Ne(g)$ in $H_2O(l)$

(c) $N_2(g)$ in $C_4H_{10}(g)$

13.12 What is the strongest type of intermolecular force between solute and solvent in each solution?

(a) $C_6H_{14}(l)$ in $C_8H_{18}(l)$ (b) $H_2C{=}O(g)$ in $CH_3OH(l)$

(c) $Br_2(l)$ in $CCl_4(l)$

13.13 Which member of each pair is more soluble in diethyl ether? Why?

(a) $NaCl(s)$ or $HCl(g)$ (b) $H_2O(l)$ or $CH_3\overset{\overset{O}{\|}}{C}H(l)$

(c) $MgBr_2(s)$ or $CH_3CH_2MgBr(s)$

13.14 Which member of each pair is more soluble in water? Why?

(a) $CH_3CH_2OCH_2CH_3(l)$ or $CH_3CH_2OCH_3(g)$

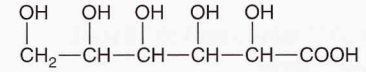
(b) $CH_2Cl_2(l)$ or $CCl_4(l)$

(c) 
cyclohexane tetrahydropyran

Problems in Context

13.15 The dictionary defines *homogeneous* as "uniform in composition throughout." River water is a mixture of dissolved compounds, such as calcium bicarbonate, and suspended soil particles. Is river water homogeneous? Explain.

13.16 Gluconic acid is a derivative of glucose used in cleaners and in the dairy and brewing industries. Caproic acid is a carboxylic acid used in the flavoring industry. Although both are six-carbon acids (see structures below), gluconic acid is soluble in water and nearly insoluble in hexane, whereas caproic acid has the opposite solubility behavior. Explain.



gluconic acid

caproic acid

Intermolecular Forces and Biological Macromolecules

Concept Review Questions

13.17 Name three intermolecular forces that stabilize the shape of a soluble, globular protein, and explain how they act.

13.18 Name three intermolecular forces that stabilize the shape of DNA, and explain how they act.

13.19 Is the sodium salt of propanoic acid as effective a soap as sodium stearate? Explain.

13.20 What intermolecular forces stabilize a lipid bilayer?

13.21 In what way do proteins embedded in a membrane differ structurally from soluble proteins?

13.22 How can wood be so strong if it consists of cellulose chains held together by relatively weak H bonds?

13.23 Histones are proteins that control gene function by attaching through salt links to exterior regions of DNA. Name an amino acid whose side chain is often found on the exterior of histones.

Why Substances Dissolve: Understanding the Solution Process

Concept Review Questions

13.24 What is the relationship between solvation and hydration?

13.25 For a general solvent, which enthalpy terms in the thermochemical solution cycle are combined to obtain $\Delta H_{solvation}$?

13.26 (a) What is the charge density of an ion, and what two properties of an ion affect it?

(b) Arrange the following in order of increasing charge density:

(c) How do the two properties in part (a) affect the ionic heat of hydration, ΔH_{hydr}?

13.27 For ΔH_{soln} to be very small, what quantities must be nearly equal in magnitude? Will their signs be the same or opposite?

13.28 Water is added to a flask containing solid NH_4Cl. As the salt dissolves, the solution becomes colder.
(a) Is the dissolving of NH_4Cl exothermic or endothermic?
(b) Is the magnitude of $\Delta H_{lattice}$ of NH_4Cl larger or smaller than the combined ΔH_{hydr} of the ions? Explain.
(c) Given the answer to (a), why does NH_4Cl dissolve in water?

13.29 An ionic compound has a highly negative ΔH_{soln} in water. Would you expect it to be very soluble or nearly insoluble in water? Explain in terms of enthalpy and entropy changes.

Skill-Building Exercises *(grouped in similar pairs)*

13.30 Sketch a qualitative enthalpy diagram for the process of dissolving $KCl(s)$ in H_2O (endothermic).

13.31 Sketch a qualitative enthalpy diagram for the process of dissolving $NaI(s)$ in H_2O (exothermic).

13.32 Which ion in each pair has greater charge density? Explain.
(a) Na^+ or Cs^+ (b) Sr^{2+} or Rb^+ (c) Na^+ or Cl^-
(d) O^{2-} or F^- (e) OH^- or SH^-

13.33 Which ion has the lower ratio of charge to volume? Explain.
(a) Br^- or I^- (b) Sc^{3+} or Ca^{2+} (c) Br^- or K^+
(d) S^{2-} or Cl^- (e) Sc^{3+} or Al^{3+}

13.34 Which has the *larger* ΔH_{hydr} in each pair of Problem 13.32?

13.35 Which has the *smaller* ΔH_{hydr} in each pair of Problem 13.33?

13.36 (a) Use the following data to calculate the combined heat of hydration for the ions in potassium bromate ($KBrO_3$):

$$\Delta H_{lattice} = 745 \text{ kJ/mol} \qquad \Delta H_{soln} = 41.1 \text{ kJ/mol}$$

(b) Which ion contributes more to the answer to part (a)? Why?

13.37 (a) Use the following data to calculate the combined heat of hydration for the ions in sodium acetate ($NaC_2H_3O_2$):

$$\Delta H_{lattice} = 763 \text{ kJ/mol} \qquad \Delta H_{soln} = 17.3 \text{ kJ/mol}$$

(b) Which ion contributes more to the answer to part (a)? Why?

13.38 State whether the entropy of the system increases or decreases in each of the following processes:
(a) Gasoline is burned in a car engine.
(b) Gold is extracted and purified from its ore.
(c) Ethanol (CH_3CH_2OH) dissolves in 1-propanol ($CH_3CH_2CH_2OH$).

13.39 State whether the entropy of the system increases or decreases in each of the following processes:
(a) Pure gases are mixed to prepare an anesthetic.
(b) Electronic-grade silicon is prepared from sand.
(c) Dry ice (solid CO_2) sublimes.

Problems in Context

13.40 Besides its use in making black-and-white film, silver nitrate ($AgNO_3$) is used similarly in forensic science. The NaCl left behind in the sweat of a fingerprint is treated with $AgNO_3$ solution to form AgCl. This precipitate is developed to show the black-and-white fingerprint pattern. Given $\Delta H_{lattice}$ of $AgNO_3$ = 822 kJ/mol and $\Delta H_{hydr} = -799$ kJ/mol, calculate its ΔH_{soln}.

Solubility as an Equilibrium Process

(Sample Problem 13.2)

Concept Review Questions

13.41 You are given a bottle of solid X and three aqueous solutions of X—one saturated, one unsaturated, and one supersaturated. How would you determine which solution is which?

13.42 Potassium permanganate ($KMnO_4$) has a solubility of 6.4 g/100 g of H_2O at 20°C and a curve of solubility vs. temperature that slopes upward to the right. How would you prepare a supersaturated solution of $KMnO_4$?

13.43 Why does the solubility of any gas in water decrease with rising temperature?

Skill-Building Exercises *(grouped in similar pairs)*

13.44 For a saturated aqueous solution of each of the following at 20°C and 1 atm, will the solubility increase, decrease, or stay the same when the indicated change occurs?
(a) $O_2(g)$, increase P (b) $N_2(g)$, increase V

13.45 For a saturated aqueous solution of each of the following at 20°C and 1 atm, will the solubility increase, decrease, or stay the same when the indicated change occurs?
(a) $He(g)$, decrease T (b) $RbI(s)$, increase P

13.46 The Henry's law constant (k_H) for O_2 in water at 20°C is 1.28×10^{-3} mol/L·atm. (a) How many grams of O_2 will dissolve in 2.00 L of H_2O that is in contact with pure O_2 at 1.00 atm? (b) How many grams of O_2 will dissolve in 2.00 L of H_2O that is in contact with air, where the partial pressure of O_2 is 0.209 atm?

13.47 Argon makes up 0.93% by volume of air. Calculate its solubility (mol/L) in water at 20°C and 1.0 atm. The Henry's law constant for Ar under these conditions is 1.5×10^{-3} mol/L·atm.

Problems in Context

13.48 Caffeine is about 10 times as soluble in hot water as in cold water. A chemist puts a hot-water extract of caffeine into an ice bath, and some caffeine crystallizes. Is the remaining solution saturated, unsaturated, or supersaturated?

13.49 The partial pressure of CO_2 gas above the liquid in a bottle of champagne at 20°C is 5.5 atm. What is the solubility of CO_2 in champagne? Assume Henry's law constant is the same for champagne as for water: at 20°C, $k_H = 3.7\times10^{-2}$ mol/L·atm.

13.50 Respiratory problems are treated with devices that deliver air with a higher partial pressure of O_2 than normal air. Why?

Quantitative Ways of Expressing Concentration

(Sample Problems 13.3 to 13.5)

Concept Review Questions

13.51 Explain the difference between molarity and molality. Under what circumstances would molality be a more accurate measure of the concentration of a prepared solution than molarity? Why?

13.52 Which way of expressing concentration includes (a) volume of solution; (b) mass of solution; (c) mass of solvent?

13.53 A solute has a solubility in water of 21 g/kg solvent. Is this value the same as 21 g/kg solution? Explain.

13.54 You want to convert among molarity, molality, and mole fraction of a solution. You know the masses of solute and solvent and the volume of solution. Is this enough information to carry out all the conversions? Explain.

13.55 When a solution is heated, which ways of expressing concentration change in value? Which remain unchanged? Explain.

Skill-Building Exercises *(grouped in similar pairs)*

13.56 Calculate the molarity of each aqueous solution:
(a) 42.3 g of table sugar ($C_{12}H_{22}O_{11}$) in 100. mL of solution
(b) 5.50 g of $LiNO_3$ in 505 mL of solution

13.57 Calculate the molarity of each aqueous solution:
(a) 0.82 g of ethanol (C_2H_5OH) in 10.5 mL of solution
(b) 1.22 g of gaseous NH_3 in 33.5 mL of solution

13.58 Calculate the molarity of each aqueous solution:
(a) 75.0 mL of 0.250 *M* NaOH diluted to 0.250 L with water
(b) 35.5 mL of 1.3 *M* HNO_3 diluted to 0.150 L with water

13.59 Calculate the molarity of each aqueous solution:
(a) 25.0 mL of 6.15 *M* HCl diluted to 0.500 L with water
(b) 8.55 mL of 2.00×10^{-2} *M* KI diluted to 10.0 mL with water

13.60 How would you prepare the following aqueous solutions?
(a) 355 mL of 8.74×10^{-2} *M* KH_2PO_4 from solid KH_2PO_4
(b) 425 mL of 0.315 *M* NaOH from 1.25 *M* NaOH

13.61 How would you prepare the following aqueous solutions?
(a) 3.5 L of 0.55 *M* NaCl from solid NaCl
(b) 17.5 L of 0.3 *M* urea $[(NH_2)_2C{=}O]$ from 2.2 *M* urea

13.62 How would you prepare the following aqueous solutions?
(a) 1.50 L of 0.257 *M* KBr from solid KBr
(b) 355 mL of 0.0956 *M* $LiNO_3$ from 0.244 *M* $LiNO_3$

13.63 How would you prepare the following aqueous solutions?
(a) 67.5 mL of 1.33×10^{-3} *M* $Cr(NO_3)_3$ from solid $Cr(NO_3)_3$
(b) 6.8×10^3 m^3 of 1.55 *M* NH_4NO_3 from 3.00 *M* NH_4NO_3

13.64 Calculate the molality of the following:
(a) A solution containing 88.4 g of glycine (NH_2CH_2COOH) dissolved in 1.250 kg of H_2O
(b) A solution containing 8.89 g of glycerol ($C_3H_8O_3$) in 75.0 g of ethanol (C_2H_6O)

13.65 Calculate the molality of the following:
(a) A solution containing 164 g of HCl in 753 g of H_2O
(b) A solution containing 16.5 g of naphthalene ($C_{10}H_8$) in 53.3 g of benzene (C_6H_6)

13.66 What is the molality of a solution consisting of 34.0 mL of benzene (C_6H_6; $d = 0.877$ g/mL) in 187 mL of hexane (C_6H_{14}; $d = 0.660$ g/mL)?

13.67 What is the molality of a solution consisting of 2.77 mL of carbon tetrachloride (CCl_4; $d = 1.59$ g/mL) in 79.5 mL of methylene chloride (CH_2Cl_2; $d = 1.33$ g/mL)?

13.68 How would you prepare the following aqueous solutions?
(a) 3.00×10^2 g of 0.115 *m* ethylene glycol ($C_2H_6O_2$) from ethylene glycol and water
(b) 1.00 kg of 2.00 mass % HNO_3 from 62.0 mass % HNO_3

13.69 How would you prepare the following aqueous solutions?
(a) 1.00 kg of 0.0555 *m* ethanol (C_2H_5OH) from ethanol and water
(b) 475 g of 15.0 mass % HCl from 37.1 mass % HCl

13.70 A solution is made by dissolving 0.30 mol of isopropanol (C_3H_7OH) in 0.80 mol of water. (a) What is the mole fraction of isopropanol? (b) What is the mass percent of isopropanol? (c) What is the molality of isopropanol?

13.71 A solution is made by dissolving 0.100 mol of NaCl in 8.60 mol of water. (a) What is the mole fraction of NaCl? (b) What is the mass percent of NaCl? (c) What is the molality of NaCl?

13.72 What mass of cesium chloride must be added to 0.500 L of water ($d = 1.00$ g/mL) to produce a 0.400 *m* solution? What are the mole fraction and the mass percent of CsCl?

13.73 What are the mole fraction and the mass percent of a solution made by dissolving 0.30 g of KBr in 0.400 L of water ($d = 1.00$ g/mL)?

13.74 Calculate the molality, molarity, and mole fraction of NH_3 in an 8.00 mass % aqueous solution ($d = 0.9651$ g/mL).

13.75 Calculate the molality, molarity, and mole fraction of $FeCl_3$ in a 28.8 mass % aqueous solution ($d = 1.280$ g/mL).

Problems in Context

13.76 Wastewater from a cement factory contains 0.22 g of Ca^{2+} ion and 0.066 g of Mg^{2+} ion per 100.0 L of solution. The solution density is 1.001 g/mL. Calculate the Ca^{2+} and Mg^{2+} concentrations in ppm (by mass).

13.77 An automobile antifreeze mixture is made by mixing equal volumes of ethylene glycol ($d = 1.114$ g/mL; $\mathcal{M} = 62.07$ g/mol) and water ($d = 1.00$ g/mL) at 20°C. The density of the mixture is 1.070 g/mL. Express the concentration of ethylene glycol as
(a) volume percent (b) mass percent (c) molarity
(d) molality (e) mole fraction

Colligative Properties of Solutions

(Sample Problems 13.6 to 13.9)

Concept Review Questions

13.78 The chemical formula of a solute does *not* affect the extent of the solution's colligative properties. What characteristic of a solute *does* affect these properties? Name a physical property of a solution that *is* affected by the chemical formula of the solute.

13.79 What is a nonvolatile nonelectrolyte? Why is this type of solute the simplest case for examining colligative properties?

13.80 In what sense is a strong electrolyte "strong"? What property of the substance makes it a strong electrolyte?

13.81 Express Raoult's law in words. Is Raoult's law valid for a solution of a volatile solute? Explain.

13.82 What are the most important differences between the phase diagram of a pure solvent and the phase diagram of a solution of that solvent?

13.83 Is the composition of the vapor at the top of a fractionating column different from the composition at the bottom? Explain.

13.84 Is the boiling point of 0.01 *m* KF(*aq*) higher or lower than that of 0.01 *m* glucose(*aq*)? Explain.

13.85 Which aqueous solution has a boiling point closer to its predicted value, 0.050 *m* NaF or 0.50 *m* KCl? Explain.

13.86 Which aqueous solution has a freezing point closer to its predicted value, 0.01 *m* NaBr or 0.01 *m* $MgCl_2$? Explain.

13.87 The freezing point depression constants of the solvents cyclohexane and naphthalene are 20.1°C/*m* and 6.94°C/*m*, respectively. Which solvent would give a more accurate result if you are using freezing point depression to determine the molar mass of a substance that is soluble in either one? Why?

Skill-Building Exercises *(grouped in similar pairs)*

13.88 Classify the following substances as strong electrolytes, weak electrolytes, or nonelectrolytes:
(a) hydrogen chloride (HCl) (b) potassium nitrate (KNO_3)
(c) glucose ($C_6H_{12}O_6$) (d) ammonia (NH_3)

13.89 Classify the following substances as strong electrolytes, weak electrolytes, or nonelectrolytes:
(a) sodium permanganate ($NaMnO_4$)
(b) acetic acid (CH_3COOH)
(c) methanol (CH_3OH) (d) calcium acetate $[Ca(C_2H_3O_2)_2]$

13.90 How many moles of solute particles are present in 1 L of each of the following aqueous solutions?
(a) 0.2 *M* KI (b) 0.070 *M* HNO_3
(c) 10^{-4} *M* K_2SO_4 (d) 0.07 *M* ethanol (C_2H_5OH)

13.91 How many moles of solute particles are present in 1 mL of each of the following aqueous solutions?

(a) 0.01 *M* $CuSO_4$ (b) 0.005 *M* $Ba(OH)_2$
(c) 0.06 *M* pyridine (C_5H_5N) (d) 0.05 *M* $(NH_4)_2CO_3$

13.92 Which solution has the lower freezing point?
(a) 10.0 g of CH_3OH in 100. g of H_2O *or* 20.0 g of CH_3CH_2OH in 200. g of H_2O
(b) 10.0 g of H_2O in 1.00 kg of CH_3OH *or* 10.0 g of CH_3CH_2OH in 1.00 kg of CH_3OH

13.93 Which solution has the higher boiling point?
(a) 35.0 g of $C_3H_8O_3$ in 250. g of ethanol *or* 35.0 g of $C_2H_6O_2$ in 250. g of ethanol
(b) 20. g of $C_2H_6O_2$ in 0.50 kg of H_2O *or* 20. g of NaCl in 0.50 kg of H_2O

13.94 Rank the following aqueous solutions in order of increasing (a) osmotic pressure; (b) boiling point; (c) freezing point; (d) vapor pressure at 50°C:
(I) 0.100 *m* $NaNO_3$ (II) 0.200 *m* glucose (III) 0.100 *m* $CaCl_2$

13.95 Rank the following aqueous solutions in order of decreasing (a) osmotic pressure; (b) boiling point; (c) freezing point; (d) vapor pressure at 298 K:
(I) 0.04 *m* urea $[(NH_2)_2C{=}O]$ (II) 0.02 *m* $AgNO_3$
(III) 0.02 *m* $CuSO_4$

13.96 Calculate the vapor pressure of a solution of 44.0 g of glycerol ($C_3H_8O_3$) in 500.0 g of water at 25°C. The vapor pressure of water at 25°C is 23.76 torr. (Assume ideal behavior.)

13.97 Calculate the vapor pressure of a solution of 0.39 mol of cholesterol in 5.4 mol of toluene at 32°C. Pure toluene has a vapor pressure of 41 torr at 32°C. (Assume ideal behavior.)

13.98 What is the freezing point of 0.111 *m* urea in water?

13.99 What is the boiling point of 0.200 *m* lactose in water?

13.100 The boiling point of ethanol (C_2H_5OH) is 78.5°C. What is the boiling point of a solution of 3.4 g of vanillin ($\mathcal{M}$ = 152.14 g/mol) in 50.0 g of ethanol (K_b of ethanol = 1.22°C/*m*)?

13.101 The freezing point of benzene is 5.5°C. What is the freezing point of a solution of 5.00 g of naphthalene ($C_{10}H_8$) in 444 g of benzene (K_f of benzene = 4.90°C/*m*)?

13.102 What is the minimum mass of ethylene glycol ($C_2H_6O_2$) that must be dissolved in 14.5 kg of water to prevent the solution from freezing at −10.0°F? (Assume ideal behavior.)

13.103 What is the minimum mass of glycerol ($C_3H_8O_3$) that must be dissolved in 11.0 mg of water to prevent the solution from freezing at −25°C? (Assume ideal behavior.)

13.104 Calculate the molality and van't Hoff factor (*i*) for the following aqueous solutions:
(a) 1.00 mass % NaCl, freezing point = −0.593°C
(b) 0.500 mass % CH_3COOH, freezing point = −0.159°C

13.105 Calculate the molality and van't Hoff factor (*i*) for the following aqueous solutions:
(a) 0.500 mass % KCl, freezing point = −0.234°C
(b) 1.00 mass % H_2SO_4, freezing point = −0.423°C

Problems in Context

13.106 Wastewater discharged into a stream by a sugar refinery contains sucrose ($C_{12}H_{22}O_{11}$) as its main impurity. The solution contains 3.42 g of sucrose/L. A government-industry project is designed to test the feasibility of removing the sugar by reverse osmosis. What pressure must be applied to the apparatus at 20.°C to produce pure water?

13.107 In a study designed to prepare new gasoline-resistant coatings, a polymer chemist dissolves 6.053 g of poly(vinyl alcohol) in enough water to make 100.0 mL of solution. At 25°C, the osmotic pressure of this solution is 0.272 atm. What is the molar mass of the polymer sample?

13.108 The U.S. Food and Drug Administration lists dichloromethane (CH_2Cl_2) and carbon tetrachloride (CCl_4) among the many chlorinated organic compounds that are carcinogenic (cancer-causing). What are the partial pressures of these substances in the vapor above a solution of 1.50 mol of CH_2Cl_2 and 1.00 mol of CCl_4 at 23.5°C? The vapor pressures of pure CH_2Cl_2 and CCl_4 at this temperature are 352 torr and 118 torr, respectively. (Assume ideal behavior.)

The Structure and Properties of Colloids

Concept Review Questions

13.109 Is the fluid inside a bacterial cell considered a solution, a colloid, or both? Explain.

13.110 What type of colloid is each of the following?
(a) milk (b) fog (c) shaving cream

13.111 What is Brownian motion, and what causes it?

13.112 In a movie theater, you can see the beam of projected light. What phenomenon does this exemplify? Why does it occur?

13.113 Why don't soap micelles coagulate and form large globules? Is soap more effective in freshwater or in seawater? Why?

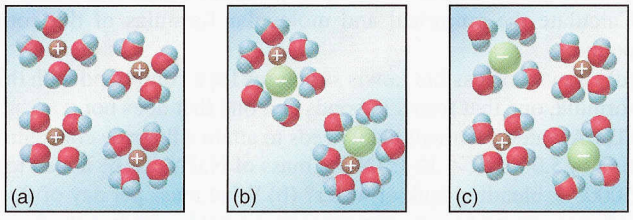
Comprehensive Problems

13.114 Nitrous oxide (N_2O) is used in whipped cream containers as the gas that makes the cream foam. Some experiments to use carbon dioxide (CO_2) instead have proven unsuccessful. What does this suggest about the relative sizes of the Henry's law constant for N_2O and CO_2 in cream? Explain.

13.115 An aqueous solution is 10.% glucose by mass (d = 1.039 g/mL at 20°C). Calculate its freezing point, boiling point at 1 atm, and osmotic pressure.

13.116 Because zinc has nearly the same atomic radius as copper (d = 8.95 g/cm^3), zinc atoms substitute for some copper atoms in the many types of brass. Calculate the density of the brass with (a) 10.0 atom % Zn and (b) 38.0 atom % Zn.

13.117 Which of the following best represents a molecular-scale view of an ionic compound in aqueous solution? Explain.



13.118 A car's gas tank is essentially a closed system containing gasoline and its vapor. If the mole fraction of octane is 0.14 and its vapor pressure is 11 torr at 20.°C, what is the partial pressure of octane at 20.°C? (Assume ideal behavior.)

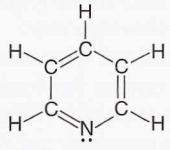
13.119 Gold occurs in seawater at an average concentration of 1.1×10^{-2} ppb. How many liters of seawater must be processed to recover 1 troy ounce of gold, assuming 79.5% efficiency (d of seawater = 1.025 g/mL; 1 troy ounce = 31.1 g)?

13.120 Use atomic properties to explain why xenon is more than 25 times as soluble as helium in water at 0°C.

13.121 Thermal pollution from industrial wastewater causes the temperature of river or lake water to increase, which can affect fish survival as the concentration of dissolved O_2 decreases. Use the following data to find the molarity of O_2 at each temperature (assume the solution density is the same as water):

Temperature (°C)	Solubility of O_2 (mg/kg H_2O)	Density of H_2O (g/mL)
0.0	14.5	0.99987
20.0	9.07	0.99823
40.0	6.44	0.99224

13.122 Pyridine (see structure below) is an essential portion of many biologically active compounds, such as nicotine and vitamin B_6. Like ammonia, it has a nitrogen with a lone pair, which makes it act as a weak base. Because it is miscible in a wide range of solvents, from water to benzene, pyridine is one of the most important bases and solvents in organic syntheses. Account for its solubility behavior in terms of intermolecular forces.



pyridine

13.123 "De-icing salt" is used to melt snow and ice on streets. The highway department of a small town is deciding whether to buy NaCl or $CaCl_2$ for the job. The town can obtain NaCl for \$0.22/kg. What is the maximum the town should pay for $CaCl_2$ to be cost effective?

13.124 Air in a smoky bar contains 4.0×10^{-6} mol/L of CO. What mass of CO is inhaled by a bartender who respires at a rate of 12 L/min during an 8.0-h shift?

13.125 Is 50% by mass of methanol dissolved in ethanol different from 50% by mass of ethanol dissolved in methanol? Explain.

13.126 An industrial chemist is studying small organic compounds for their potential use as an automobile antifreeze. When 0.243 g of a compound is dissolved in 25.0 mL of water, the freezing point of the solution is −0.201°C.

(a) Calculate the molar mass of the compound (d of water = 1.00 g/mL at the temperature of the experiment).

(b) The compositional analysis of the compound shows that it is 53.31 mass % C and 11.18 mass % H, the remainder being O. Calculate the empirical and molecular formulas of the compound.

(c) Draw two possible Lewis structures for a compound with this formula, one that forms H bonds and one that does not.

13.127 A water treatment plant needs to attain a fluoride concentration of 5.00×10^{-5} M. (a) What mass of NaF must be added to a 5000.- L blending tank of water? (b) What mass per day of fluoride is ingested by a person who drinks 2.0 L of this water?

13.128 Give brief answers for each of the following:

(a) Why are lime (CaO) and cake alum [$Al_2(SO_4)_3$] added during water purification?

(b) Why is water that contains large amounts of Ca^{2+}, Mg^{2+}, or Fe^{2+} difficult to use for cleaning?

(c) What is the meaning of "reverse" in reverse osmosis?

(d) Why might a water treatment plant use ozone as the final disinfectant instead of chlorine, even though ozone costs more?

(e) How does passing a saturated NaCl solution through a "spent" ion-exchange resin regenerate the resin?

13.129 Which ion in each pair has the *larger* ΔH_{hydr}?

(a) Mg^{2+} or Ba^{2+} (b) Mg^{2+} or Na^{+} (c) NO_3^- or CO_3^{2-}
(d) SO_4^{2-} or ClO_4^- (e) Fe^{3+} or Fe^{2+} (f) Ca^{2+} or K^{+}

13.130 β-Pinene ($C_{10}H_{16}$) and α-terpineol ($C_{10}H_{18}O$) are two of the many compounds used in perfumes and cosmetics to provide a "fresh pine" scent. At 367 K, the pure substances have vapor pressures of 100.3 torr and 9.8 torr, respectively. What is the composition of the vapor (in terms of mole fractions) above a solution containing equal masses of these compounds at 367 K? (Assume ideal behavior.)

13.131 A solution made by dissolving 1.50 g of solute in 25.0 mL of H_2O at 25°C has a boiling point of 100.45°C.

(a) What is the molar mass of the solute if it is a nonvolatile nonelectrolyte and the solution behaves ideally (d of H_2O at 25°C = 0.997 g/mL)?

(b) Conductivity measurements indicate that the solute is actually ionic with general formula AB_2 or A_2B. What is the molar mass of the compound *if* the solution behaves ideally?

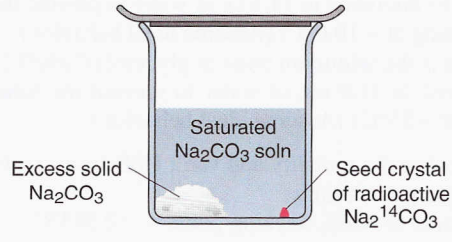
(c) Analysis indicates an empirical formula of CaN_2O_6. Explain the difference between the actual formula mass and that calculated from the boiling point elevation experiment.

(d) Calculate the van't Hoff factor (i) for this solution.

13.132 A pharmaceutical preparation made with ethanol (C_2H_5OH) is contaminated with methanol (CH_3OH). A sample of vapor above the liquid mixture contains a 97:1 mass ratio of C_2H_5OH:CH_3OH. What is the mass ratio of these alcohols in the liquid? At the temperature of the liquid, the vapor pressures of C_2H_5OH and CH_3OH are 60.5 torr and 126.0 torr, respectively.

13.133 Water-treatment plants commonly use chlorination to destroy bacteria. A by-product is chloroform ($CHCl_3$), a suspected carcinogen, produced when HOCl, formed by reaction of Cl_2 and water, reacts with dissolved organic matter. The U.S., Canada, and the World Health Organization have set a limit of 100. ppb of $CHCl_3$ in drinking water. Convert this concentration into molarity, molality, mole fraction, and mass percent.

13.134 A saturated Na_2CO_3 solution is prepared, and a small excess of solid is present. A seed crystal of $Na_2{}^{14}CO_3$ (^{14}C is a radioactive isotope of ^{12}C) is introduced (see the figure), and the radioactivity is measured over time.



(a) Would you expect radioactivity in the solution? Explain.

(b) Would you expect radioactivity in all the solid or just in the seed crystal? Explain.

13.135 A biochemical engineer isolates a bacterial gene fragment and dissolves a 10.0-mg sample of the material in enough water to make 30.0 mL of solution. The osmotic pressure of the solution is 0.340 torr at 25°C.

(a) What is the molar mass of the gene fragment?

(b) If the solution density is 0.997 g/mL, how large is the freezing point depression for this solution (K_f of water = 1.86°C/m)?

13.136 A river is contaminated with 0.75 mg/L of dichloroethylene ($C_2H_2Cl_2$). What is the concentration (in ng/L) of dichloroethyl-

ene at 21°C in the air breathed by the people sitting along the riverbank (k_H for $C_2H_2Cl_2$ in water is 0.033 mol/L·atm)?

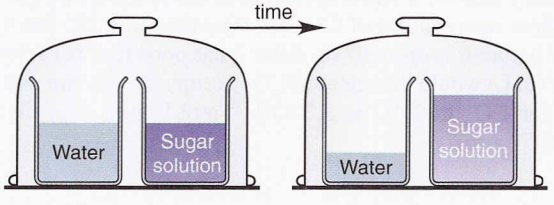
13.137 At an air-water interface, fatty acids such as oleic acid lie in a one-molecule-thick layer (*monolayer*), with the heads in the water and the tails perpendicular in the air. When 2.50 mg of oleic acid is placed on a water surface, it forms a circular monolayer 38.6 cm in diameter. Find the surface area (in cm^2) occupied by one molecule ($\mathcal{M}$ of oleic acid = 283 g/mol).

13.138 A simple device used for estimating the concentration of total dissolved solids in an aqueous solution works by measuring the electrical conductivity of the solution. The method assumes that equal concentrations of different solids give approximately the same conductivity, and that the conductivity is proportional to concentration. The table below gives some actual electrical conductivities (in arbitrary units) for solutions of selected solids at the indicated concentrations (in ppm by mass):

	Conductivity		
Sample	0 ppm	5.00×10^3 ppm	10.00×10^3 ppm
$CaCl_2$	0.0	8.0	16.0
K_2CO_3	0.0	7.0	14.0
Na_2SO_4	0.0	6.0	11.0
Seawater (dil)	0.0	8.0	15.0
Sucrose ($C_{12}H_{22}O_{11}$)	0.0	0.0	0.0
Urea [$(NH_2)_2C{=}O$]	0.0	0.0	0.0

(a) Comment on the reliability of these measurements for estimating concentrations of dissolved solids.
(b) For what types of substances is this method likely to be seriously in error? Why?
(c) Based on this method, an aqueous $CaCl_2$ solution has a conductivity of 14.0 units. Calculate its mole fraction and molality.

13.139 Two beakers are placed in a closed container (*below, left*). One beaker contains water, the other a concentrated aqueous sugar solution. With time, the solution volume increases and the water volume decreases (*right*). Explain on the molecular level.



13.140 Glyphosate is the active ingredient in a common weed and grass killer. It is sold as an 18.0% by mass solution with a density of 8.94 lb/gal. (a) How many grams of Glyphosate are in a 16.0 fl oz container (1 gal = 128 fl oz)? (b) To treat a patio area of 300. ft^2, it is recommended that 3.00 fl oz be diluted with water to 1.00 gal. What is the mass percent of Glyphosate in the diluted solution (1 gal = 3.785 L)?

13.141 Although other solvents are available, dichloromethane (CH_2Cl_2) is still often used to "decaffeinate" foods because the solubility of caffeine in CH_2Cl_2 is 8.35 times that in water.
(a) A 100.0-mL sample of cola containing 10.0 mg of caffeine is extracted with 60.0 mL of CH_2Cl_2. What mass of caffeine remains in the aqueous phase?
(b) A second identical cola sample is extracted with two successive 30.0-mL portions of CH_2Cl_2. What mass of caffeine remains in the aqueous phase after each extraction?
(c) Which approach extracts more caffeine?

13.142 How do you prepare 250. g of 0.150 *m* aqueous $NaHCO_3$?

13.143 Tartaric acid can be produced from crystalline residues found in wine vats. It is used in baking powders and as an additive in foods. Analysis shows that it contains 32.3% by mass carbon and 3.97% by mass hydrogen; the balance is oxygen. When 0.981 g of tartaric acid is dissolved in 11.23 g of water, the solution freezes at −1.26°C. Use these data to find the empirical and molecular formulas of tartaric acid.

13.144 Methanol (CH_3OH) and ethanol (C_2H_5OH) are miscible because the strongest intermolecular force for both compounds is hydrogen bonding. In some methanol-ethanol solutions, the mole fraction of methanol is higher, but the mass percent of ethanol is higher. What is the range of mole fraction of methanol for these solutions?

13.145 A solution of 5.0 g of benzoic acid (C_6H_5COOH) in 100.0 g of carbon tetrachloride has a boiling point of 77.5°C.
(a) Calculate the molar mass of benzoic acid in the solution.
(b) Suggest a reason for the difference between the molar mass based on the formula and that found in part (a).

13.146 Derive a general equation that expresses the relationship between the molarity and the molality of a solution, and use it to explain why the numerical values of these two terms are approximately equal for very dilute aqueous solutions.

13.147 A florist prepares a solution of nitrogen-phosphorus fertilizer by dissolving 5.66 g of NH_4NO_3 and 4.42 g of $(NH_4)_3PO_4$ in enough water to make 20.0 L of solution. What are the molarities of NH_4^+ and of PO_4^{3-} in the solution?

13.148 Suppose coal-fired power plants used water in scrubbers to remove SO_2 from smokestack gases (see Chemical Connections, p. 245).
(a) If the partial pressure of SO_2 in the stack gases is 2.0×10^{-3} atm, what is the solubility of SO_2 in the scrubber liquid (k_H for SO_2 in water is 1.23 mol/L·atm at 200.°C)?
(b) From your answer to part (a), why are basic solutions, such as lime-water slurries [$Ca(OH)_2$], used in scrubbers?

13.149 Urea is a white crystalline solid used as a fertilizer, in the pharmaceutical industry, and in the manufacture of certain polymer resins. Analysis of urea reveals that, by mass, it is 20.1% carbon, 6.7% hydrogen, 46.5% nitrogen and the balance oxygen.
(a) Calculate the empirical formula of urea.
(b) A 5.0 g/L solution of urea in water has an osmotic pressure of 2.04 atm, measured at 25°C. What is the molar mass and molecular formula of urea?

13.150 The total concentration of dissolved particles in blood is 0.30 *M*. An intravenous (IV) solution must be isotonic with blood, which means it must have the same concentration.
(a) To relieve dehydration, a patient is given 100. mL/h of IV glucose ($C_6H_{12}O_6$) for 2.5 h. What mass (g) of glucose did she receive?
(b) If isotonic saline (NaCl) were used, what is the molarity of the solution?
(c) If the patient is given 150. mL/h of IV saline for 1.5 h, how many grams of NaCl did she receive?

13.151 To avoid the "bends," divers breathe mixtures of He and O_2, because He has very low solubility in blood. At a pressure of 4.00 atm, what is the molarity of He needed to maintain the molarities that O_2 and N_2 have at 1.00 atm (k_H in water at 37°C is

1.1×10^{-3} mol/L·atm for O_2, 6.2×10^{-4} mol/L·atm for N_2, and 3.7×10^{-4} mol/L·atm for He)?

13.152 The survival of fish depends on the solubility of air in water, which is 0.147 cm^3 of air (measured at STP) per gram of water at 20.°C and 0.10 MPa (megapascal) pressure.

(a) What is the solubility in a mountain stream where the pressure is 0.060 MPa?

(b) Calculate k_H of air in water at 20.°C.

(c) At 20.°C and 0.50 MPa, the solubility is 0.825 cm^3 of air (at STP) per gram of water. What solubility is calculated from Henry's law? Calculate the error, as a percent of the measured solubility, from relying on Henry's law at this high pressure.

13.153 Iodine (I_2) dissolves in a variety of nonpolar or slightly polar solvents: 2.7 g of I_2 dissolves in 100.0 g of chloroform ($CHCl_3$), 2.5 g dissolves in 100.0 g of carbon tetrachloride, and 16 g dissolves in 100.0 g of carbon disulfide. Calculate the mass percent, mole fraction, and molality of I_2 in each solution.

13.154 Volatile organic solvents have been implicated in smog formation and in adverse health effects of industrial workers. Greener methods are phasing them out (see the margin note, p. 493). Rank the solvents in Table 13.6 (p. 518) in terms of increasing volatility.

13.155 At ordinary temperatures, water is a poor solvent for organic substances. But at high pressure and above 200°C, water develops many properties of organic solvents. Find the minimum pressure needed to maintain water as a liquid at 200.°C (ΔH_{vap} = 40.7 kJ/mol at 100°C and 1.00 atm; assume it remains constant with temperature).

13.156 In ice-cream making, the temperature of the ingredients is kept below 0.0°C in an ice-salt bath.

(a) Assuming that NaCl dissolves completely and forms an ideal solution, what mass of it is needed to lower the melting point of 5.5 kg of ice to −5.0°C?

(b) Given the same assumptions as in part (a), what mass of $CaCl_2$ is needed?

13.157 Several different ionic compounds are each being recrystallized by the following procedure:

Step 1. A saturated aqueous solution of the compound is prepared at 50°C.

Step 2. The mixture is filtered to remove undissolved compound.

Step 3. The filtrate is cooled to 0°C.

Step 4. The crystals that form are filtered, dried, and weighed.

(a) Using Figure 13.21 (p. 508), which of the following compounds would have the highest percent recovery and which the lowest: KNO_3, $KClO_3$, KCl, NaCl? Explain.

(b) Starting with 100. g of each compound in your answer to part (a), how many grams of each can be recovered?

13.158 The solubility of N_2 in blood can be a serious problem (the "bends") for divers breathing compressed air (78% N_2 by volume) at depths greater than 50 ft (see the margin note, p. 510).

(a) What is the molarity of N_2 in blood at 1.00 atm?

(b) What is the molarity of N_2 in blood at a depth of 50. ft?

(c) Find the volume (in mL) of N_2, measured at 25°C and 1.00 atm, released per liter of blood when a diver at a depth of 50. ft rises to the surface (k_H for N_2 in water at 25°C is 7.0×10^{-4} mol/L·atm and at 37°C is 6.2×10^{-4} mol/L·atm; assume d of water is 1.00 g/mL).

13.159 Figure 12.9B (p. 435) describes the phase changes when only water is present. Consider how the diagram would change if air were present at 1 atm and dissolved in the water.

(a) Would the three phases of water still attain equilibrium at some temperature? Explain.

(b) Would that temperature be higher, lower, or the same as the triple point for pure water? Explain.

(c) Would ice sublime at a few degrees below the freezing point under this pressure? Explain.

(d) Would the liquid have the same vapor pressure as that shown in Figure 12.9B at 100°C? At 120°C?

13.160 On top of a 1.00×10^4-L pool of water is fitted an airtight covering filled with N_2 and maintained at 1.20 atm.

(a) What volume (in L) of N_2, measured at 25°C and 1.20 atm, is equal to the moles of N_2 that dissolve in the water (k_H for N_2 at 25°C is 7.0×10^{-4} mol/L·atm)?

(b) Repeat the calculation in part (a) for CO_2 (k_H for CO_2 at 25°C is 2.3×10^{-2} mol/L·atm).

(c) Why are the volumes of CO_2 and N_2 so different?

13.161 Eighty proof whiskey is 40% ethanol (C_2H_5OH) by volume. A man has 7.0 L of blood and drinks a 58-mL shot of the whiskey, of which 22% of the ethanol goes into his blood. (a) What concentration (in g/mL) of ethanol is in his blood (d of ethanol = 0.789 g/mL)? (b) What volume (in mL) of whiskey would raise his blood alcohol level to 0.0030 g/mL, at which level a person is considered intoxicated?

13.162 Carbonated soft drinks are canned under 4 atm of CO_2 and release much of it when opened (see the margin note, p. 510). (a) How many moles of CO_2 are dissolved in a 355-mL can of soda before it is opened? (b) After it has gone flat? (c) What volume (in L) would the released CO_2 occupy at 1.00 atm and 25°C (k_H for CO_2 at 25°C is 3.3×10^{-2} mol/L·atm; P_{CO_2} in air is 3×10^{-4} atm)?

The Basis of Element Behavior The dramatic chemical change that occurs when sodium reacts with water is just one example of the countless reactions of the main-group elements. As you have seen, this behavior is based on atomic and molecular properties, which we revisit in the upcoming pages.

INTERCHAPTER
A Perspective on the Properties of the Elements

Topic 1 The Key Atomic Properties
Topic 2 Characteristics of Chemical Bonding
Topic 3 Metallic Behavior
Topic 4 Acid-Base Behavior of the Element Oxides
Topic 5 Redox Behavior of the Elements
Topic 6 Physical States and Phase Changes

Chemistry has a central, underlying principle: *The behavior of a sample of matter emerges from the properties of its component atoms*. This illustrated Interchapter reviews many ideas about these properties from earlier chapters so that you can see in upcoming chapters how they lead to the behavior of the main-group elements. Keep in mind that, despite our categories, clear dividing lines rarely appear in nature; instead, the periodic properties of matter display gradual changes from one substance to another.

The Key Atomic Properties

Four atomic properties are critical to the behavior of an element: *electron configuration, atomic size, ionization energy,* and *electronegativity.*

	s Block		p Block

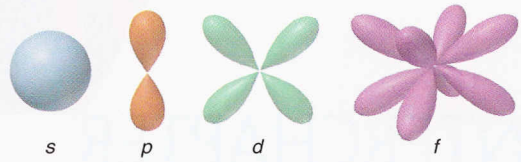
Inner Transition Elements (*f* block)

Electron configuration ($nl^{\#}$) is the distribution of electrons in the energy levels and sublevels of an atom *(Sections 7.4 and 8.3):*

- The n value (positive integer) indicates the *energy* and *relative distance* from the nucleus of orbitals in a level.
- The l value (or its more commonly used letter designation s, p, d, f) indicates the *shape* of orbitals in the sublevel *(right).*
- The superscript ($^{\#}$) tells the *number* of electrons in the sublevel.

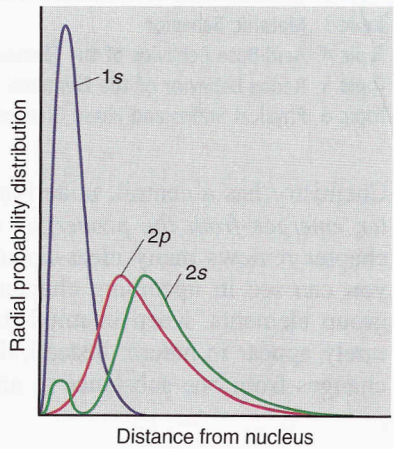


The periodic table above shows the sublevel blocks of elements and the ground-state (lowest energy), outer (valence) electron configuration of the main-group (s- and p-block) elements. Note that

- The ***s* block** lies to the left of the transition elements and the ***p* block** lies to the right. [Although H is not an alkali metal, like the elements in Group 1A(1), and He belongs in Group 8A(18), both are part of the s block.]
- Outer electron configurations are *similar within a group.*
- Outer electron configurations are *different within a period.*
- Outer electrons occupy the ns and np sublevels (n = period number).
- Four valence-level orbitals (one ns + three np) occur among the main-group elements.
- Outer electrons *are* the valence electrons of the main-group elements.
- The A-group number (**1**A to **8**A) equals the number of valence electrons.

Outer electrons are *shielded* from the full nuclear charge by electrons in the same level and, especially, by those in lower energy levels. Shielding reduces the attraction they experience to a much lower *effective nuclear charge* (Z_{eff}) *(Section 8.2).* Within a level, electrons that *penetrate* more (spend more time near the nucleus) shield others more effectively. The extent of penetration is in the order $s > p > d > f$. The radial probability distribution curves *(right)* show that

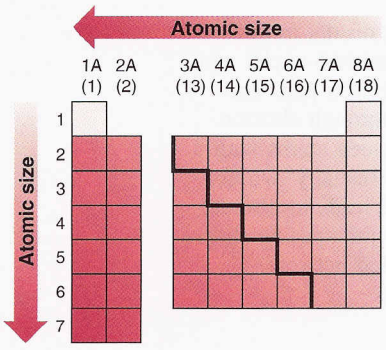
- Inner ($n = 1$) electrons shield outer ($n = 2$) electrons very effectively.
- $2s$ electrons shield $2p$ electrons somewhat because $2s$ electrons spend more time near the nucleus.



Z_{eff} greatly influences atomic properties. In general,

- Z_{eff} increases significantly left to right *across* a period.
- Z_{eff} increases slightly *down* a group.

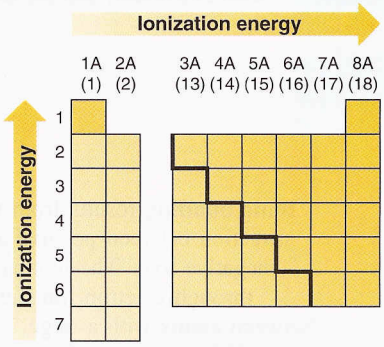
Atomic size is based on atomic radius, one-half the distance between nuclei of identical, bonded atoms *(Section 8.4)*. The small red periodic table shows the trends in atomic size among the main-group elements. Note that



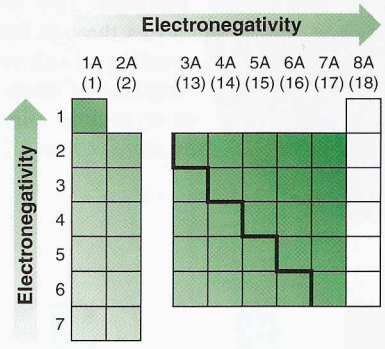
- Atomic size generally *decreases left to right across a period:* increasing Z_{eff} pulls outer electrons closer.
- Atomic size generally *increases down a group:* outer electrons in higher periods lie farther from the nucleus.

Ionization energy (IE) is the energy required to remove the highest energy electron from 1 mol of gaseous atoms *(Section 8.4)*. The relative magnitude of the IE influences the types of bonds an atom forms: an element with a *low IE* is more likely to *lose* electrons, and one with a *high IE* is more likely to *share (or gain)* electrons (excluding the noble gases). From the small yellow periodic table, note that

- IE generally *increases left to right across a period:* higher Z_{eff} holds electrons tighter.
- IE generally *decreases down a group:* greater distance from the nucleus lowers the attraction for electrons.



Thus, the trends in IE are *opposite* those in atomic size: it is easier to remove an electron (lower IE) that is farther from the nucleus (larger atomic size).



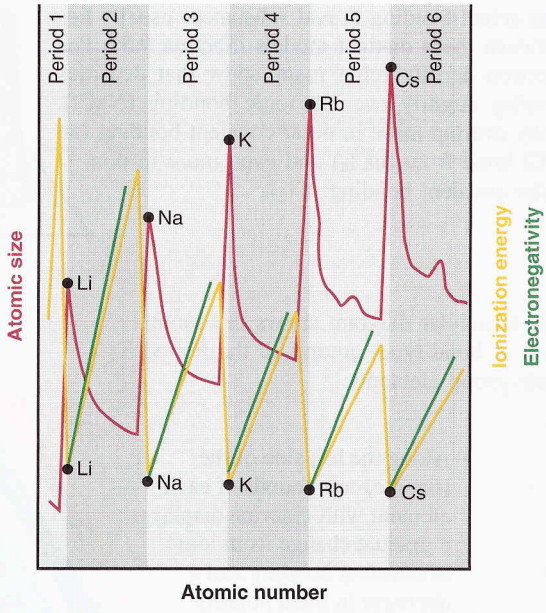
Electronegativity (EN) is a number that refers to the relative ability of an atom in a covalent bond to attract shared electrons *(Section 9.5)*. From the small green periodic table, note that

- EN generally *increases left to right across a period:* higher Z_{eff} and shorter distance from the nucleus strengthen the attraction for the shared pair.
- EN generally *decreases down a group:* greater distance from the nucleus weakens the attraction for the shared pair. (Group 8A is not shaded because the noble gases form few compounds.)

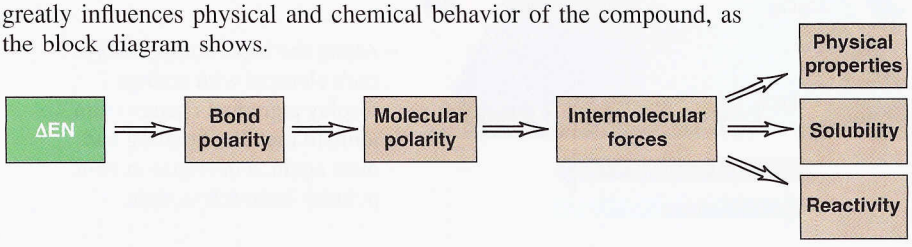
Thus, the trends in EN are *opposite* those in atomic size and the *same* as those in IE.

The graph shows simplified plots of atomic size *(red)*, ionization energy *(yellow)*, and electronegativity *(green)* versus atomic number. Note that

- Atomic size decreases gradually left to right within a period *(vertical gray band)* and then increases suddenly at the beginning of the next period.
- IE and EN display the opposite pattern, increasing left to right within a period and decreasing at the beginning of the next period.



The difference in electronegativity (ΔEN) between the atoms in a bond greatly influences physical and chemical behavior of the compound, as the block diagram shows.



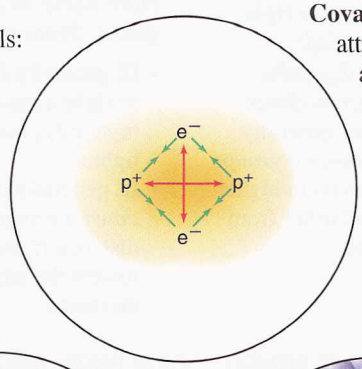
TOPIC 2

Characteristics of Chemical Bonding

Chemical bonds are the forces that hold atoms (or ions) together in an element or compound. The type of bonding, bond properties, nature of orbital overlap, and number of bonds determine physical and chemical behavior.

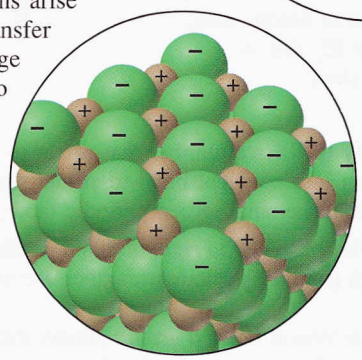
Types of Bonding

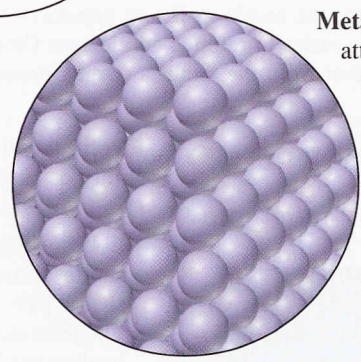
There are three idealized bonding models: *ionic*, *covalent*, and *metallic*.



Covalent bonding results from the attraction between two nuclei and a localized electron pair. The bond arises through electron sharing between atoms with a small ΔEN (usually two nonmetals) and leads to discrete molecules with specific shapes or to extended networks *(Section 9.3)*.

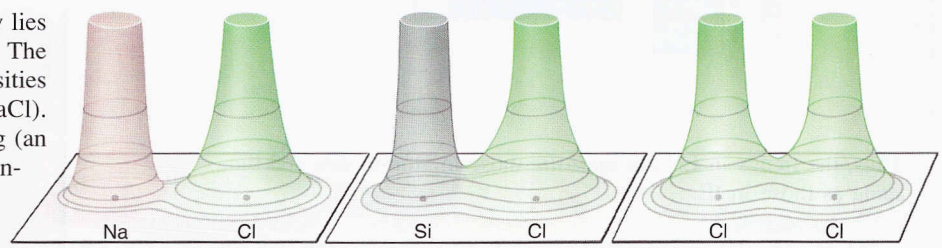
Ionic bonding results from the attraction between positive and negative ions. The ions arise through electron transfer between atoms with a large ΔEN (from metal to nonmetal). This bonding leads to crystalline solids with ions packed tightly in regular arrays *(Section 9.2)*.





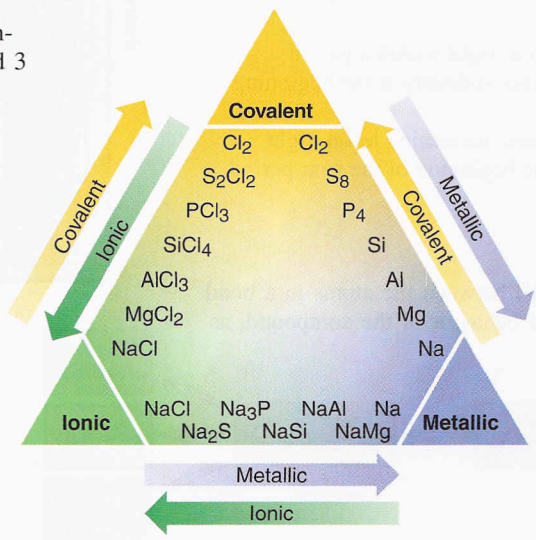
Metallic bonding results from the attraction between the cores of metal atoms (metal cations) and their delocalized valence electrons. This bonding arises through the shared pooling of valence electrons from many atoms and leads to crystalline solids *(Sections 9.5 and 12.6)*.

The actual bonding in real substances usually lies between these distinct models *(Section 9.5)*. The electron density relief maps show that densities overlap slightly even in ionic bonding (NaCl). They overlap more in polar covalent bonding (an SiCl bond from $SiCl_4$) and even more in nonpolar covalent bonding (Cl_2).



The triangular diagram shows the continuum of bond types among all the Period 3 main-group elements:

- Along the left side of the triangle, compounds of each element with chlorine display a gradual change from ionic to covalent bonding and a *decrease* in bond polarity from bottom to top.



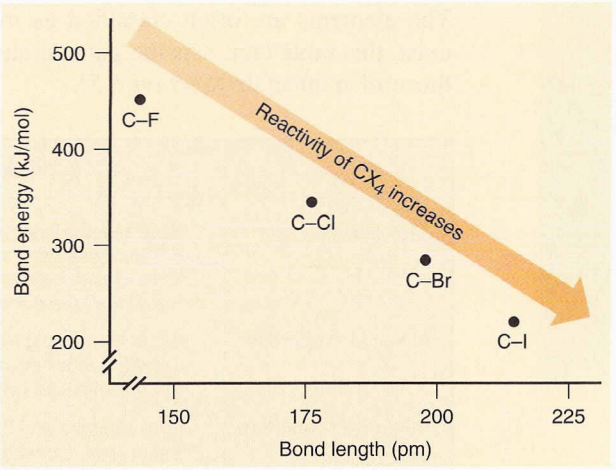
- Along the right side, the elements themselves display a gradual change from covalent to metallic bonding.
- Along the base, compounds of each element with sodium display a gradual change from ionic to metallic bonding and, once again, a *decrease* in bond polarity from left to right.

Bond Properties

There are two important properties of a covalent bond *(Section 9.3)*:
Bond length is the distance between the nuclei of bonded atoms.
Bond energy (bond strength) is the enthalpy change required to break a given bond in 1 mol of gaseous molecules.

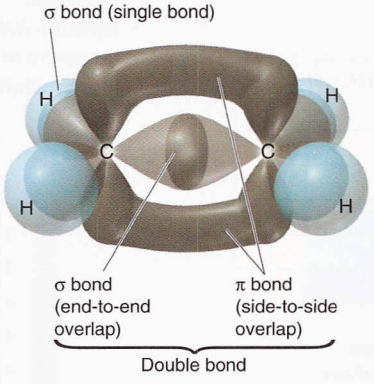
Among similar compounds, these bond properties are related to each other and to reactivity, as shown in the graph for the carbon tetrahalides (CX_4). Note that

- *As bond length increases, bond energy decreases:* shorter bonds are stronger bonds.
- *As bond energy decreases, reactivity increases.*



Nature of Orbital Overlap

In a covalent bond, the shared electrons reside in the entire region composed of the overlapping orbitals of the two atoms. The diagram depicts the bonding in ethylene (C_2H_4).



Bond order is one-half the number of electrons shared. Bond orders of 1 (single bond) and 2 (double bond) are common; a bond order of 3 (triple bond) is much less common. Fractional bond orders occur when there are resonance structures for species with adjacent single and double bonds *(Sections 9.3 and 10.1)*.

Orbitals overlap in two ways, which leads to two types of bonds *(Section 11.2)*:

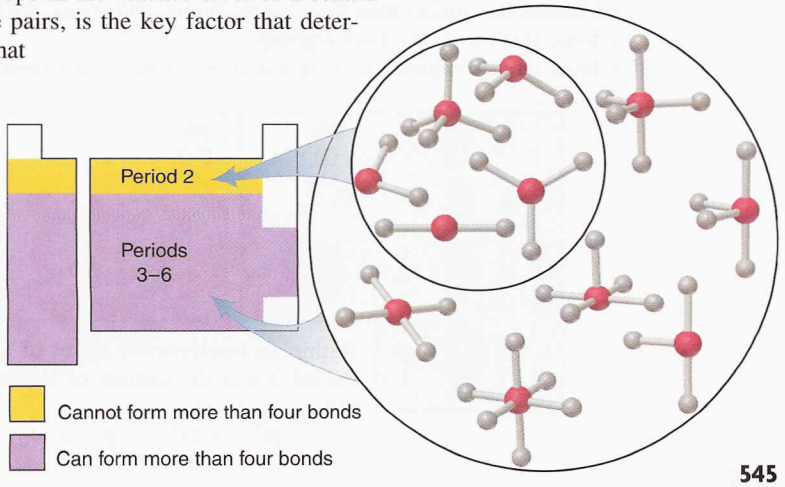
- **End-to-end overlap** (of *s*, *p*, and hybrid atomic orbitals) leads to a sigma (σ) bond, one with electron density distributed symmetrically along the bond axis. A single bond is a σ bond.
- **Side-to-side overlap** (of *p* with *p*, or sometimes *d*, orbitals) leads to a pi (π) bond, one with electron density distributed above and below the bond axis. A double bond consists of one σ bond and one π bond. A π bond restricts rotation around the bond axis, allowing for different spatial arrangements of the atoms and, therefore, different molecules. Pi bonds are often sites of reactivity; for example,

$$CH_2{=}CH_2(g) + H{-}Cl(g) \longrightarrow CH_3{-}CH_2{-}Cl(g)$$
$$CH_3{-}CH_3(g) + H{-}Cl(g) \longrightarrow \text{no reaction}$$

Number of Bonds and Molecular Shape

The shape of a molecule is defined by the positions of the nuclei of the bonded atoms. According to VSEPR theory *(Section 10.2)*, the number of electron groups in the valence level of a central atom, which is based on the number of bonding and lone pairs, is the key factor that determines molecular shape. The small periodic table shows that

- *The elements in Period 2 cannot form more than four bonds* because they have a maximum of four (one *s* and three *p*) valence orbitals. (Only carbon forms four bonds routinely.) Molecular shapes *(small circle)* are based on linear, trigonal planar, and tetrahedral electron-group arrangements.
- *Many elements in Period 3 or higher can form more than four bonds* by using empty *d* orbitals and, thus, expanding their valence levels. Shapes include those above and others based on trigonal bipyramidal and octahedral electron-group arrangements *(large circle)*.



TOPIC 3

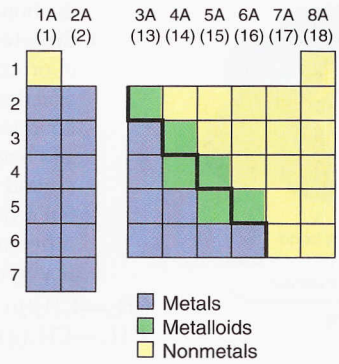
Metallic Behavior

The elements are often classified as metals, metalloids, or nonmetals. Although exceptions exist, this table contrasts the general atomic, physical, and chemical properties of metals with those of nonmetals *(Section 8.5)*.

	Metals	Nonmetals
Atomic Properties	Have fewer valence electrons (in period) Have larger atomic size Have lower ionization energies Have lower electronegativities	Have more valence electrons (in period) Have smaller atomic size Have higher ionization energies Have higher electronegativities
Physical Properties	Occur as solids at room temperature Conduct electricity and heat well Are malleable and ductile	Occur in all three physical states Conduct electricity and heat poorly Are not malleable or ductile
Chemical Properties	Lose electron(s) to become cations React with nonmetals to form ionic compounds Mix with other metals to form solid solutions (alloys)	Gain electron(s) to become anions React with metals to form ionic compounds React with other nonmetals to form covalent compounds

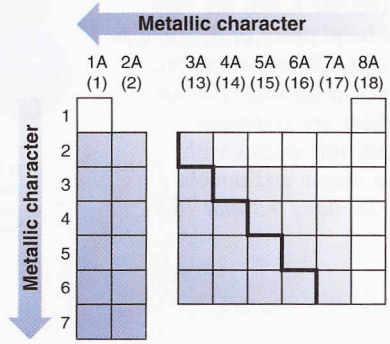
This small periodic table shows the location of metals, metalloids, and nonmetals among the main-group elements. Note that

- Metals lie in the lower-left portion of the table.
- Nonmetals lie in the upper-right portion of the table.
- Metalloids lie between the metals and the nonmetals. These elements have intermediate values of atomic size, IE, and EN and display an intermediate metallic character: shiny solids with low conductivity; cation-like with nonmetals (e.g., AsF_3); and anion-like with metals (e.g., Na_3As).



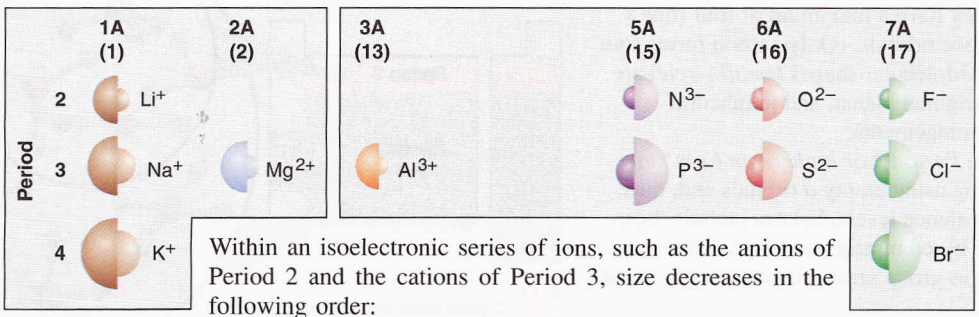
From the blue, shaded periodic table, note that

- *Metallic behavior* changes gradually among the elements.
- *Metallic behavior parallels atomic size:* Larger members of a group *(bottom)* or period *(left)* are more metallic; smaller members are less metallic.



Metals and nonmetals typically form crystalline ionic compounds when they react with each other, and ionic size and charge determine the packing in these solids. Monatomic ions exhibit clear size trends:

- Cations are smaller than their parent atoms, and anions are larger.
- Ionic size *increases down* a group.
- Ionic size *decreases left to right across* a period, but anions are much larger than cations.



Within an isoelectronic series of ions, such as the anions of Period 2 and the cations of Period 3, size decreases in the following order:

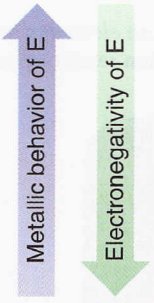
$$N^{3-} > O^{2-} > F^- > Na^+ > Mg^{2+} > Al^{3+}$$

Acid-Base Behavior of the Element Oxides

Oxides are known for almost every element. The metallic behavior of an element correlates with the acid-base behavior of its oxide in water *(Section 8.5)*. Recall that

- An acid produces H^+ ions when dissolved in water and reacts with a base to form a salt and water.
- A base produces OH^- ions when dissolved in water and reacts with an acid to form a salt and water.

This chart shows that the electronegativity and metallic behavior of an element (E) determine the type of bonding (E-to-O) in its oxide and, therefore, the acid-base behavior of the oxide dissolved in water.



Basic Oxide (Ionic E-to-O)	+ H_2O ⟶ more OH^- + acid ⟶ salt (E cation) + H_2O
Amphoteric Oxide	+ acid ⟶ salt (E cation) + H_2O + base ⟶ salt (E oxoanion) + H_2O
Acidic Oxide (Covalent E-to-O)	+ base ⟶ salt (E oxoanion) + H_2O + H_2O ⟶ more H^+

Note that, among the main groups,

- *Elements with low EN (metals) form basic oxides.* The E-to-O bonding is ionic. The O^{2-} ion is the basic species:

  $O^{2-}(s) + H_2O(l) \longrightarrow 2OH^-(aq)$

  For example, barium forms the basic oxide BaO:

  Reacts with water: $BaO(s) + H_2O(l) \longrightarrow Ba^{2+}(aq) + 2OH^-(aq)$
  Reacts with acid: $BaO(s) + 2H^+(aq) \longrightarrow Ba^{2+}(aq) + H_2O(l)$
- *Elements with high EN (nonmetals) form acidic oxides.* The E-to-O bonding is covalent. Water bonds to E of the oxide to form an acid, which releases H^+. For example, sulfur forms the acidic oxide SO_2:

  Reacts with water: $SO_2(g) + H_2O(l) \rightleftharpoons H_2SO_3(aq) \rightleftharpoons H^+(aq) + HSO_3^-(aq)$
  Reacts with base: $SO_2(g) + 2OH^-(aq) \longrightarrow SO_3^{2-}(aq) + H_2O(l)$
- *Elements with intermediate EN (some metalloids and metals) form amphoteric oxides, which react with acid and base.* For example, Al_2O_3 is an amphoteric oxide:

  Reacts with acid: $Al_2O_3(s) + 6H^+(aq) \longrightarrow 2Al^{3+}(aq) + 3H_2O(l)$
  Reacts with base: $Al_2O_3(s) + 2OH^-(aq) + 3H_2O(l) \longrightarrow 2Al(OH)_4^-(aq)$

	1A (1)	2A (2)	3A (13)	4A (14)	5A (15)	6A (16)	7A (17)	8A (18)
1								
2	Li_2O	BeO	B_2O_3	CO_2	N_2O_5 N_2O_3			
3	Na_2O	MgO	Al_2O_3	SiO_2	P_4O_{10} P_4O_6	SO_3 SO_2	Cl_2O_7 Cl_2O	
4	K_2O	CaO	Ga_2O_3	GeO_2	As_2O_5 As_4O_6	SeO_3 SeO_2	Br_2O	
5	Rb_2O	SrO	In_2O_3 In_2O	SnO_2 SnO	Sb_2O_5 Sb_4O_6	TeO_3 TeO_2	I_2O_5	
6	Cs_2O	BaO	Tl_2O	PbO_2 PbO	Bi_2O_3	PoO_2 PoO		
7	Fr_2O	RaO						

Strongly basic
Weakly basic
Amphoteric
Strongly acidic
Moderately acidic
Weakly acidic

The periodic table shows the acid-base behavior of many main-group oxides in water. Note that

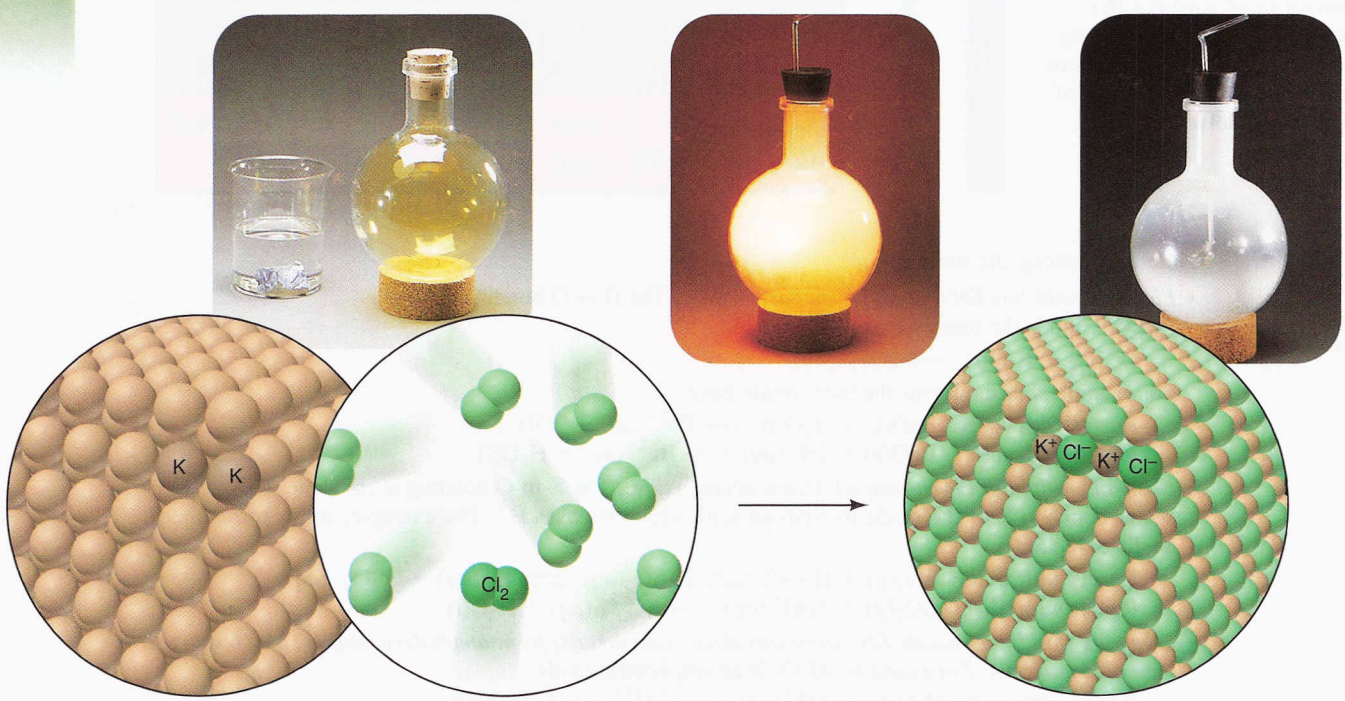
- *Oxide acidity increases left to right across a period and decreases down a group,* which is *opposite* the trend in metallic behavior (and atomic size).
- When an element forms two oxides, *the element has a higher oxidation number in the more acidic oxide* (see also Topic 5). Thus, for example, SO_2 forms the weak acid H_2SO_3, whereas SO_3 forms the strong acid H_2SO_4.

TOPIC 5

Redox Behavior of the Elements

The relative ability of an element to lose or gain electrons (or electron charge) when reacting with other elements defines its redox (oxidation-reduction) behavior *(Section 4.5)*:

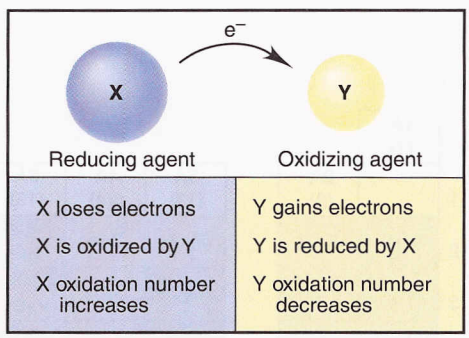
- *The oxidation number, O.N. (or oxidation state)* of an atom in an element is zero. In a compound, the O.N. is the number of electrons that have shifted away from the atom (positive O.N.) or toward it (negative O.N.). O.N. values are determined by a set of rules *(Section 4.5)*.
- *An oxidation-reduction (redox) reaction* occurs when the O.N. values of any atoms in the reactants are different from those in the products.
- Among the countless redox reactions are all those that involve *an elemental substance as reactant or product*. These include all combustion reactions and all formation reactions, such as this one between potassium and chlorine: $2K + Cl_2 \longrightarrow 2KCl$

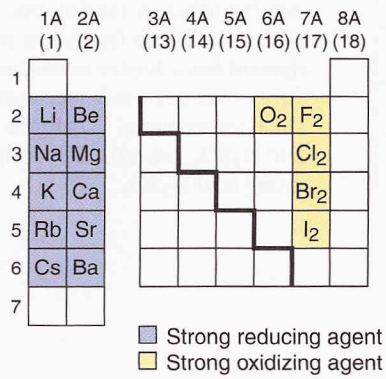


Reducing and Oxidizing Agents

All redox reactions include a reducing *and* an oxidizing agent among the reactants. This chart shows that

- The reducing agent gives electrons *to* (reduces) the oxidizing agent and becomes oxidized (more positive O.N.).
- The oxidizing agent removes electrons *from* (oxidizes) the reducing agent and becomes reduced (more negative O.N.).





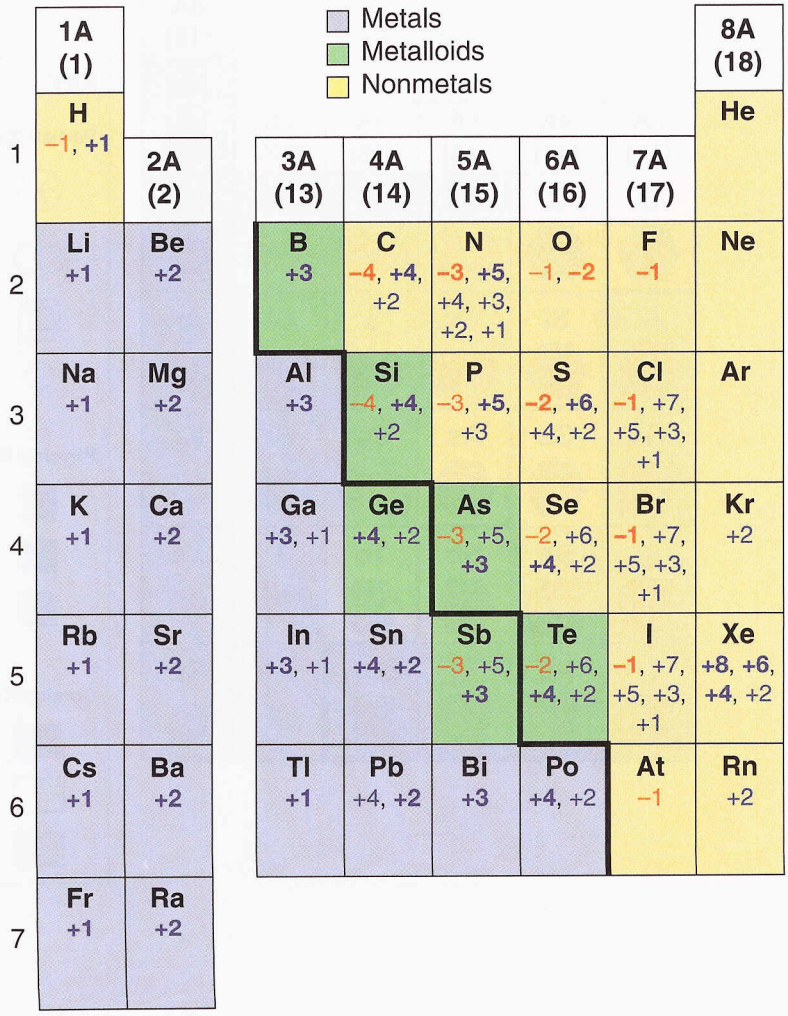
The small periodic table shows that oxidizing and reducing ability are related to atomic properties:

- Elements with low IE and low EN [Groups 1A(1) and 2A(2)] are *strong reducing agents*.
- Elements with high IE and high EN [Group 7A(17) and oxygen in Group 6A(16)] are *strong oxidizing agents*.

Oxidation States of the Main-Group Elements

The periodic table below shows some oxidation states (most common states in **bold** type) of the elements in their compounds. Note that

- *The highest (most positive) state in a group equals the A-group number.* It occurs when all of an atom's outer (valence) electrons shift toward a *more* electronegative atom.
- *Among nonmetals, the lowest (most negative) state equals the A-group number minus eight.* It occurs when a nonmetal atom fills its outer level with electrons that shift away from a *less* electronegative atom.
- *Nonmetals have more oxidation states than metals* in the same group or period. (Oxygen and fluorine are exceptions.)
- Odd-numbered oxidation states are the most common ones in odd-numbered groups, and even-numbered states are the most common ones in even-numbered groups. *Oxidation states differ by units of two* because electrons are lost (or gained) in pairs *(Section 14.9)*.
- For many metals and metalloids with more than one oxidation state [Groups 3A(13) to 5A(15)], *the lower state becomes more common down the group*. This state results when *np* electrons only are lost *(Section 8.5)*.
- An element with more than one oxidation state exhibits *greater metallic behavior in its lower state*. For example, arsenic(III) oxide is more basic, more like a metal oxide, than is arsenic(V) oxide (see Topic 4).



TOPIC 6

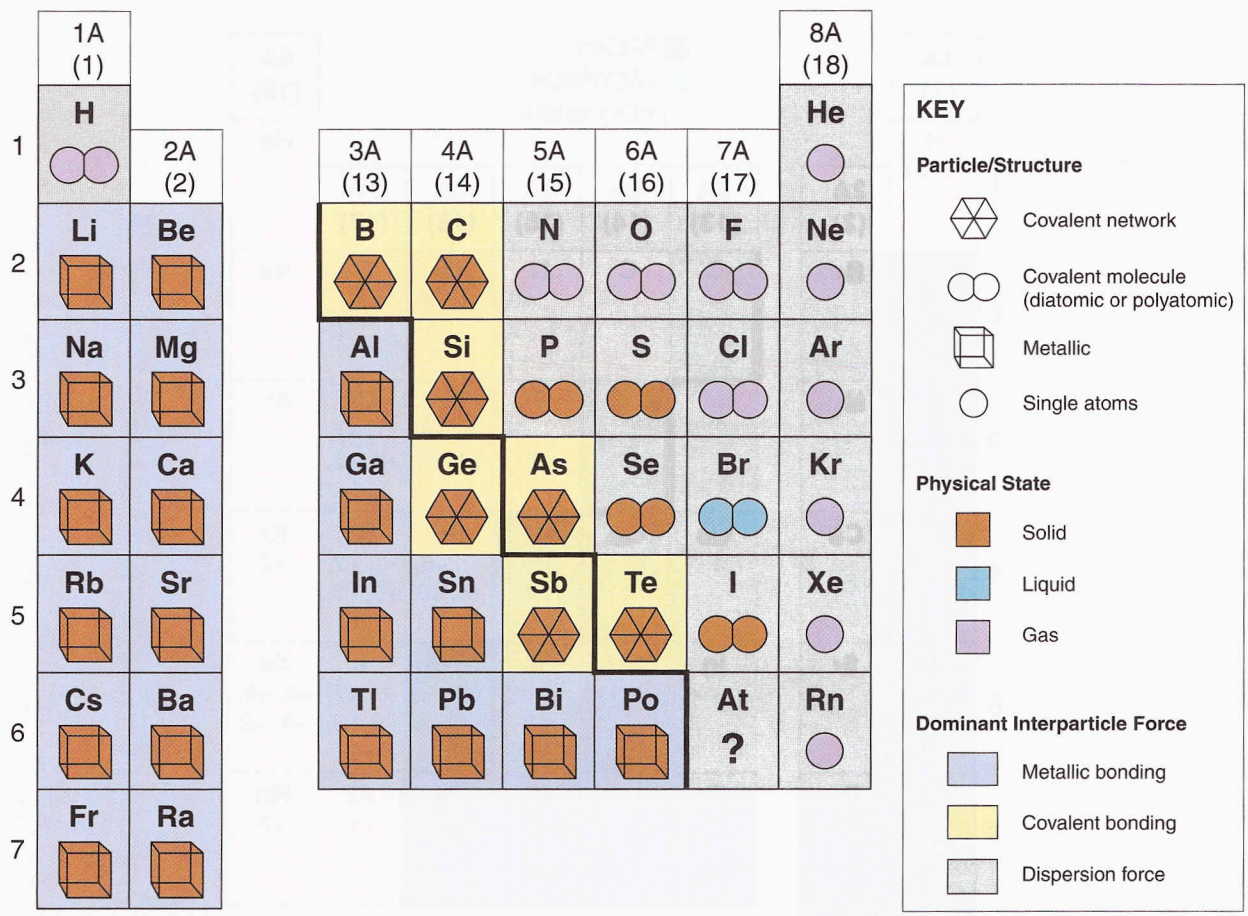
Physical States and Phase Changes

Physical state and the heat of a phase change reflect the relative strengths of the bonding and/or intermolecular forces between the atoms, ions, or molecules that make up an element or compound *(Sections 12.2, 12.3, and 12.6)*.

Physical States of the Elements

The large periodic table shows the type of particle or solid structure *(shape in box)*, physical state *(color of shape)*, and dominant interparticle force *(background color of box)* in the most common form of each of the main-group elements at room temperature. Note that

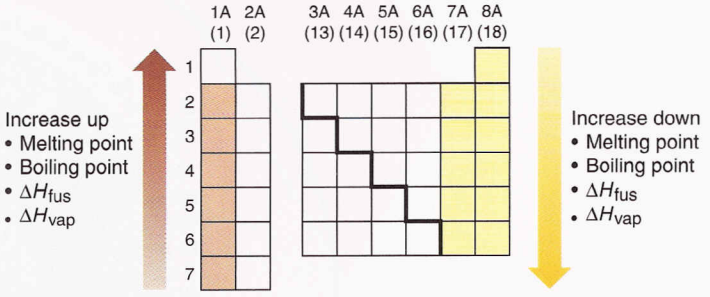
- *Metals (left and bottom) are solids:* strong metallic bonding holds the atoms in their crystal structures.
- *Metalloids (along staircase line) and carbon are solids:* strong covalent bonding holds the atoms together in extensive networks.
- *Lighter nonmetals and Group 8A(18) (right and top) are gases:* dispersion forces are weak between molecules (H_2, N_2, O_2, F_2, Cl_2) or atoms with smaller, less polarizable electron clouds.
- *Heavier nonmetals are liquid (Br_2) or soft solids (P_4, S_8, and I_2):* dispersion forces are stronger between molecules with larger, more polarizable electron clouds.



Phase Changes of the Elements

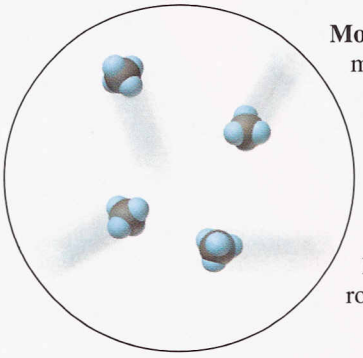
The small periodic table shows trends in melting point, boiling point, ΔH_{fus}, and ΔH_{vap} for Groups 1A(1), 7A(17), and 8A(18):

- In Group 1A(1), these properties generally *increase up* the group: smaller atom cores attract delocalized electrons more strongly, which leads to stronger metallic bonding.
- In Groups 7A(17) and 8A(18), these properties generally *increase down* the group: dispersion forces become stronger with larger, more polarizable atoms.
- In Groups 3A(13) to 6A(16), these properties reflect changes in interparticle forces down the group: lower values for molecular nonmetals, higher values for covalent networks of metalloids (and carbon), and intermediate values for metals.



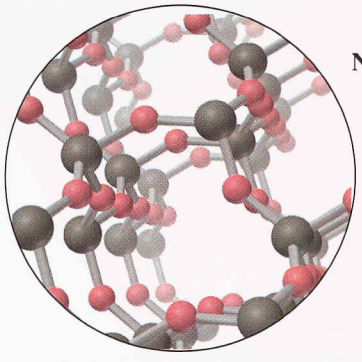
Physical Properties of Compounds

Compounds have physical properties based on the types of bonding and intermolecular forces.

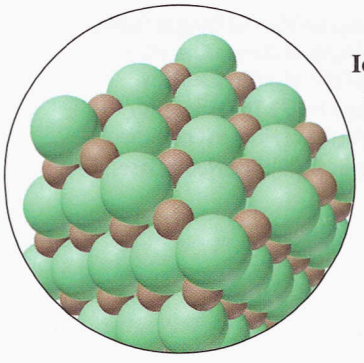


Molecular compounds, such as methane, have a physical state that depends on intermolecular forces. For polar compounds, dipole-dipole forces dominate; for nonpolar compounds, dispersion forces are most important. Most of these substances are gases, liquids, or low-melting solids at room temperature.

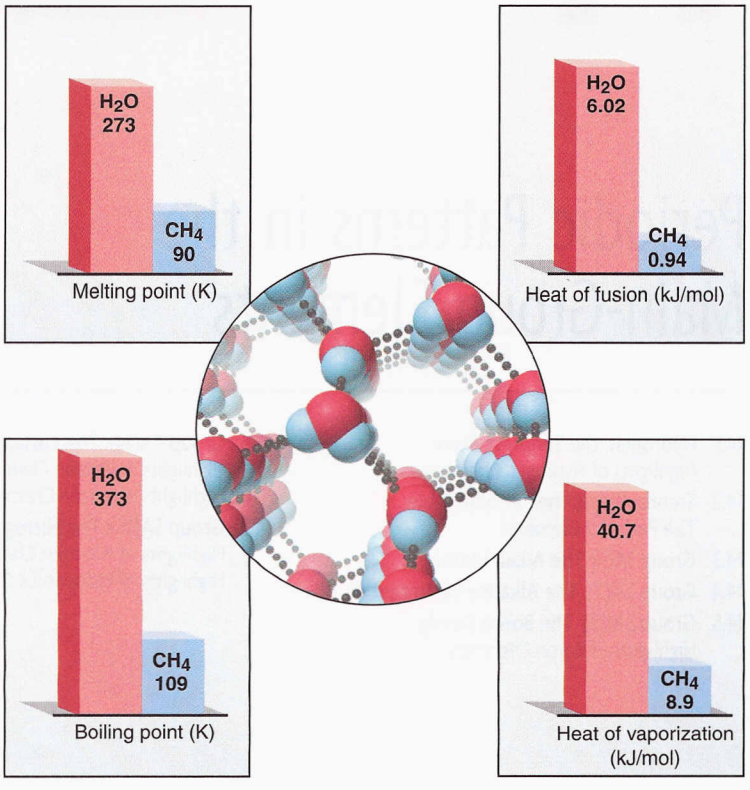
Hydrogen bonding arises when H is bonded to N, O, or F. It has a major effect on physical properties. For example, despite similar molar masses, H bonding in H_2O (18.02 g/mol) gives it a much higher melting point, boiling point, ΔH_{fus}, and ΔH_{vap} than CH_4 (16.04 g/mol). Water's unusually high specific heat capacity, surface tension, and viscosity also result from H bonding *(Section 12.5)*.



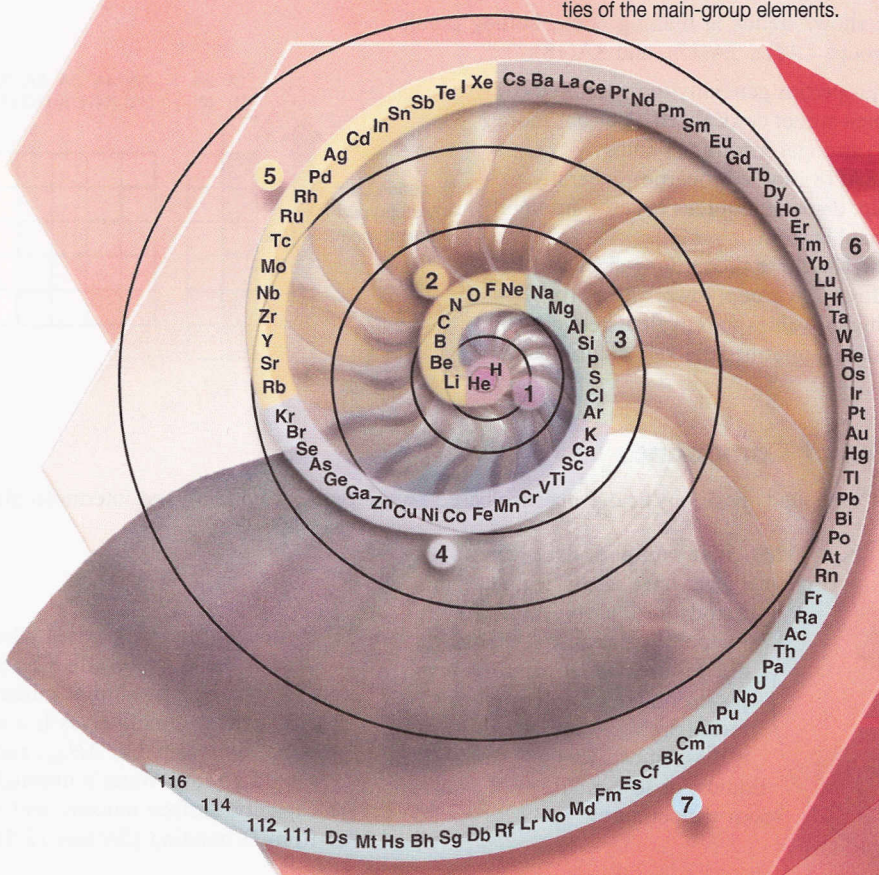
Network covalent compounds, such as silica, have extremely high melting points, boiling points, ΔH_{fus}, and ΔH_{vap}.



Ionic compounds, such as sodium chloride, have very high melting points, boiling points, ΔH_{fus}, and ΔH_{vap}.



Periodic patterns in nature The regular increase in the spiral of the *Nautilus* shell is mimicked by the arrangement of this periodic table (colored by period and redrawn from the 1905 text *Outline of Inorganic Chemistry,* by F. A. Gooch and C. F. Walker). In this chapter, we examine the patterns in physical and chemical behavior that emerge from the recurring atomic properties of the main-group elements.



14

Periodic Patterns in the Main-Group Elements

Concepts & Skills to Review

before you study this chapter

- see the Interchapter

In your study of chemistry so far, you've learned how to name compounds, balance equations, and calculate reaction yields. You've seen how heat is related to chemical and physical change, how electron configuration influences atomic properties, how elements bond to form compounds, and how the arrangement of bonding and lone pairs accounts for molecular shapes. You've learned modern theories of bonding and, most recently, seen how atomic and molecular properties give rise to the macroscopic properties of gases, liquids, solids, and solutions.

The purpose of this knowledge, of course, is to make sense of the magnificent diversity of chemical and physical behavior around you. The periodic table, which organizes much of this diversity, was derived from chemical facts observed in countless hours of 18th- and 19th-century research. One of the greatest achievements in science is 20th-century quantum theory, which provides a theoretical foundation for the periodic table's arrangement. But bear in mind that one theory can rarely account for *all* the facts. Therefore, be amazed by the predictive power of the patterns in the table, but do not be concerned by the occasional exceptions to these patterns. After all, our models are simple, but nature is complex.

IN THIS CHAPTER . . . We apply general ideas of bonding, structure, and reactivity to the main-group elements and see how their behavior correlates with their position in the periodic table. We begin with hydrogen, the simplest and, in some ways, most important of the elements, and then consider Period 2 to survey the general changes across the periodic table. In each of the remaining sections, we deal with one of the eight families of main-group elements. We explore vertical trends in each group and also keep an eye on horizontal trends involving neighboring groups. Especially important elements—boron, carbon, silicon, nitrogen, phosphorus, oxygen, sulfur, and the halogens—receive greater attention. (If you haven't already read the Interchapter preceding this chapter, now is the perfect time.)

14.1 HYDROGEN, THE SIMPLEST ATOM

A hydrogen atom consists of a nucleus with a single positive charge, surrounded by a single electron. Despite this simple structure, or perhaps because of it, hydrogen may be the most important element of all. In the Sun, hydrogen (H) nuclei combine to form helium (He) nuclei in a process that provides nearly all Earth's energy. About 90% of all the atoms in the universe are H atoms, making it the most abundant element by far. On Earth, only tiny amounts of the free element occur naturally (as H_2), but hydrogen is abundant in combination with oxygen in water. Because of its simple structure and low molar mass, nonpolar gaseous H_2 is colorless and odorless, and its extremely weak dispersion forces result in very low melting (−259°C) and boiling points (−253°C).

Where Does Hydrogen Fit in the Periodic Table?

Hydrogen has no perfectly suitable position in the periodic table (Figure 14.1). Because of its single valence electron and common +1 oxidation state, some think it almost fits in Group 1A(1). However, unlike the alkali metals, hydrogen *shares* its electron with nonmetals rather than losing it to them. Moreover, like a nonmetal, it has a relatively high ionization energy (IE = 1311 kJ/mol)—much higher than that of lithium (IE = 520 kJ/mol), whose IE is the highest in Group 1A—and a much higher electronegativity as well (EN of H = 2.1; EN of Li = 1.0).

Others think hydrogen almost fits in Group 7A(17). Like the halogens, it occurs as diatomic molecules and fills its outer (valence) level either by electron sharing or by gaining one electron from a metal to form a monatomic anion, the hydride ion (H^-; O.N. = −1). However, hydrogen has a lower electronegativity

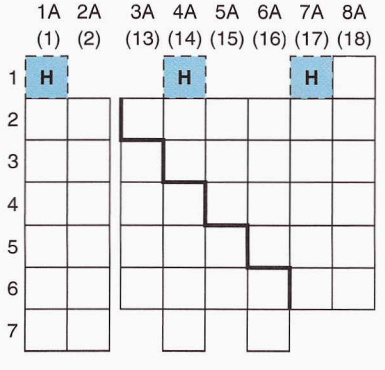

Figure 14.1 Where does hydrogen belong? Hydrogen's small size and single electron confer properties that are not fully consistent with the members of any one periodic group. Depending on the property, hydrogen may fit better in Group 1A(1), 4A(14), or 7A(17).

(EN = 2.1) than any of the halogens (ENs range from 2.2 to 4.0) and lacks their three valence electron pairs. Moreover, the H^- ion is rare and reactive, whereas halide ions are common and stable.

And, still others think that, because of a half-filled valence level and similarities in ionization energy, electron affinity, electronegativity, and bond energies, hydrogen fits best in Group 4A(14).

Hydrogen's unique behavior is attributable to its tiny size. Hydrogen has a high IE because its electron is very close to the nucleus, with no inner electrons to shield it from the positive charge. It has a low EN (for a nonmetal) because it has only one proton to attract bonding electrons. In this chapter, hydrogen will appear in either Group 1A(1) or 7A(17) depending on the property being considered.

Highlights of Hydrogen Chemistry

In Chapters 12 and 13, we discussed hydrogen bonding and its impact on physical properties (melting and boiling points, heats of fusion and vaporization, and specific heat capacities) and solubilities. You learned that H bonding plays a critical part in stabilizing Earth's climate as well as your body temperature, and you glimpsed its role in the functional structures of biomolecules. In Chapter 6 (see Chemical Connections, p. 247) we considered the possible future use of hydrogen as a fuel, and in Chapter 22 we'll see how hydrogen is used to recover some metals from their ores. Hydrogen is very reactive, combining with nearly every element, so we focus here on the three types of hydrides.

Ionic (Saltlike) Hydrides With very reactive metals, such as those in Group 1A(1) and the larger members of Group 2A(2) (Ca, Sr, and Ba), hydrogen forms *saltlike hydrides*—white, crystalline solids composed of the metal cation and the hydride ion:

$$2Li(s) + H_2(g) \longrightarrow 2LiH(s)$$
$$Ca(s) + H_2(g) \longrightarrow CaH_2(s)$$

In water, H^- is a strong base that pulls H^+ from surrounding H_2O molecules to form H_2 and OH^-:

$$NaH(s) + H_2O(l) \longrightarrow Na^+(aq) + OH^-(aq) + H_2(g)$$

The hydride ion is also a powerful reducing agent; for example, it reduces Ti(IV) to the free metal:

$$TiCl_4(l) + 4LiH(s) \longrightarrow Ti(s) + 4LiCl(s) + 2H_2(g)$$

Covalent (Molecular) Hydrides Hydrogen reacts with nonmetals to form many *covalent hydrides,* such as CH_4, NH_3, H_2O, and HF. Most are gases consisting of small molecules, but many hydrides of boron and carbon are liquids or solids that consist of much larger molecules. In most covalent hydrides, hydrogen has an oxidation number of +1 because the other nonmetal has a higher electronegativity than hydrogen.

Conditions for preparing the covalent hydrides depend on the reactivity of the other nonmetal. For example, with stable, triple-bonded N_2, hydrogen reacts at high temperatures (~400°C) and pressures (~250 atm), and the reaction needs a catalyst to proceed at any practical speed:

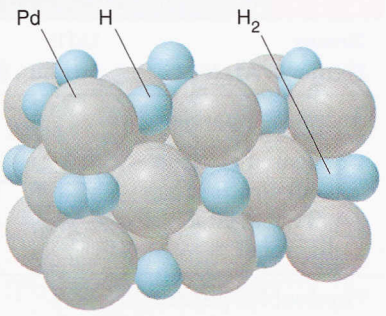
$$N_2(g) + 3H_2(g) \xrightarrow{\text{catalyst}} 2NH_3(g) \qquad \Delta H^0_{rxn} = -91.8 \text{ kJ}$$

Industrial facilities throughout the world use this reaction to produce millions of tons of ammonia each year for fertilizers, explosives, and synthetic fibers. On the

other hand, hydrogen combines rapidly with reactive, single-bonded F_2, even at extremely low temperatures (−196°C):

$$F_2(g) + H_2(g) \longrightarrow 2HF(g) \quad \Delta H^0_{rxn} = -546 \text{ kJ}$$

Metallic (Interstitial) Hydrides Many transition elements form *metallic (interstitial) hydrides,* in which H_2 molecules (and H atoms) occupy the holes in the metal's crystal structure. Thus, such hydrides are *not* compounds but gas-solid solutions. Also, unlike ionic and covalent hydrides, interstitial hydrides, such as $TiH_{1.7}$, typically lack a single, stoichiometric formula because the metal can incorporate variable amounts of hydrogen, depending on the pressure and temperature of the gas.



Fill 'Er Up with Hydrogen? Not Soon Dreams of a future hydrogen economy had included using metallic hydrides as "storage containers" for hydrogen fuel in cars. Just drive up to your local refueling station, insert a cylinder of H-packed metal in your car, and zip away again! It is true that some metals, such as palladium (see figure) and niobium, and some alloys, such as $LaNi_5$, store large amounts of hydrogen. However, research uncovered some serious problems, especially the facts that the metals that store the most hydrogen are expensive and heavy and they hold the gas tightest, releasing it only at very high temperatures. As a result, in 1996, U.S. government funding for the research stopped. Some researchers are keeping the dream alive, however, through their studies of carbon nanotubes, which store large amounts of H_2, and of an Na/Al alloy that is lightweight, stores 5% H_2 by mass, and releases it below 200°C. Only time and careful testing will tell!

14.2 TRENDS ACROSS THE PERIODIC TABLE: THE PERIOD 2 ELEMENTS

Table 14.1 on the next two pages presents the trends in atomic properties of the Period 2 elements, lithium through neon, and the physical and chemical properties that emerge from them. In general, these trends apply to the other periods as well. Note the following points:

- Electrons fill the one *ns* and the three *np* orbitals according to Pauli's exclusion principle and Hund's rule.
- As a result of increasing nuclear charge and the addition of electrons to orbitals of the same energy level (same *n* value), atomic size generally decreases, whereas first ionization energy and electronegativity generally increase (see bar graphs on p. 557).
- Metallic character decreases with increasing nuclear charge as period members change from metals to metalloids to nonmetals.
- Reactivity is highest at the left and right ends of the period, except for the inert noble gas.
- Bonding between atoms of an element changes from metallic, to covalent in networks, to covalent in individual molecules, to none (noble gases exist as separate atoms). As expected, physical properties, such as melting point, change abruptly at the network/molecule boundary, which occurs in Period 2 between carbon (solid) and nitrogen (gas).
- Bonding between each element and an active nonmetal changes from ionic, to polar covalent, to covalent. Bonding between each element and an active metal changes from metallic to polar covalent to ionic.
- The acid-base behavior of the common element oxide in water changes from basic to amphoteric to acidic as the bond between the element and oxygen becomes more covalent.
- Reducing strength decreases through the metals, and oxidizing strength increases through the nonmetals. In Period 2, common oxidation numbers (O.N.s) equal the A-group number for Li and Be and the A-group number minus eight for O and F. Boron has several O.N.s, Ne has none, and C and N show all possible O.N.s for their groups.

One point that will be coming up frequently but is not shown in Table 14.1 is the *anomalous behavior of the Period 2 elements within their groups*. Later, we'll highlight some particularly clear examples of such *un*representative behavior, which arises from their relatively *small size* and *small number of orbitals* in the outer energy level.

Table 14.1 Trends in Atomic, Physical, and Chemical Properties of the Period 2 Elements

Group: Element/At. No.:	1A(1) Lithium (Li) $Z = 3$	2A(2) Beryllium (Be) $Z = 4$	3A(13) Boron (B) $Z = 5$	4A(14) Carbon (C) $Z = 6$

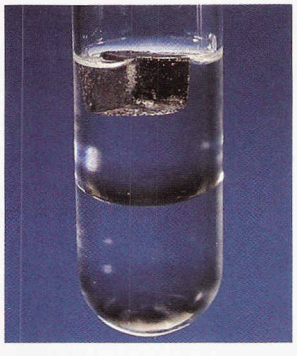
14.3 GROUP 1A(1): THE ALKALI METALS

The first group of elements in the periodic table is named for the alkaline (basic) nature of their oxides and for the basic solutions the elements form in water. Group 1A(1) provides the best example of regular trends with no significant exceptions. All the elements in the group—lithium (Li), sodium (Na), potassium (K), rubidium (Rb), cesium (Cs), and rare, radioactive francium (Fr)*—are very reactive metals. The Family Portrait of Group 1A(1), on pages 560 and 561, is the first in a series that provides an overview of each of the main groups. Atomic and physical properties are summarized on the left-hand page; representative reactions and some important compounds appear on the right-hand page. Refer to these family portraits during the discussions for supporting information.

Why Are the Alkali Metals Soft, Low Melting, and Lightweight?



Lithium floating in oil floating on water.

Unlike most metals, the alkali metals are soft: Na has the consistency of cold butter, and K can be squeezed like clay. The alkali metals also have lower melting and boiling points than any other group of metals. Except for Li, they all melt below 100°C, and Cs melts a few degrees above room temperature. They have lower densities than most metals: Li floats on lightweight household oil (see photo).

The unusual physical behavior of the alkali metals can be traced to their atomic size, the largest in their respective periods, and to the ns^1 valence electron configuration. Because the single valence electron is relatively far from the nucleus, there is only a weak attraction between the delocalized electrons and the metal-ion cores in the crystal structure. This weak metallic bonding means that the alkali metal crystal structure can be easily deformed or broken down, which results in a soft consistency and low melting point. These elements also have the lowest molar masses in their periods; with their large atomic radii, they therefore have relatively low densities.

Why Are the Alkali Metals So Reactive?

The alkali metals are extremely reactive elements. They are *powerful reducing agents* and, thus, always occur in nature as 1+ cations rather than as free metals. (As we discuss in Section 22.4, highly endothermic reduction processes are required to prepare the free metals industrially from their molten salts.) The alkali metals reduce the halogens and form ionic solids in reactions that release large quantities of heat. They reduce the hydrogen in water, reacting vigorously (Rb and Cs explosively) to form H_2 and a metal hydroxide solution. They reduce O_2 in the air, and thus tarnish rapidly. Because of this reactivity, Na and K are usually kept under mineral oil (an unreactive liquid) in the laboratory, and Rb and Cs are handled with gloves under an inert argon atmosphere.

The ns^1 configuration, which is the basis for their physical properties, is also the reason these metals form salts so readily. In a Born-Haber cycle of the reaction between an alkali metal and a nonmetal, for example, the solid metal separates into gaseous atoms, each of the atoms transfers its outer electron to the nonmetal, and the resulting cations and anions attract each other to form an ionic solid (Section 9.2). Properties based on the ns^1 configuration relate to each step.

1. *Low heat of atomization* (ΔH^0_{atom}). Consistent with the alkali metals' low melting and boiling points, their weak metallic bonding leads to low values for ΔH^0_{atom} (the energy needed to convert the solid into individual gaseous atoms), which decrease down the group:†

$$E(s) \longrightarrow E(g) \qquad \Delta H_{atom}\ (Li > Na > K > Rb > Cs)$$

*Francium is so rare (estimates indicate only 15 g of the element in the top kilometer of Earth's crust) that its properties are largely unknown. Therefore, we will mention it only occasionally in the discussion.

†Throughout the chapter, we use E to represent any element in a group.

2. *Low IE and small ionic radius.* Each alkali metal has the largest size and the lowest IE in its period. A great *decrease* in size occurs when the outer electron is lost: the volume of the Li^+ ion is less than 13% that of the Li atom! Thus, Group 1A(1) ions are small spheres with considerable charge density.

3. *High lattice energy.* When Group 1A salts crystallize, large amounts of energy are released because the small cations lie close to the anions. Thus, the endothermic atomization and ionization steps are easily outweighed by the highly exothermic formation of the solid. For a given anion, the trend in lattice energy is the inverse of the trend in cation size: *as the cation becomes larger, the lattice energy becomes smaller.* This steady decrease in lattice energy within the Group 1A(1) and 2A(2) chlorides is shown in Figure 14.2.

Despite the strong ionic attractions in the solid, *nearly all Group 1A salts are water soluble.* The attraction between the ions and water molecules creates a highly exothermic heat of hydration (ΔH_{hydr}), and a large increase in entropy occurs when ions in the organized crystal become dispersed and hydrated in solution; together, these factors outweigh the high lattice energy.

The magnitude of the hydration energy *decreases* as ionic size increases:

$$E^+(g) \longrightarrow E^+(aq) \qquad \Delta H = -\Delta H_{hydr}\ (Li^+ > Na^+ > K^+ > Rb^+ > Cs^+)$$

Interestingly, the *smaller* ions attract water molecules strongly enough to form *larger hydrated ions.* This size trend has a major effect on the function of nerves, kidneys, and cell membranes because the *sizes* of $Na^+(aq)$ and $K^+(aq)$, the most common cations in cell fluids, influence their movement in and out of cells.

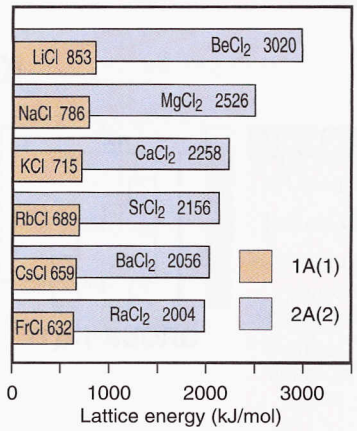


Figure 14.2 Lattice energies of the Group 1A(1) and 2A(2) chlorides. The lattice energy decreases regularly in both groups of metal chlorides as the cations become larger. Lattice energies for the Group 2A chlorides are greater because the 2A cations have higher charge and smaller size.

The Anomalous Behavior of Lithium

As we noted in discussing Table 14.1, all the Period 2 elements display some anomalous (unrepresentative) behavior within their groups. Even within the regular, predictable trends of Group 1A(1), Li has some atypical properties. It is the only member that forms a simple oxide and nitride, Li_2O and Li_3N, on reaction with O_2 and N_2 in air. Only Li forms molecular compounds with hydrocarbon groups from organic halides:

$$2Li(s) + CH_3CH_2Cl(g) \longrightarrow CH_3CH_2Li(s) + LiCl(s)$$

Organolithium compounds, such as CH_3CH_2Li, are liquids or low-melting solids that dissolve in nonpolar solvents and contain polar covalent $^{\delta-}C—Li^{\delta+}$ bonds. They are important reactants in the synthesis of organic compounds.

Because of its small size, Li^+ has a relatively high charge density. Therefore, it can deform nearby electron clouds to a much greater extent than the other 1A ions can, which increases orbital overlap and gives many lithium salts significant covalent character (Figure 14.3). Thus, LiCl, LiBr, and LiI are much more soluble in polar organic solvents, such as ethanol and acetone, than are the halides of Na and K, because the lithium halide dipole interacts with these solvents through dipole-dipole forces. The small, highly positive Li^+ makes dissociation of Li salts into ions more difficult in water; thus, the fluoride, carbonate, hydroxide, and phosphate of Li are much less soluble in water than those of Na and K.

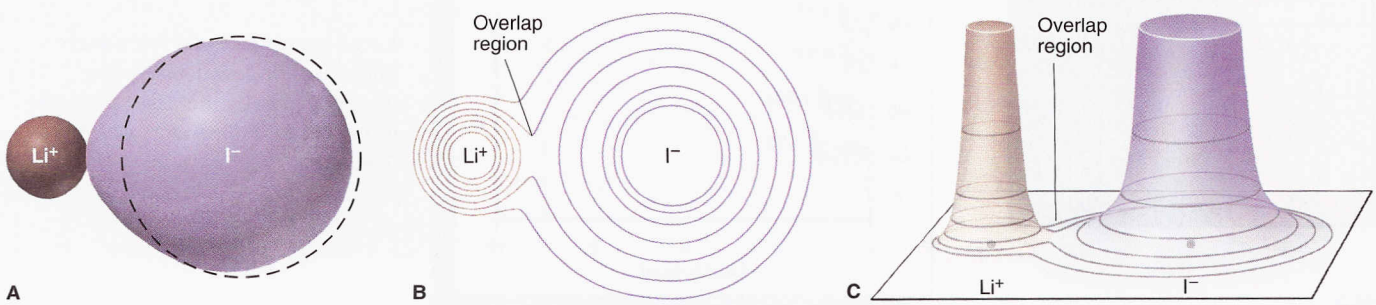

Figure 14.3 The effect of Li^+ charge density on a nearby electron cloud. The ability of the Li^+ ion to deform nearby electron clouds gives rise to many anomalous properties. In this case, Li^+ polarizes an I^- ion, which gives some covalent character to lithium iodide, LiI, as depicted by a space-filling model **(A)**, an electron density contour **(B)**, and an electron density relief map **(C)**.

Group 1A(1): The Alkali Metals

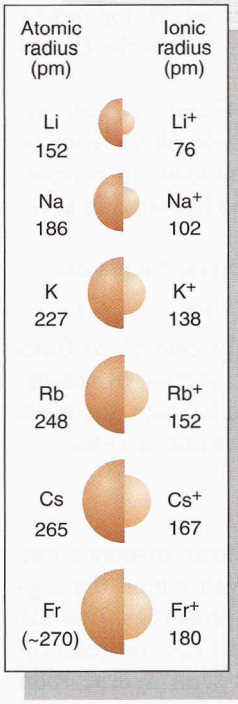
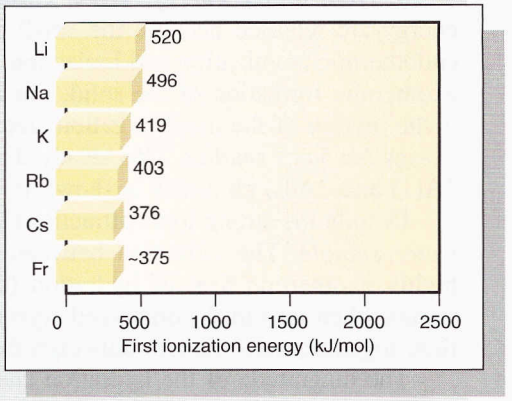
Atomic Properties

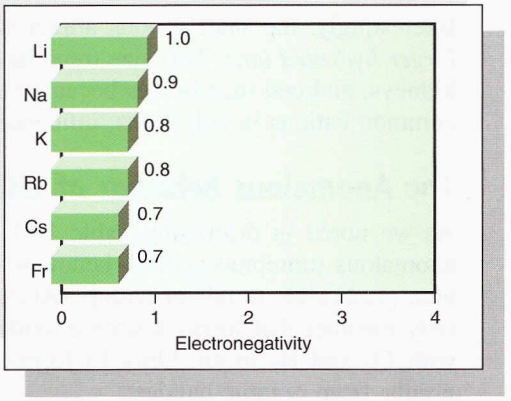


Group electron configuration is ns^1. All members have the +1 oxidation state and form an E^+ ion.

Atoms have the largest size and lowest IE and EN in their periods.

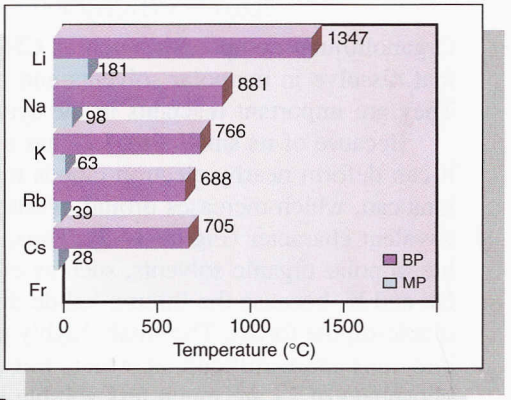
Down the group, atomic and ionic size increase, while IE and EN decrease.

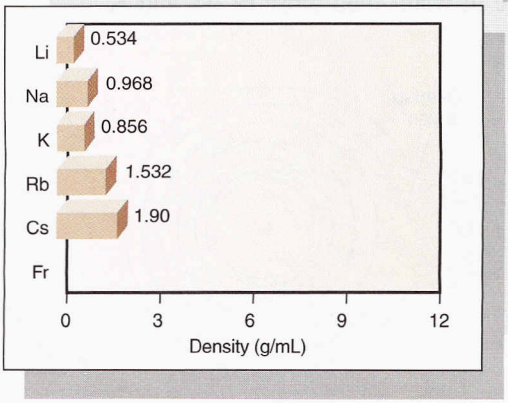




Physical Properties

Metallic bonding is relatively weak because there is only one valence electron. Therefore, these metals are soft with relatively low melting and boiling points. These values decrease down the group because larger atom cores attract delocalized electrons less strongly.





Large atomic size and low atomic mass result in low density; thus density generally increases down the group because mass increases more than size.

Some Reactions and Compounds

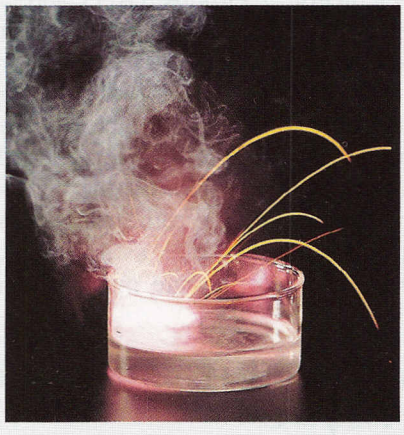
Important Reactions

The reducing power of the alkali metals (E) is shown in reactions 1 to 4. Some industrial applications of Group 1A(1) compounds are shown in reactions 5 to 7.

1. The alkali metals reduce H in H_2O from the +1 to the 0 oxidation state:

$$2E(s) + 2H_2O(l) \longrightarrow 2E^+(aq) + 2OH^-(aq) + H_2(g)$$

The reaction becomes more vigorous down the group (*see photo*).



Potassium reacting with water

2. The alkali metals reduce oxygen, but the product depends on the metal. Li forms the oxide, Li_2O; Na forms the peroxide, Na_2O_2; K, Rb, and Cs form the superoxide, EO_2:

$$4Li(s) + O_2(g) \longrightarrow 2Li_2O(s)$$

$$K(s) + O_2(g) \longrightarrow KO_2(s)$$

In emergency breathing units, KO_2 reacts with H_2O and CO_2 in exhaled air to release O_2.

3. The alkali metals reduce hydrogen to form ionic (saltlike) hydrides:

$$2E(s) + H_2(g) \longrightarrow 2EH(s)$$

NaH is an industrial base and reducing agent that is used to prepare other reducing agents, such as $NaBH_4$.

4. The alkali metals reduce halogens to form ionic halides:

$$2E(s) + X_2 \longrightarrow 2EX(s) \quad (X = F, Cl, Br, I)$$

5. Sodium chloride is the most important alkali metal halide.

(a) In the Downs process for the production of sodium metal (*Section 22.4*), reaction 4 is reversed by supplying electricity to molten NaCl:

$$2NaCl(l) \xrightarrow{\text{electricity}} 2Na(l) + Cl_2(g)$$

(b) In the chlor-alkali process (*Section 22.5*), NaCl(*aq*) is electrolyzed to form several key industrial chemicals:

$$2NaCl(aq) + 2H_2O(l) \longrightarrow 2NaOH(aq) + H_2(g) + Cl_2(g)$$

(c) In its reaction with sulfuric acid, NaCl forms two major products:

$$2NaCl(s) + H_2SO_4(aq) \longrightarrow Na_2SO_4(aq) + 2HCl(g)$$

Sodium sulfate is important in the paper industry; HCl is essential in steel, plastics, textile, and food production.

6. Sodium hydroxide is used in the formation of bleaching solutions:

$$2NaOH(aq) + Cl_2(g) \longrightarrow NaClO(aq) + NaCl(aq) + H_2O(l)$$

7. In an ion-exchange process (*Chemical Connections, pp. 529–530*), water is "softened" by removal of dissolved hard-water cations, which displace Na^+ from a resin:

$$M^{2+}(aq) + Na_2Z(s) \longrightarrow MZ(s) + 2Na^+(aq)$$

$$(M = Mg, Ca; Z = \text{resin})$$

Important Compounds

1. Lithium chloride and lithium bromide, LiCl and LiBr. Because the Li^+ ion is so small, Li salts have a high affinity for H_2O and yet a positive heat of solution. Thus, they are used in dehumidifiers and air-cooling units.

2. Lithium carbonate, Li_2CO_3. Used to make porcelain enamels and toughened glasses and as a drug in the treatment of bipolar disorders.

3. Sodium chloride, NaCl. Millions of tons used in the industrial production of Na, NaOH, Na_2CO_3/$NaHCO_3$, Na_2SO_4, and HCl or purified for use as table salt.

4. Sodium carbonate and sodium hydrogen carbonate, Na_2CO_3 and $NaHCO_3$. Carbonate used as an industrial base and to make glass. Hydrogen carbonate, which releases CO_2 at low temperatures (50° to 100°C), used in baking powder and in fire extinguishers.

5. Sodium hydroxide, NaOH. Most important industrial base; used to make bleach, sodium phosphates, and alcohols.

6. Potassium nitrate, KNO_3. Powerful oxidizing agent used in gunpowder and fireworks (*see photo*).

14.4 GROUP 2A(2): THE ALKALINE EARTH METALS

The Group 2A(2) elements are called *alkaline earth metals* because their oxides give basic (alkaline) solutions and melt at such high temperatures that they remained as solids ("earths") in the alchemists' fires. The group includes a fascinating collection of elements: rare beryllium (Be), common magnesium (Mg) and calcium (Ca), less familiar strontium (Sr) and barium (Ba), and radioactive radium (Ra). The Group 2A(2) Family Portrait (pp. 564 and 565) presents an overview of these elements.

Versatile Magnesium Magnesium, second of the alkaline earths, forms a tough, adherent oxide coating that prevents further reaction of the metal in air and confers stability for many uses. The metal can be rolled, forged, welded, and riveted into virtually any shape, and it forms strong, low-density alloys: some weigh 25% as much as steel but are just as strong. Alloyed with aluminum and zinc, magnesium is used for everyday objects, such as camera bodies, luggage, and the "mag" wheels of bicycles and sports cars. Alloyed with the lanthanides (first series of inner transition elements), it is used in objects that require great strength at high temperatures, such as auto engine blocks and missile parts.

How Do the Physical Properties of the Alkaline Earth and Alkali Metals Compare?

In general terms, the elements in Groups 1A(1) and 2A(2) behave as close cousins. Whatever differences occur between the groups are those of degree, not kind, and are due to the change in outer electron configuration: ns^2 vs. ns^1. Two electrons are available from each 2A atom for metallic bonding, and the nucleus contains one additional positive charge. These factors make the attraction between delocalized electrons and atom cores greater. Consequently, melting and boiling points are much higher for 2A metals than for the corresponding 1A metals; in fact, the 2A elements melt at around the same temperatures as the 1A elements boil! Compared with transition metals, such as iron and chromium, the alkaline earths are soft and lightweight, but they are much harder and more dense than the alkali metals.

How Do the Chemical Properties of the Alkaline Earth and Alkali Metals Compare?

The alkaline earth metals display a wider range of chemical behavior than the alkali metals, largely because of the behavior of beryllium, as you'll see shortly. Because the second valence electron lies in the same sublevel as the first, it is not shielded from the additional nuclear charge very well, and so Z_{eff} is greater. Therefore, Group 2A(2) elements have smaller atomic radii and higher ionization energies than Group 1A(1) elements. Despite the higher IEs, *all the alkaline earths (except Be) form ionic compounds* as 2+ cations. Beryllium behaves differently because so much energy is needed to remove two electrons from this tiny atom that it never forms discrete Be^{2+} ions, and its bonds are polar covalent.

Lime: The Most Useful Metal Oxide Calcium oxide (lime) is a slightly soluble, basic oxide that is among the five most heavily produced industrial compounds in the world; it is made by roasting limestone to high temperatures [Group 2A(2) Family Portrait, reaction 7]. It has essential roles in steelmaking, water treatment, and smokestack "scrubbing." Lime reacts with carbon to form calcium carbide, which is used to make acetylene, and with arsenic acid (H_3AsO_4) to make insecticides for treating cotton, tobacco, and potato plants. Most glass contains about 12% lime by mass. The paper industry uses lime to prepare the bleach [$Ca(ClO)_2$] that whitens paper. Farmers "dust" fields with lime to "sweeten" acidic soil. The food industry uses it to neutralize compounds in milk to make cream and butter and to neutralize impurities in crude sugar.

Like the alkali metals, the alkaline earth metals are *strong reducing agents*. Each element reduces O_2 in air to form the oxide (Ba also forms the peroxide, BaO_2). Except for Be and Mg, which form adherent oxide coatings, the alkaline earths reduce H_2O at room temperature to form H_2. And, except for Be, they reduce the halogens, N_2, and H_2 to form ionic compounds. The Group 2A oxides are strongly basic (except for amphoteric BeO) and react with acidic oxides to form salts, such as sulfites and carbonates; for example,

$$SrO(s) + CO_2(g) \longrightarrow SrCO_3(s)$$

Natural carbonates, such as limestone and marble, are major structural materials and the commercial sources for most 2A compounds.

The alkaline earth metals are reactive because the high lattice energies of their compounds more than compensate for the large total IE needed to form the 2+ cation (Section 9.2). Group 2A salts have much higher lattice energies than Group 1A salts (see Figure 14.2) because the 2A cations are smaller and doubly charged.

One of the main differences between the two groups is the lower solubility of 2A salts in water. Their ions are smaller and more highly charged than 1A ions, resulting in much higher charge densities. Even though this factor increases heats of hydration, it increases lattice energies even more. In fact, most 2A fluorides, carbonates, phosphates, and sulfates are considered insoluble, unlike the corresponding 1A compounds. Nevertheless, the ion-dipole attraction of 2+ ions

for water is so strong that many slightly soluble 2A salts crystallize as hydrates; two examples are Epsom salt, $MgSO_4 \cdot 7H_2O$, used as a soak for inflammations, and gypsum, $CaSO_4 \cdot 2H_2O$, used as the bonding material between the paper sheets in wallboard and as the cement in surgical casts.

The Anomalous Behavior of Beryllium

The Period 2 element Be displays far more anomalous behavior than Li in Group 1A(1). If the Be^{2+} ion did exist, its high charge density would polarize nearby electron clouds very strongly and cause extensive orbital overlap. In fact, *all Be compounds exhibit covalent bonding*. Even BeF_2, the most ionic Be compound, has a relatively low melting point and, when melted, a low electrical conductivity.

With only two valence electrons, Be does not attain an octet in its simple gaseous compounds (Section 10.1). When it bonds to an electron-rich atom, however, this electron deficiency is overcome as the gas condenses. Consider beryllium chloride ($BeCl_2$) (Figure 14.4). At temperatures greater than 900°C, it consists of linear molecules in which two *sp* hybrid orbitals hold four electrons around the central Be. As it cools, the molecules bond together, solidifying in long chains, with each Be sp^3 hybridized to finally attain an octet.

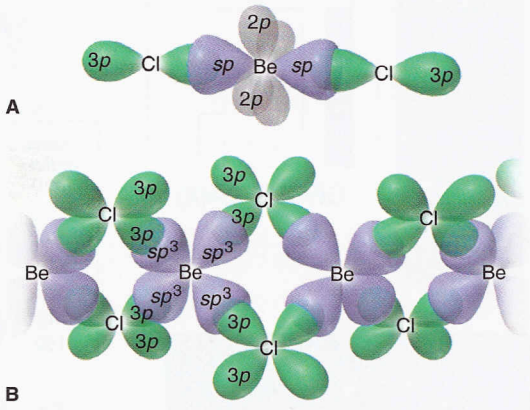


Figure 14.4 Overcoming electron deficiency in beryllium chloride. A, At high temperatures, $BeCl_2$ is a gas with only four electrons around each Be. **B,** Solid $BeCl_2$ occurs in long chains with each Cl bridging two Be atoms, which gives each Be an octet.

Diagonal Relationships: Lithium and Magnesium

One of the clearest ways in which atomic properties influence chemical behavior appears in the **diagonal relationships,** similarities between a Period 2 element and one diagonally down and to the right in Period 3 (Figure 14.5).

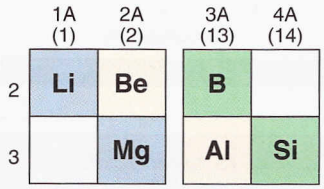

Figure 14.5 Three diagonal relationships in the periodic table. Certain Period 2 elements exhibit behaviors that are very similar to those of the Period 3 elements immediately below and to the right. Three such diagonal relationships exist: Li and Mg, Be and Al, and B and Si.

The first of three such relationships occurs between Li and Mg and reflects similarities in atomic and ionic size. Note that *one period down increases atomic (or ionic) size and one group to the right decreases it.* Thus, Li has a radius of 152 pm and Mg has a radius of 160 pm; the Li^+ radius is 76 pm and that of Mg^{2+} is 72 pm. From similar atomic properties emerge similar chemical properties. Both elements form nitrides with N_2, hydroxides and carbonates that decompose easily with heat, organic compounds with a polar covalent metal-carbon bond, and salts with similar solubilities. We'll discuss the diagonal relationships between Be and Al and between B and Si in later sections.

Looking Backward and Forward: Groups 1A(1), 2A(2), and 3A(13)

Throughout this chapter, comparing the previous, current, and upcoming groups (Figure 14.6) will help you to keep horizontal trends in mind while examining vertical groups. Not much changes from 1A to 2A, and the elements behave as metals both physically and chemically. With smaller atomic sizes and stronger metallic bonding, 2A elements are harder, higher melting, and denser than those in 1A. Nearly all 1A and most 2A compounds are ionic. The higher ionic charge in Group 2A (2+ vs. 1+) leads to higher lattice energies and less soluble salts. The range of behavior in 2A is wider than that in 1A because of Be, and the range widens much further in Group 3A, from metalloid boron to metallic thallium.

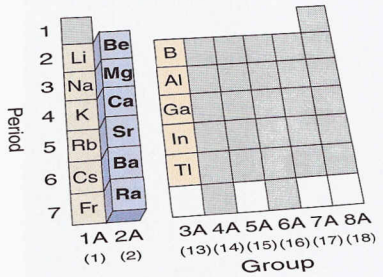

Figure 14.6 Standing in Group 2A(2), looking backward to 1A(1) and forward to 3A(13).

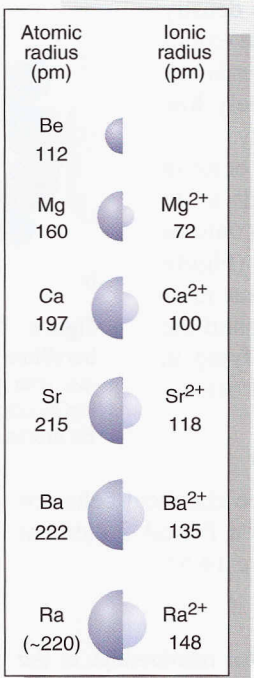
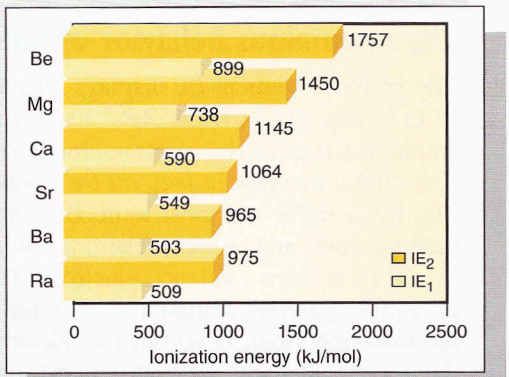
Atomic Properties

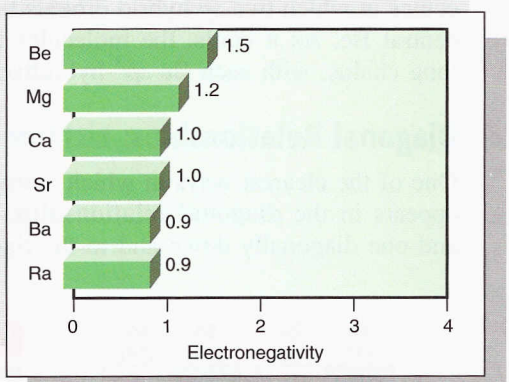


Group electron configuration is ns^2 (filled ns sublevel). All members have the +2 oxidation state and, except for Be, form compounds with an E^{2+} ion.

Atomic and ionic sizes increase down the group but are smaller than for the corresponding 1A(1) element.

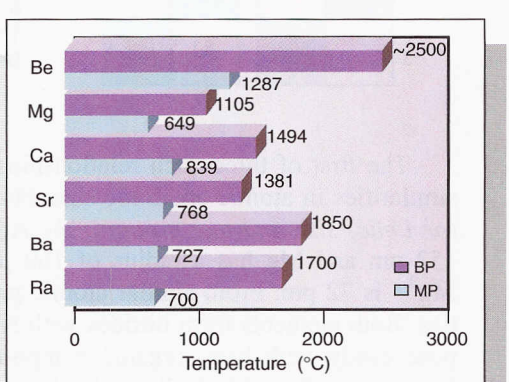
IE and EN decrease down the group but are higher than for the corresponding 1A(1) element.

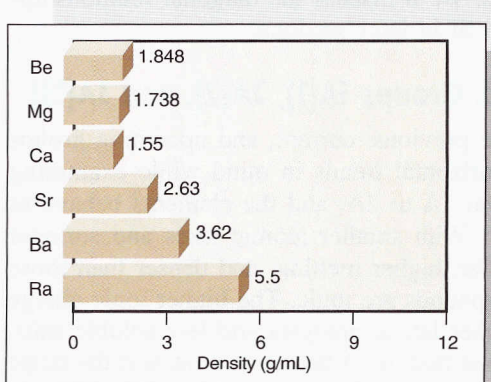




Physical Properties

Metallic bonding involves two valence electrons. These metals are still relatively soft but are much harder than the 1A(1) metals.





Melting and boiling points generally decrease, and densities generally increase down the group. These values are much higher than for 1A(1) elements, and the trend is not as regular.

Some Reactions and Compounds

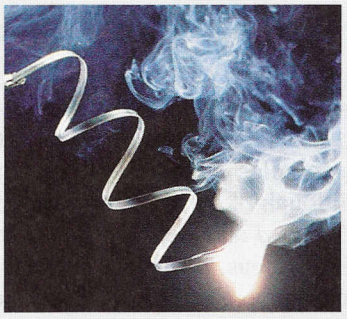
Important Reactions

The elements (E) act as reducing agents in reactions 1 to 5; note the similarity to reactions of Group 1A(1). Reaction 6 shows the general basicity of the 2A(2) oxides; reaction 7 shows the general instability of their carbonates at high temperature.

1. The metals reduce O_2 to form the oxides:

$$2E(s) + O_2(g) \longrightarrow 2EO(s)$$

Ba also forms the peroxide, BaO_2.



Magnesium ribbon burning

2. The larger metals reduce water to form hydrogen gas:

$$E(s) + 2H_2O(l) \longrightarrow E^{2+}(aq) + 2OH^-(aq) + H_2(g) \quad (E = Ca, Sr, Ba)$$

Be and Mg form an adherent oxide coating that allows only slight reaction.

3. The metals reduce halogens to form ionic halides:

$$E(s) + X_2 \longrightarrow EX_2(s) \quad (X = F, Cl, Br, I)$$

4. Most of the elements reduce hydrogen to form ionic hydrides:

$$E(s) + H_2(g) \longrightarrow EH_2(s) \quad (E = \text{all except Be})$$

5. Most of the elements reduce nitrogen to form ionic nitrides:

$$3E(s) + N_2(g) \longrightarrow E_3N_2(s) \quad (E = \text{all except Be})$$

6. Except for amphoteric BeO, the element oxides are basic:

$$EO(s) + H_2O(l) \longrightarrow E^{2+}(aq) + 2OH^-(aq)$$

$Ca(OH)_2$ is a component of cement and mortar.

7. All carbonates undergo thermal decomposition to the oxide:

$$ECO_3(s) \xrightarrow{\Delta} EO(s) + CO_2(g)$$

This reaction is used to produce CaO (lime) in huge amounts from naturally occurring limestone (*margin note, p. 562*).

Important Compounds

1. Beryl, $Be_3Al_2Si_6O_{18}$. Beryl, the industrial source of Be metal, also occurs as a gemstone with a variety of colors (*see photo*). It is chemically identical to emerald, except for the trace of Cr^{3+} that gives emerald its green color.

2. Magnesium oxide, MgO. Because of its high melting point (2852°C), MgO is used as a refractory material for furnace brick (*see photo*) and wire insulation.

Industrial kiln

3. Alkylmagnesium halides, RMgX (R = hydrocarbon group; X = halogen). These compounds are used to synthesize many organic compounds. Organotin agricultural fungicides are made by treating RMgX with $SnCl_4$:

$$3RMgCl + SnCl_4 \longrightarrow 3MgCl_2 + R_3SnCl$$

4. Calcium carbonate, $CaCO_3$. Occurs as enormous natural deposits of limestone, marble, chalk, and coral. Used as a building material, to make lime, and, in high purity, as a toothpaste abrasive and an antacid (*see photo*).

Antacid tablet Limestone

14.5 GROUP 3A(13): THE BORON FAMILY

The third family of main-group elements contains some unusual members and some familiar ones, some exotic bonding, and some strange physical properties. Boron (B) heads the family, but, as you'll see, its properties certainly do not represent the other members. Metallic aluminum (Al) has properties that are more typical of the group, but its great abundance and importance contrast with the rareness of gallium (Ga), indium (In), and thallium (Tl). The atomic, physical, and chemical properties of these elements are summarized in the Group 3A(13) Family Portrait (pp. 568 and 569).

How Do Transition Elements Influence Group 3A(13) Properties?

Group 3A(13) is the first of the *p* block. If you look at the main groups only, the elements of this group seem to be just one group away from those of Group 2A(2). In Period 4 and higher, however, a large gap separates the two groups (see Figure 8.11, p. 302). The gap holds 10 transition elements (*d* block) each in Periods 4, 5, and 6 and an additional 14 inner transition elements (*f* block) in Period 6. Recall from Section 8.2 that *d* and *f* electrons penetrate very little, and so spend very little time near the nucleus. Thus, the heavier 3A members—Ga, In, and Tl—have nuclei with many more protons, but their outer (*s* and *p*) electrons are only partially shielded from the much higher positive charge; as a result, these elements have greater Z_{eff} values than the two lighter members of the group.

Many properties of these heavier 3A elements are influenced by this stronger nuclear attraction. Figure 14.7 compares several properties of Group 3A(13) with those of Group 3B(3) (the first group of transition elements), in which the additional protons of the *d* block and *f* block have *not* been added. Note the regular changes exhibited by the 3B elements in contrast to the irregular patterns for those in 3A. The deviations for Ga reflect the *d*-block *contraction in size* and can be explained by limited shielding by the *d* electrons of the 10 additional protons of the first transition series. Similarly, the deviations for Tl reflect the *f*-block (lanthanide) contraction and can be explained by limited shielding by the *f* electrons of the 14 additional protons of the first inner transition series.

Physical properties are influenced by the type of bonding that occurs in the element. Boron is a network covalent metalloid—black, hard, and very high melting. The other group members are metals—shiny and relatively soft and low melting. Aluminum's low density and three valence electrons make it an exceptional conductor: for a given mass, aluminum conducts a current twice as effectively as copper. Gallium has the largest liquid temperature range of any element: it melts in your hand (see photo, p. 568) but does not boil until 2403°C. Its metallic bonding is too weak to keep the Ga atoms fixed when the solid is warmed, but strong enough to keep them from escaping the molten metal until it is very hot.

Gallium Arsenide: The New Wave of Semiconductors An important modern use of gallium is in the production of gallium arsenide (GaAs) semiconductors. Electrons move 10 times faster through GaAs than through Si-based chips. GaAs chips also have novel optical properties: a current is created when they absorb light, and, conversely, they emit light when a current is supplied. GaAs devices are already used in light-powered calculators, wristwatches, and solar panels. In addition, GaAs-based lasers are much smaller and more powerful than other types.

What New Features Appear in the Chemical Properties of Group 3A(13)?

Looking down Group 3A(13), we see a wide range of chemical behavior. Boron, the anomalous member from Period 2, is the first metalloid we've encountered so far and the only one in the group. It is much less reactive at room temperature than the other members and forms covalent bonds exclusively. Although aluminum acts like a metal physically, its halides exist in the gas phase as covalent *dimers*—molecules formed by joining two identical smaller molecules (Figure 14.8)—and its oxide is amphoteric rather than basic. Most of the other 3A compounds are ionic, but they have more covalent character than similar 2A compounds. Because the 3A cations are smaller and more highly charged than the 2A cations, they polarize an anion's electron cloud more effectively.

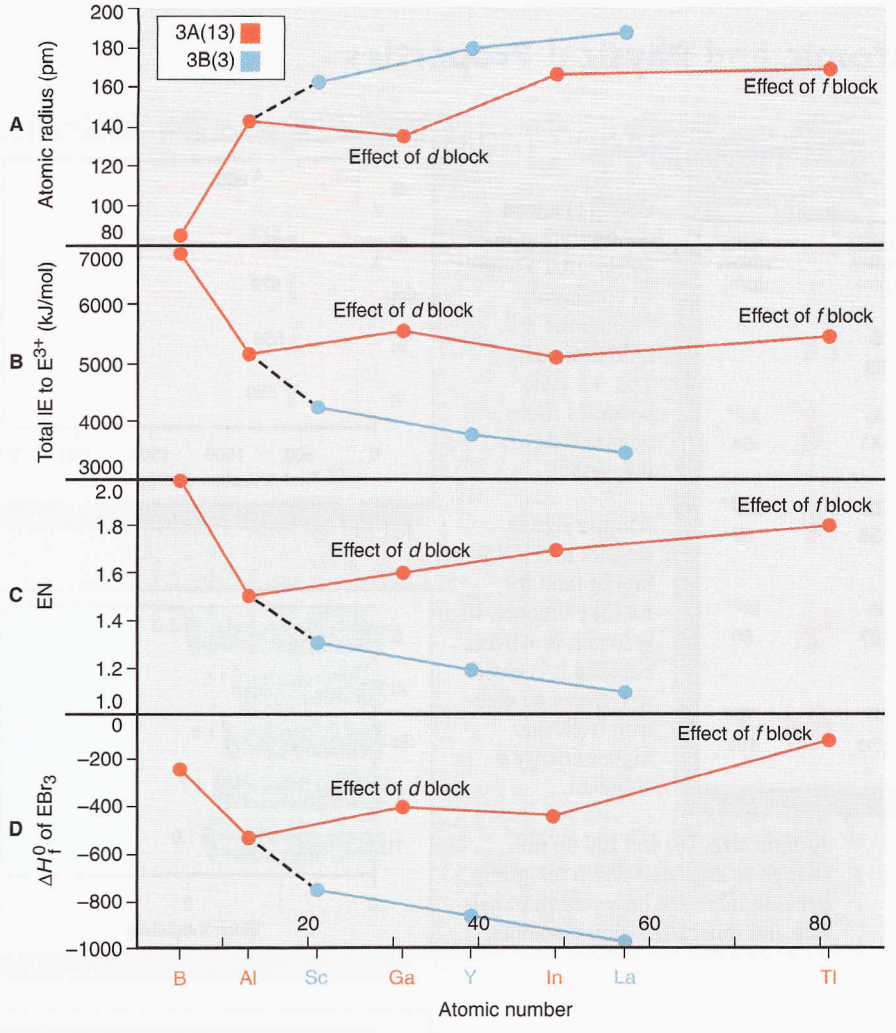


Figure 14.7 The effect of transition elements on properties: Group 3B(3) vs. Group 3A(13). The additional protons in the nuclei of transition elements exert an exceptionally strong attraction because *d* and *f* electrons shield the nuclear charge poorly. This greater effective nuclear charge affects the *p*-block elements in Periods 4 to 6, as can be seen by comparing properties of Group 3B(3), the first group after the *s* block, with those of Group 3A(13), the first group after the *d* block. **A,** Atomic size. In Group 3B, size increases smoothly, whereas in 3A, Ga and Tl are smaller than expected. **B,** Total ionization energy for E^{3+}. The deviations in size lead to deviations in total IE ($IE_1 + IE_2 + IE_3$). Note the regular decrease for Group 3B and the unexpectedly higher values for Ga and Tl in 3A. **C,** Electronegativity. The deviations in size also make Ga and Tl more electronegative than expected. **D,** Heat of formation of EBr_3. The higher IE values for Ga and Tl mean less heat is released upon formation of the ionic compound; thus, the magnitudes of the ΔH_f^0 values for $GaBr_3$ and $TlBr_3$ are smaller than expected.

The redox behavior of the elements in this group provides a chance to note three general principles that appear in Groups 3A(13) to 6A(16):

1. *Presence of multiple oxidation states.* Many of the larger elements in these groups also have an important oxidation state *two lower than the A-group number.* The lower state occurs when the atoms lose their *np* electrons only, not their two *ns* electrons. This fact is often called the *inert-pair effect* (Section 8.5), but it has nothing to do with any inertness of *ns* electrons; for example, the 6*s* electrons in Tl are lost *more* easily than the 4*s* electrons in Ga. The reason for the common appearance of the lower state involves bond energies of the compounds. Bond energy decreases as atomic size, and therefore bond length, increases. Consider the Tl—Cl bond. It is relatively long and weak, and it takes more energy to remove the two 6*s* electrons from Tl^+ to make Tl^{3+} than is released when two more weak Tl—Cl bonds form in $TlCl_3$. In fact, $TlCl_3$ is so unstable that it decomposes readily to Cl_2 gas and TlCl.

2. *Increasing prominence of the lower oxidation state.* When a group exhibits more than one oxidation state, *the lower state becomes more prominent going down the group.* In Group 3A(13), for instance, all members exhibit the +3 state, but the +1 state first appears with some compounds of gallium and becomes the only important state of thallium.

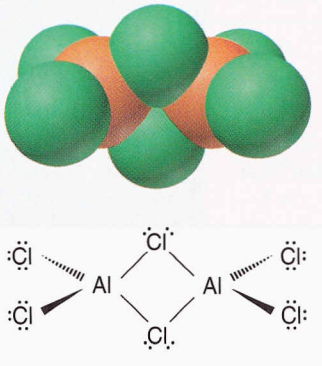

Figure 14.8 The dimeric structure of gaseous aluminum chloride. Despite its name, aluminum trichloride exists in the gas phase as the dimer, Al_2Cl_6.

Group 3A(13): The Boron Family

Key Atomic and Physical Properties

KEY
Atomic No.

GROUP 3A(13)

5 **B** 10.81 $2s^22p^1$ **+3**	
13 **Al** 26.98 $3s^23p^1$ **+3**	31 **Ga** 69.72 $4s^24p^1$ **+3, +1**	49 **In** 114.8 $5s^25p^1$ **+3, +1**	81 **Tl** 204.4 $6s^26p^1$ **+1**	

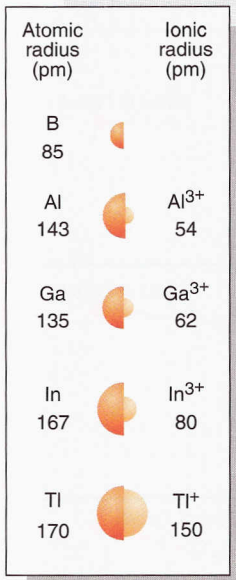
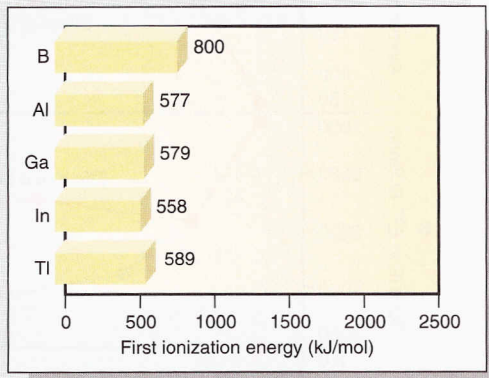
Atomic Properties

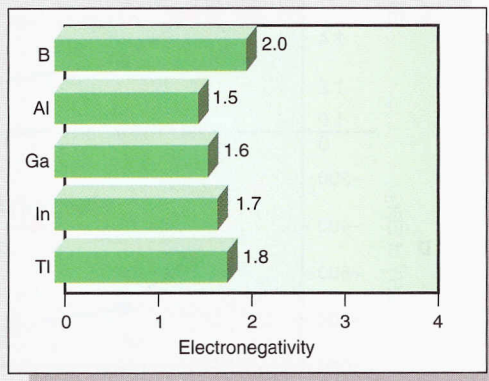


Group electron configuration is ns^2np^1. All except Tl commonly display the +3 oxidation state. The +1 state becomes more common down the group.

Atomic size is smaller and EN is higher than for 2A(2) elements; IE is lower, however, because it is easier to remove an electron from the higher energy *p* sublevel.

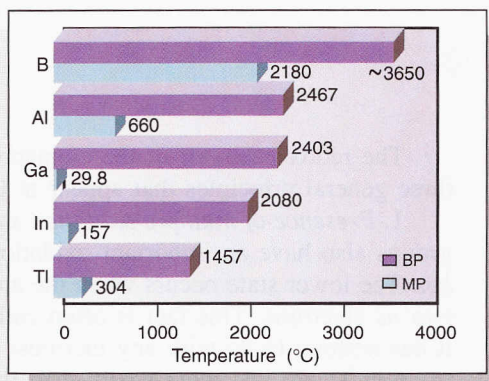
Atomic size, IE, and EN do not change as expected down the group because there are intervening transition and inner transition elements.

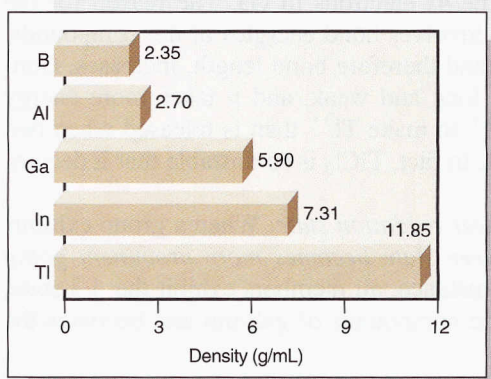




Physical Properties

Bonding changes from network covalent in B to metallic in the rest of the group. Thus, B has a much higher melting point than the others, but there is no overall trend. Boiling points decrease down the group.





Densities increase down the group.

Some Reactions and Compounds

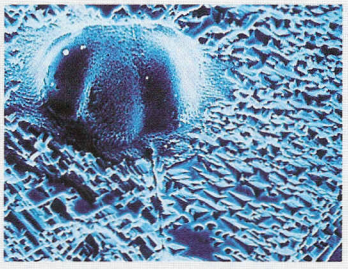
Important Reactions

In reactions 1 to 3, the elements (E) usually require higher temperatures to react than those of Groups 1A(1) and 2A(2); note the lower oxidation state of Tl. Reactions 4 to 6 show some compounds in key industrial processes.

1. The elements react sluggishly, if at all, with water:

$$2Ga(s) + 6H_2O(hot) \longrightarrow 2Ga^{3+}(aq) + 6OH^-(aq) + 3H_2(g)$$
$$2Tl(s) + 2H_2O(steam) \longrightarrow 2Tl^+(aq) + 2OH^-(aq) + H_2(g)$$

Al becomes covered with a layer of Al_2O_3 that prevents further reaction (*see photo*).



Electron micrograph of oxide coating on Al surface

2. When strongly heated in pure O_2, all members form oxides:

$$4E(s) + 3O_2(g) \xrightarrow{\Delta} 2E_2O_3(s) \qquad (E = B, Al, Ga, In)$$
$$4Tl(s) + O_2(g) \xrightarrow{\Delta} 2Tl_2O(s)$$

Oxide acidity decreases down the group: B_2O_3 (weakly acidic) > Al_2O_3 > Ga_2O_3 > In_2O_3 > Tl_2O (strongly basic), and the +1 oxide is more basic than the +3 oxide.

3. All members reduce halogens (X_2):

$$2E(s) + 3X_2 \longrightarrow 2EX_3 \qquad (E = B, Al, Ga, In)$$
$$2Tl(s) + X_2 \longrightarrow 2TlX(s)$$

The BX_3 compounds are volatile and covalent.
Trihalides of Al, Ga, and In are (mostly) ionic solids but occur as covalent dimers in the gas phase; in this way, the 3A atom attains a filled outer level.

4. Acid treatment of Al_2O_3 is important in water purification:

$$Al_2O_3(s) + 3H_2SO_4(l) \longrightarrow Al_2(SO_4)_3(s) + 3H_2O(l)$$

In water, $Al_2(SO_4)_3$ and CaO form a colloid that aids in removing suspended particles.

5. The overall reaction in the production of aluminum metal is a redox process:

$$2Al_2O_3(s) + 3C(s) \longrightarrow 4Al(s) + 3CO_2(g)$$

This process is carried out electrochemically in the presence of cryolite (Na_3AlF_6), which lowers the melting point of the reactant mixture and takes part in the change (*Section 22.4*).

6. A displacement reaction produces gallium arsenide, GaAs (*margin note, p. 566*):

$$(CH_3)_3Ga(g) + AsH_3(g) \longrightarrow 3CH_4(g) + GaAs(s)$$

Important Compounds

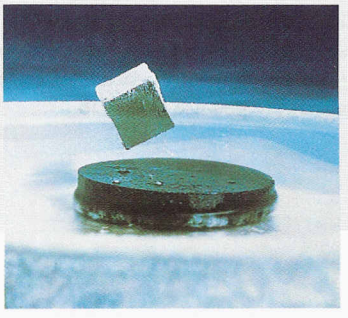
1. Boron oxide, B_2O_3. Used in the production of borosilicate glass (*see margin note, p. 570*).
2. Borax, $Na_2[B_4O_5(OH)_4]\cdot 8H_2O$. Major mineral source of boron compounds and B_2O_3. Used as a fireproof insulation material and as a washing powder (20-Mule Team Borax).
3. Boric acid, H_3BO_3 [or $B(OH)_3$]. Used as external disinfectant, eyewash, and insecticide.
4. Diborane, B_2H_6. A powerful reducing agent for possible use as a rocket fuel. Used to synthesize higher boranes, compounds that led to new theories of chemical bonding.

5. Aluminum sulfate (cake alum), $Al_2(SO_4)_3\cdot 18H_2O$. Used in purifying water, tanning leather, and sizing paper; as a fixative for dyeing cloth (*see photo*); and as an antiperspirant.

6. Aluminum oxide, Al_2O_3. Major compound in natural source (bauxite) of Al metal. Used as abrasive in sandpaper, sanding and cutting tools, and toothpaste. Large crystals with metal ion impurities often of gemstone quality (*see photo*). Inert support for chromatography. In fibrous forms, woven into heat-resistant fabrics; also used to strengthen ceramics and metals.

Ruby

7. $Tl_2Ba_2Ca_2Cu_3O_{10}$. Becomes a high-temperature superconductor at 125 K, which is readily attained with liquid N_2 (*see photo*).



Magnet levitated by superconductor

3. *Relative basicity of oxides.* In general, *oxides with the element in a lower oxidation state are more basic than oxides with the element in a higher oxidation state.* A good example in Group 3A is that In_2O is more basic than In_2O_3. In general, when an element has more than one oxidation state, *it acts more like a metal in its lower state*, and this, too, is related to ionic charge density. In this example, the lower charge of In^+ does not polarize the O^{2-} ion as much as the higher charge of In^{3+} does. Thus, in compounds of general formula E_2O, the E-to-O bonding is more ionic than it is in E_2O_3 compounds, so the O^{2-} ion is more available to act as a base (Interchapter, Topic 4).

Highlights of Boron Chemistry

Like the other Period 2 elements, the chemical behavior of boron is strikingly different from that of the other members of its group. As was pointed out earlier, *all boron compounds are covalent,* and unlike the other Group 3A(13) members, boron forms network covalent compounds or large molecules with metals, H, O, N, and C. The unifying feature of many boron compounds is the element's *electron deficiency,* but boron adopts two strategies to fill its outer level: accepting a bonding pair from an electron-rich atom and forming bridge bonds with electron-poor atoms.

Accepting a Bonding Pair from an Electron-Rich Atom In gaseous boron trihalides (BX_3), the B atom is electron deficient, with only six electrons around it (Section 10.1). To attain an octet, the B atom accepts a lone pair of electrons from an electron-rich atom and forms a covalent bond:

$$BF_3(g) + :NH_3(g) \longrightarrow F_3B{-}NH_3(g)$$

(Such reactions, in which one reactant accepts an electron pair from another to form a covalent bond, are very widespread in inorganic, organic, and biochemical processes. They are known as *Lewis acid-base reactions,* and we'll discuss them in Chapters 18 and 23 and see examples of them throughout the second half of the text.)

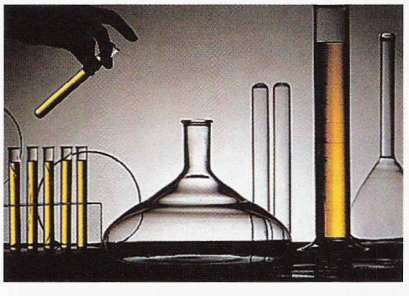
Similarly, B has only six electrons in boric acid, $B(OH)_3$ (sometimes written as H_3BO_3). In water, the acid itself does not release a proton. Rather, it accepts an electron pair from the O in H_2O, forming a fourth bond and releasing an H^+ ion:

$$B(OH)_3(s) + H_2O(l) \rightleftharpoons B(OH)_4^-(aq) + H^+(aq)$$

Boron's outer shell is filled in the wide variety of borate salts, such as the mineral borax (sodium borate), $Na_2[B_4O_5(OH)_4]\cdot 8H_2O$, used for decades as a household cleaning agent.

Boron also attains an octet in several boron-nitrogen compounds whose crystal or molecular structures are amazingly similar to those of elemental carbon and some of its organic compounds (Figure 14.9). These similarities are due to the fact that the size, IE, and EN of C are between those of B and N (see Table 14.1). Moreover, C has four valence electrons, whereas B has three and N has five, so the $\cdot\dot{C}{-}\dot{C}\cdot$ and $\cdot\dot{B}{-}\dot{N}\cdot$ groupings have the same number of valence electrons. Therefore, $H_3C{-}CH_3$ (ethane) and $H_3B{-}NH_3$ (amine-borane) are isoelectronic, as are benzene and borazine (Figure 14.9A and B).

Boron nitride (Figure 14.9C) has a structure consisting of hexagons fused into sheets, very similar to that of graphite. Moreover, like graphite, its π electrons are highly delocalized through resonance. However, molecular-orbital calculations show that there is a large energy gap between the filled valence band and the empty conductance band in boron nitride, but no such gap in graphite (see Figure 12.37, p. 462). As a result, boron nitride is a white electrical insulator, whereas graphite is a black electrical conductor. At high pressure and temperature, boron nitride forms borazon (Figure 14.9D), which has a crystal structure like that of diamond and is extremely hard and abrasive.



Borates in Your Labware Strong heating of boric acid (or borate salts) drives off water molecules and gives molten boron oxide:

$$2B(OH)_3(s) \xrightarrow{\Delta} B_2O_3(l) + 3H_2O(g)$$

The molten oxide dissolves metal oxides to form borate glasses. When mixed with silica (SiO_2), it forms borosilicate glass. Its high transparency and small change in size when heated or cooled make borosilicate glass useful in cookware and in the glassware you use in the lab.

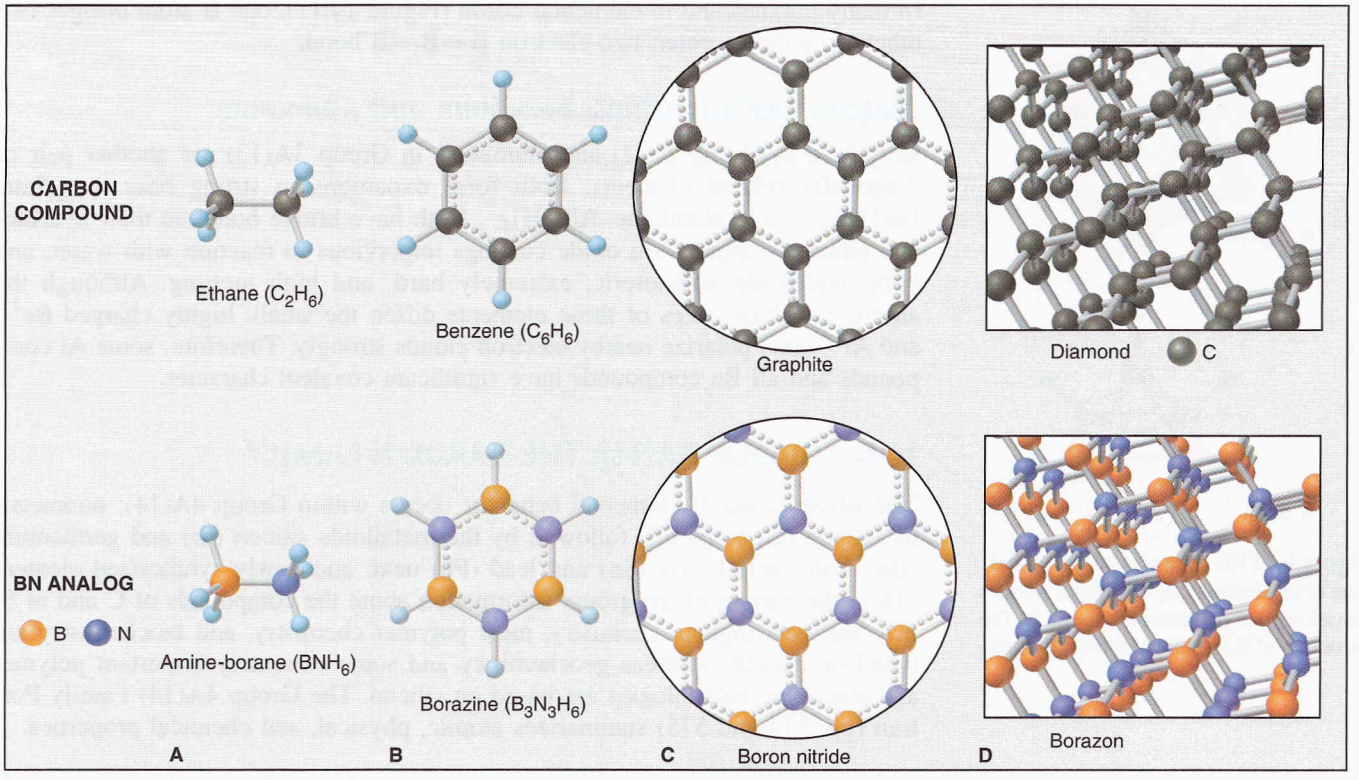


Figure 14.9 Similarities between substances with C—C bonds and those with B—N bonds. Note that in each case, B attains an octet of electrons by bonding with electron-rich N. **A,** Ethane and its BN analog. **B,** Benzene and borazine, which is often referred to as "inorganic" benzene. **C,** Graphite and the similar extended hexagonal sheet structure of boron nitride. **D,** Diamond and borazon have the same crystal structure and are among the hardest substances known.

Forming Bridge Bonds with Electron-Poor Atoms In elemental boron and its many hydrides (boranes), there is no electron-rich atom to supply boron with electrons. In these substances, boron attains an octet through some unusual bonding. In diborane (B_2H_6) and many larger boranes, for example, two types of B—H bonds exist. The first type is a typical electron-pair bond. The valence bond picture in Figure 14.10 shows an sp^3 orbital of B overlapping a 1*s* orbital of H in each of the four terminal B—H bonds, using two of the three electrons in the valence level of each B atom.

The other type of bond is a hydride **bridge bond** (or three-center, two-electron bond), in which *each B—H—B grouping is held together by only two electrons*. Two sp^3 orbitals, one from *each* B, overlap an H 1*s* orbital between them. Two electrons move through this extended bonding orbital—one from one of the B atoms and the other from the H atom—and join the two B atoms via the H atom bridge. Notice that *each B atom is surrounded by eight electrons:* four from the two normal B—H bonds and four from the two B—H—B bridge bonds.

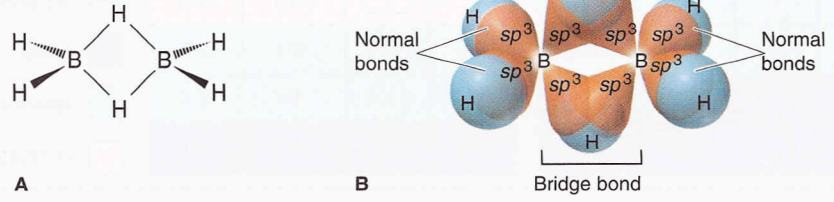

Figure 14.10 The two types of covalent bonding in diborane. A, A perspective diagram of B_2H_6 shows the unusual B—H—B bridge bond and the tetrahedral arrangement around each B atom. **B,** A valence bond depiction shows each sp^3-hybridized B forming normal covalent bonds with two hydrogens and two bridge bonds, in which two electrons bind three atoms, at the two central B—H—B groupings.

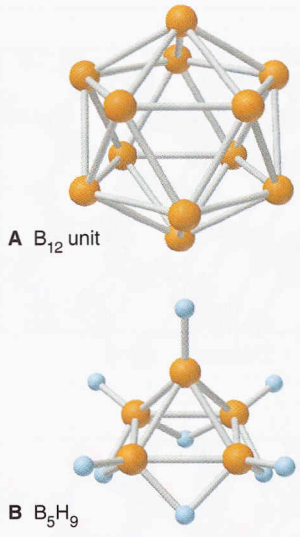

Figure 14.11 The boron icosahedron and one of the boranes. A, The icosahedral structural unit of elemental boron. **B,** The structure of B_5H_9, one of many boranes.

In many boranes and in elemental boron (Figure 14.11), one B atom bridges two others in a three-center, two-electron B—B—B bond.

Diagonal Relationships: Beryllium and Aluminum

Beryllium in Group 2A(2) and aluminum in Group 3A(13) are another pair of diagonally related elements. Both form oxoanions in strong base: beryllate, $Be(OH)_4^{2-}$, and aluminate, $Al(OH)_4^-$. Both have bridge bonds in their hydrides and chlorides. Both form oxide coatings impervious to reaction with water, and both oxides are amphoteric, extremely hard, and high melting. Although the atomic and ionic sizes of these elements differ, the small, highly charged Be^{2+} and Al^{3+} ions polarize nearby electron clouds strongly. Therefore, some Al compounds and all Be compounds have significant covalent character.

14.6 GROUP 4A(14): THE CARBON FAMILY

The whole range of elemental behavior occurs within Group 4A(14): nonmetallic carbon (C) leads off, followed by the metalloids silicon (Si) and germanium (Ge), with metallic tin (Sn) and lead (Pb) next, and newly synthesized element 114 at the bottom of the group. Information about the compounds of C and of Si fills libraries: organic chemistry, most polymer chemistry, and biochemistry are based on carbon, whereas geochemistry and some extremely important polymer and electronic technologies are based on silicon. The Group 4A(14) Family Portrait (pp. 574 and 575) summarizes atomic, physical, and chemical properties.

How Does the Bonding in an Element Affect Physical Properties?

The elements of Group 4A(14) and their neighbors in Groups 3A(13) and 5A(15) illustrate how physical properties, such as melting point and heat of fusion (ΔH_{fus}), depend on the type of bonding in an element (Table 14.2). Within Group 4A, the large decrease in melting point between the network covalent solids C and Si is due to longer, weaker bonds in the Si structure; the large decrease between Ge and Sn is due to the change from covalent network to metallic bonding. Similarly, considering horizontal trends, the large increases in melting point and ΔH_{fus} across a period between Al and Si and between Ga and Ge reflect the change from metallic to covalent network bonding. Note the abrupt rises in the values for these properties from metallic Al, Ga, and Sn to the network covalent metalloids Si, Ge, and Sb, and note the abrupt drops from the covalent networks of C and Si to the individual molecules of N and P in Group 5A.

Table 14.2 Bond Type and the Melting Process in Groups 3A(13) to 5A(15)

Period	Group 3A(13)				Group 4A(14)				Group 5A(15)			
	Element	Bond Type	Melting Point (°C)	ΔH_{fus} (kJ/mol)	Element	Bond Type	Melting Point (°C)	ΔH_{fus} (kJ/mol)	Element	Bond Type	Melting Point (°C)	ΔH_{fus} (kJ/mol)
2	B		2180	23.6	C		4100	Very high	N		−210	0.7

Allotropism: Different Forms of an Element Striking variations in physical properties often appear among **allotropes,** different crystalline or molecular forms of a substance. One allotrope is usually more stable than another at a particular pressure and temperature. Group 4A(14) provides the first dramatic example of allotropism, in the forms of carbon. It is difficult to imagine two substances made entirely of the same atom that are more different than graphite and diamond. Graphite is a black electrical conductor that is soft and "greasy," whereas diamond is a colorless electrical insulator that is extremely hard. Graphite is the standard state of carbon, the more stable form at ordinary temperature and pressure, as the phase diagram in Figure 14.12 shows. Fortunately for jewelry owners, diamond changes to graphite at a negligible rate under normal conditions.

In the mid-1980s, a newly discovered allotrope of carbon began generating great interest. Mass spectrometric analysis of soot had shown evidence for a soccer ball–shaped molecule of formula C_{60} (Figure 14.13A; see also the Gallery, p. 386). More recently, the molecule has also been found in geological samples formed by meteorite impacts, even the one that occurred around the time the dinosaurs became extinct. The molecule has been dubbed *buckminsterfullerene* (informally called a "buckyball") after the architect-engineer R. Buckminster Fuller, who designed structures with similar shapes. Excitement rose in 1990, when scientists learned how to prepare multigram quantities of C_{60} and related fullerenes, enough to study macroscopic behavior and possible applications. Since then, metal atoms have been incorporated into the structure and many different atoms and groups (fluorine, hydroxyl groups, sugars, etc.) have been attached, resulting in compounds with a range of useful properties.

Then, in 1991, scientists passed an electric discharge through graphite rods sealed with helium gas in a container and obtained extremely thin (~1 nm in diameter) graphite-like tubes with fullerene ends (Figure 14.13B). These *nanotubes* are rigid and, on a mass basis, much stronger than steel along their long axis. They also conduct electricity along this axis because of the delocalized electrons. Reports about fullerenes and nanotubes appear almost daily in scientific journals. With potential applications in nanoscale electronics, catalysis, polymers, and medicine, fullerene and nanotube chemistry will receive increasing attention well into the 21st century.

Tin has two allotropes. White β-tin is stable at room temperature and above, whereas gray α-tin is the more stable form below 13°C (56°F). When white tin is kept for long periods at a low temperature, some converts to microcrystals of gray tin. The random formation and growth of these regions of gray tin, which has a different crystal structure, weaken the metal and make it crumble. In the unheated cathedrals of medieval northern Europe, tin pipes of magnificent organs sometimes crumbled as a result of "tin disease" caused by this allotropic transition from white to gray tin.

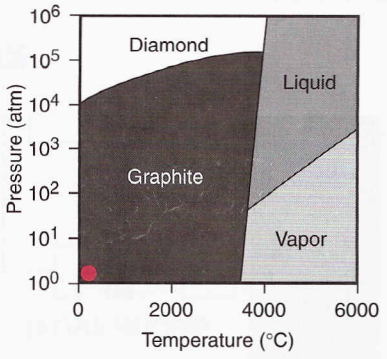

Figure 14.12 Phase diagram of carbon. Graphite is the more stable form of carbon at ordinary conditions (*small red circle at extreme lower left*). Diamond is more stable at very high pressure.

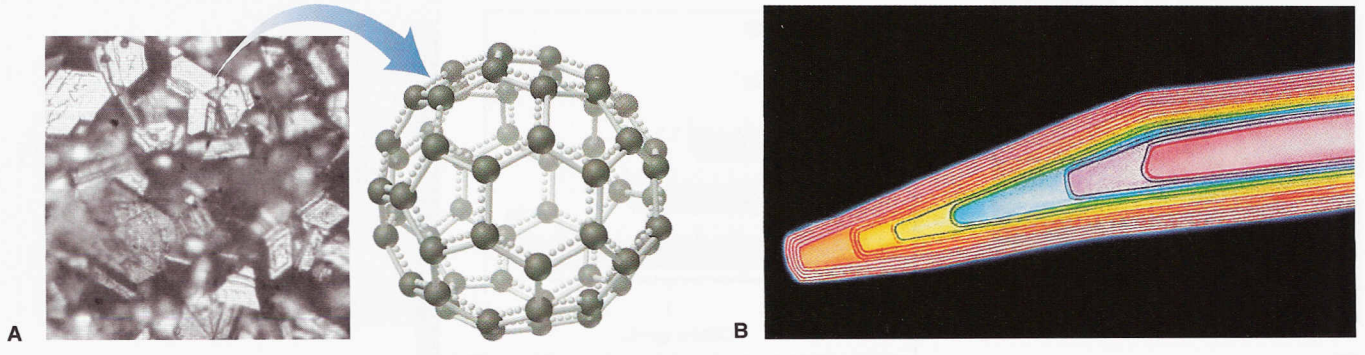

Figure 14.13 Buckyballs and nanotubes. **A,** Crystals of buckminsterfullerene (C_{60}) are shown leading to a ball-and-stick model. The parent of the fullerenes, the "buckyball," is a soccer ball–shaped molecule of 60 carbon atoms. **B,** Nanotubes are single or, as shown in this colorized transmission electron micrograph, concentric graphite-like tubes with fullerene ends (see the Gallery, p. 386).

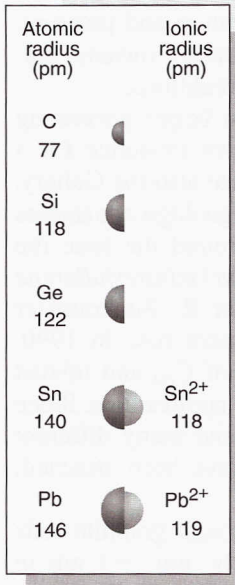
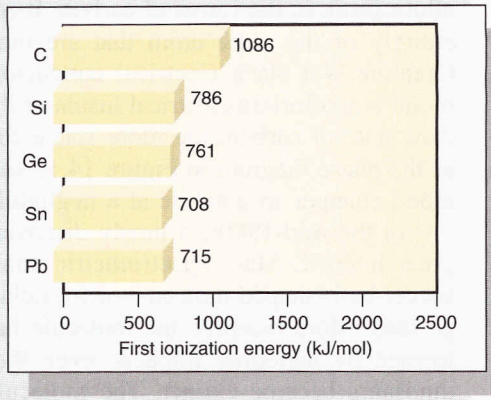
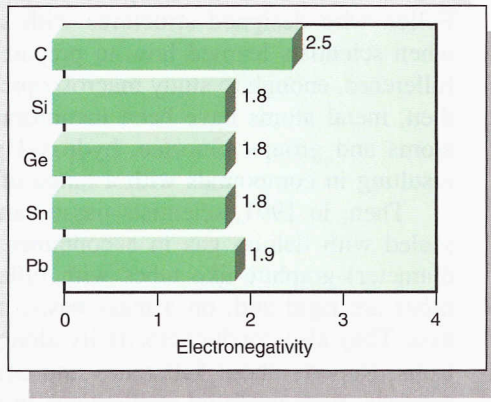
Atomic Properties



Group electron configuration is ns^2np^2. Down the group, the number of oxidation states decreases, and the lower (+2) state becomes more common.

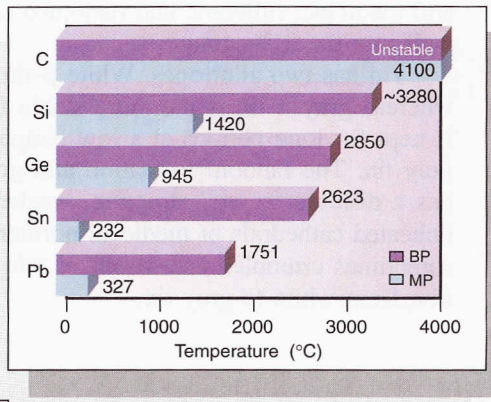
Down the group, size increases. Because transition and inner transition elements intervene, IE and EN do not decrease smoothly.

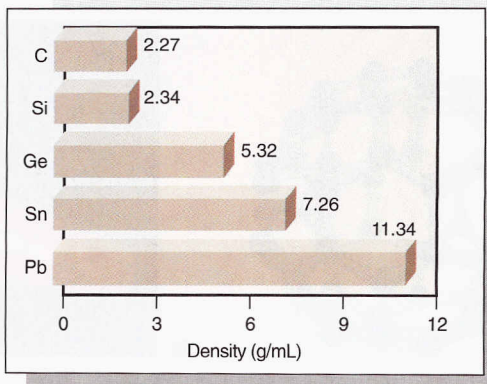




Physical Properties

Trends in properties, such as decreasing hardness and melting point, are due to changes in types of bonding within the solid: network covalent in C, Si, and Ge; metallic in Sn and Pb (*see text*).





Down the group, density increases because of several factors, including differences in crystal packing.

Some Reactions and Compounds

Important Reactions

Reactions 1 and 2 pertain to all the elements (E); reactions 3 to 7 concern industrial uses for compounds of C and Si.

1. The elements are oxidized by halogens:

$$E(s) + 2X_2 \longrightarrow EX_4 \quad (E = C, Si, Ge)$$

The +2 halides are more stable for tin and lead, SnX_2 and PbX_2.

2. The elements are oxidized by O_2:

$$E(s) + O_2(g) \longrightarrow EO_2 \quad (E = C, Si, Ge, Sn)$$

Pb forms the +2 oxide, PbO. Oxides become more basic down the group. The reaction of CO_2 and H_2O provides the weak acidity of natural unpolluted waters:

$$CO_2(g) + H_2O(l) \rightleftharpoons [H_2CO_3(aq)] \rightleftharpoons H^+(aq) + HCO_3^-(aq)$$

3. Air and steam passed over hot coke produce gaseous fuel mixtures (producer gas and water gas):

$$C(s) + \text{air}(g) + H_2O(g) \longrightarrow CO(g) + CO_2(g) + N_2(g) + H_2(g) \quad \text{[not balanced]}$$

4. Hydrocarbons react with O_2 to form CO_2 and H_2O. The reaction for methane is adapted to yield heat or electricity:

$$CH_4(g) + 2O_2(g) \longrightarrow CO_2(g) + 2H_2O(g)$$

Oxyacetylene torch

5. Certain metal carbides react with water to produce acetylene:

$$CaC_2(s) + 2H_2O(l) \longrightarrow Ca(OH)_2(aq) + C_2H_2(g)$$

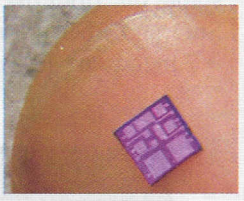
The gas is used to make other organic compounds and as a fuel in welding (*see photo*).

6. Freons (chlorofluorocarbons) are formed by fluorinating carbon tetrachloride:

$$CCl_4(l) + HF(g) \longrightarrow CFCl_3(g) + HCl(g)$$

Production of trichlorofluoromethane (Freon-11), the most widely used refrigerant in the world, is being eliminated because of adverse effects on the environment (*margin note, p. 577*).

7. Silica is reduced to form elemental silicon:



$$SiO_2(s) + 2C(s) \longrightarrow Si(s) + 2CO(g)$$

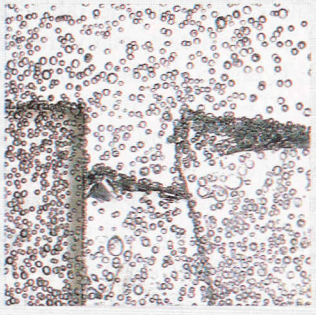
This crude silicon is made ultrapure through zone refining (*Gallery, p. 521*) for the manufacture of computer chips (*see photo*).

Computer chip

Important Compounds

1. Carbon monoxide, CO. Used as a gaseous fuel, as a precursor for organic compounds, and as a reactant in the purification of nickel. Formed in internal combustion engines and released as a toxic air pollutant.

2. Carbon dioxide, CO_2. Atmospheric component used by photosynthetic plants to make carbohydrates and O_2. The final oxidation product of all carbon-based fuels; its increase in the atmosphere is causing global warming. Used industrially as a refrigerant gas, a blanketing gas in fire extinguishers, and an effervescent gas in beverages (*see photo*). Combined with NH_3 to form urea for fertilizers and plastics manufacture.

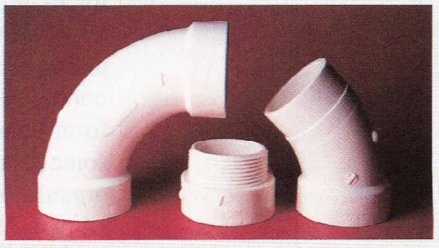


3. Methane, CH_4. Used as a fuel and in the production of many organic compounds. Major component of natural gas. Formed by anaerobic decomposition of plants (swamp gas) and by microbes in termites and certain mammals. May contribute to global warming.

4. Silicon dioxide, SiO_2. Occurs in many amorphous (glassy) and crystalline forms, quartz being the most common. Used to make glass and as an inert chromatography support material.

5. Silicon carbide, SiC. Known as *carborundum*, a major industrial abrasive and a highly refractory ceramic for tough, high-temperature uses. Can be doped to form a high-temperature semiconductor.

6. Organotin compounds, R_4Sn. Used to stabilize PVC, or poly(vinyl chloride), plastics (*see photo*) and to cure silicone rubbers. Agricultural biocide for insects, fungi, and weeds.



7. Tetraethyl lead, $(C_2H_5)_4Pb$. Once used as a gasoline additive to improve fuel efficiency, but now banned because of its inactivation of auto catalytic converters. Major source of lead as a toxic air pollutant.

How Does the Type of Bonding Change in Group 4A(14) Compounds?

The Group 4A(14) elements display a wide range of chemical behavior, from the covalent compounds of carbon to the ionic compounds of lead. Carbon's intermediate EN of 2.5 ensures that it virtually always forms covalent bonds, but the larger members of the group form bonds with increasing ionic character. With nonmetals, Si and Ge form strong polar covalent bonds, such as the Si—O bond, one of the strongest of any Period 3 element (BE = 368 kJ/mol). This bond is responsible for the physical and chemical stability of Earth's solid surface, as we discuss later in this section. Although individual Sn or Pb ions rarely exist, the bonding of either element with a nonmetal has considerable ionic character.

The pattern of elements with more than one oxidation state that we observed in Group 3A(13) also appears here. After Si, the shift to greater importance of the lower oxidation state occurs: compounds with Si in the +4 state are much more stable than those with Si in the +2 state, whereas compounds with Pb in the +2 state are more stable than those with Pb in the +4 state. The elements also behave more like metals in the lower oxidation state. Consider the chlorides and oxides of Sn and Pb. The +2 chlorides $SnCl_2$ and $PbCl_2$ are white, relatively high-melting, water-soluble crystals—typical properties of a salt (Figure 14.14). In contrast, $SnCl_4$ is a volatile, benzene-soluble liquid, and $PbCl_4$ is a thermally unstable oil. Both likely consist of individual, tetrahedral molecules. The +2 oxides SnO and PbO are more basic than the +4 oxides SnO_2 and PbO_2: because the +2 metals are less able to polarize the O^{2-} ion, the E-to-O bonding is more ionic.

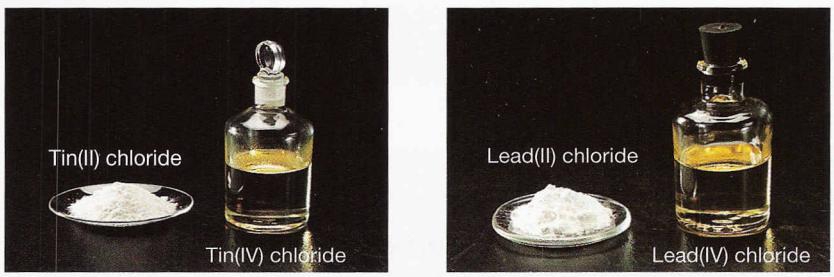


Figure 14.14 The greater metallic character of tin and lead in the lower oxidation state. Metals with more than one oxidation state exhibit more metallic behavior in the lower state. Tin(II) and lead(II) chlorides are white, crystalline, saltlike solids. In contrast, tin(IV) and lead(IV) chlorides are volatile liquids, indicating the presence of individual molecules.

Highlights of Carbon Chemistry

Like the other Period 2 elements, carbon is an anomaly in its group; indeed, it may be an anomaly in the entire periodic table. Carbon forms bonds with the smaller Group 1A(1) and 2A(2) metals, many transition metals, the halogens, and its neighbors B, Si, N, O, P, and S. It also exhibits every oxidation state possible for its group, from +4 in CO_2 and halides like CCl_4 through −4 in CH_4.

Two features stand out in the chemistry of carbon: its ability to bond to itself to form chains, a process known as *catenation*, and its ability to form multiple bonds. As a result of its small size and its capacity for four bonds, carbon can form chains, branches, and rings that lead to myriad structures. Add a lot of H, some O and N, a bit of S, P, halogens, and a few metals, and you have the whole organic world! Figure 14.15 shows three of the several million organic compounds known. Multiple bonds are common in carbon structures because the C—C bond is short enough for side-to-side overlap of two half-filled $2p$ orbitals to form π bonds. (In Chapter 15, we discuss in detail how the atomic properties of carbon give rise to the diverse structures and reactivities of organic compounds.)

Because the other 4A members are larger, E—E bonds become longer and weaker down the group; thus, in terms of bond strength, C—C > Si—Si > Ge—Ge. The empty d orbitals of these larger atoms make the chains much more

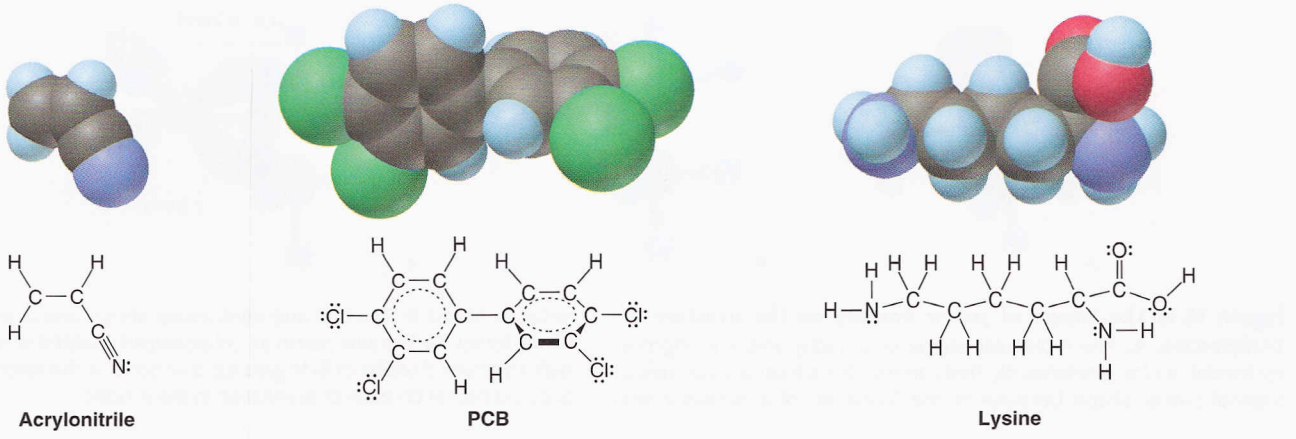

Figure 14.15 Three of the several million known organic compounds of carbon. Acrylonitrile, a precursor of acrylic fibers. PCB (one of the polychlorinated biphenyls). Lysine, one of about 20 amino acids that occur in proteins.

susceptible to chemical attack. Thus, some compounds with long Si chains are known but they are very reactive, and the longest Ge chain has only eight atoms. Moreover, longer bonds do not typically allow sufficient overlap of *p* orbitals for π bonding. Only very recently have compounds with π bonds between Si atoms or between Ge atoms been prepared, and they are also extremely reactive.

In contrast to its organic compounds, carbon's inorganic compounds are simple. Metal carbonates are the main mineral form. Marble, limestone, chalk, coral, and several other types are found in enormous deposits throughout the world. Many of these compounds are remnants of fossilized marine organisms. Carbonates are used in several common antacids because they react with the HCl in stomach acid [see the Group 2A(2) Family Portrait, compound 4, p. 565]:

$$CaCO_3(s) + 2HCl(aq) \longrightarrow CaCl_2(aq) + CO_2(g) + H_2O(l)$$

Identical net ionic reactions with sulfuric and nitric acids protect lakes bounded by limestone deposits from the harmful effects of acid rain.

Unlike the other 4A members, which form only solid network-covalent or ionic oxides, carbon forms two common gaseous oxides, CO_2 and CO. Carbon dioxide is essential to all life: it is the primary source of carbon in plants and animals through photosynthesis. Its aqueous solution is the cause of acidity in natural waters. However, its atmospheric buildup from deforestation and excessive use of fossil fuels may severely affect the global climate. Carbon monoxide forms when carbon or its compounds burn in an inadequate supply of O_2:

$$2C(s) + O_2(g) \longrightarrow 2CO(g)$$

Carbon monoxide is a key component of syngas fuels (see Chemical Connections, p. 245) and is widely used in the production of methanol, formaldehyde, and other major industrial compounds.

CO binds strongly to many transition metals. When inhaled in cigarette smoke or polluted air, it enters the blood and binds strongly to the Fe(II) in hemoglobin, preventing the normal binding of O_2, and to other iron-containing proteins. The cyanide ion (CN^-) is *isoelectronic* with CO:

$$[:C{\equiv}N:]^- \quad \text{same electronic structure as} \quad :C{\equiv}O:$$

Cyanide binds to many of the same iron-containing proteins and is also toxic.

Monocarbon halides (or halomethanes) are tetrahedral molecules whose stability to heat and light decreases as the size of the halogen atom increases and the C—X bond becomes longer (weaker) (see the Interchapter, Topic 2). The chlorofluorocarbons (CFCs, or Freons) have important industrial uses; their short, strong carbon-halogen bonds are exceptionally stable, however, and the environmental persistence of these compounds has created major problems.

CFCs: The Good, the Bad, and the Strong The strengths of the C—F and C—Cl bonds make CFCs, such as Freon-12, shown here, both useful and harmful. Chemically and thermally stable, nontoxic, and nonflammable, they are excellent cleaners for electronic parts, coolants in refrigerators and air conditioners, and propellants in aerosol cans. However, their bond strengths also mean that CFCs decompose *very* slowly near Earth's surface. In the lower atmosphere, they contribute to climate warming, absorbing infrared radiation 16,000 times as effectively as CO_2. Once in the stratosphere, however, they are bombarded by ultraviolet (UV) radiation, which breaks the otherwise stable C—Cl bonds, releasing free Cl atoms that initiate ozone-destroying reactions (Chapter 16). Legal production of CFCs has ended in the United States, but international production and smuggling are widespread.

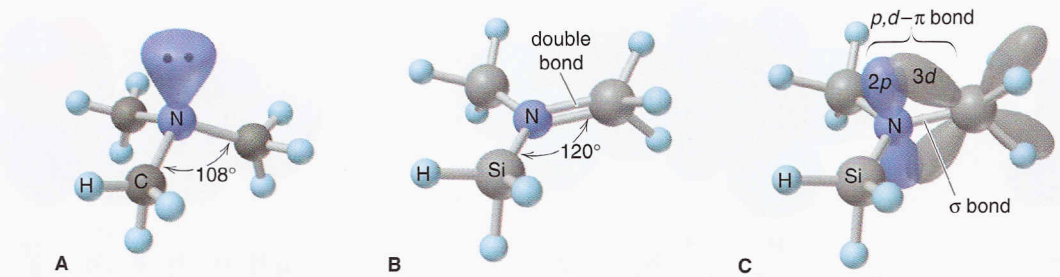

Figure 14.16 The impact of *p,d*–π bonding on the structure of trisilylamine. A, The molecular shape of trimethylamine is trigonal *pyramidal*, as for ammonia. **B,** Trisilylamine, the silicon analog, has a trigonal *planar* shape because of the formation of a double bond between N and Si. The ball-and-stick model shows one of three resonance forms. **C,** The lone pair in an unhybridized *p* orbital of N overlaps with an empty *d* orbital of Si to give a *p,d*–π bond. In the resonance hybrid, a *d* orbital on each Si is involved in the π bond.

Highlights of Silicon Chemistry

Silicon halides are more reactive than carbon halides because Si has empty *d* orbitals that are available for bond formation. Surprisingly, the silicon halides have longer yet *stronger* bonds than the corresponding carbon halides (see Tables 9.2 and 9.3, pp. 341 and 342). One explanation for this unusual strength is that the Si—X bond has some double-bond character because of the presence of a σ bond *and* a different type of π bond, called a *p,d–π bond*. This bond arises from side-to-side overlap of an Si *d* orbital and a halogen *p* orbital. A similar type of *p,d*–π bonding leads to the trigonal planar molecular shape of trisilylamine, in contrast to the trigonal pyramidal shape of trimethylamine (Figure 14.16).

To a great extent, the chemistry of silicon is the chemistry of the *silicon-oxygen bond*. Just as carbon forms unending C—C chains, the —Si—O— grouping repeats itself endlessly in a wide variety of **silicates,** the most important minerals on the planet, and in **silicones,** synthetic polymers that have many applications:

1. *Silicate minerals.* From common sand and clay to semiprecious amethyst and carnelian, silicate minerals are the dominant form of matter in the nonliving world. Oxygen, the most abundant element on Earth, and silicon, the next most abundant, compose these minerals and thus account for four of every five atoms on the surface of the planet!

The silicate building unit is the *orthosilicate* grouping, $—SiO_4—$, a tetrahedral arrangement of four oxygens around a central silicon. Several well-known minerals contain SiO_4^{4-} ions or small groups of them linked together. The gemstone zircon ($ZrSiO_4$) contains one unit; hemimorphite [$Zn_4(OH)_2Si_2O_7 \cdot H_2O$] contains two units linked through an oxygen corner; and beryl ($Be_3Al_2Si_6O_{18}$), the major source of beryllium, contains six units joined into a cyclic ion (Figure 14.17). As you'll see shortly, in addition to these separate ions, SiO_4 units are linked more extensively to create much of the planet's mineral structure.

2. *Silicone polymers.* Unlike the naturally occurring silicates, silicone polymers are manufactured substances, consisting of alternating Si and O atoms with two organic groups also bonded to each Si atom. A key starting material is formed by the reaction of silicon with methyl chloride:

$$Si(s) + 2CH_3Cl(g) \xrightarrow[\sim 300°C]{\text{Cu catalyst}} (CH_3)_2SiCl_2(g)$$

Although the corresponding carbon compound [$(CH_3)_2CCl_2$] is inert in water, the empty *d* orbitals of Si make $(CH_3)_2SiCl_2$ reactive:

$$(CH_3)_2SiCl_2(l) + 2H_2O(l) \longrightarrow (CH_3)_2Si(OH)_2(l) + 2HCl(g)$$

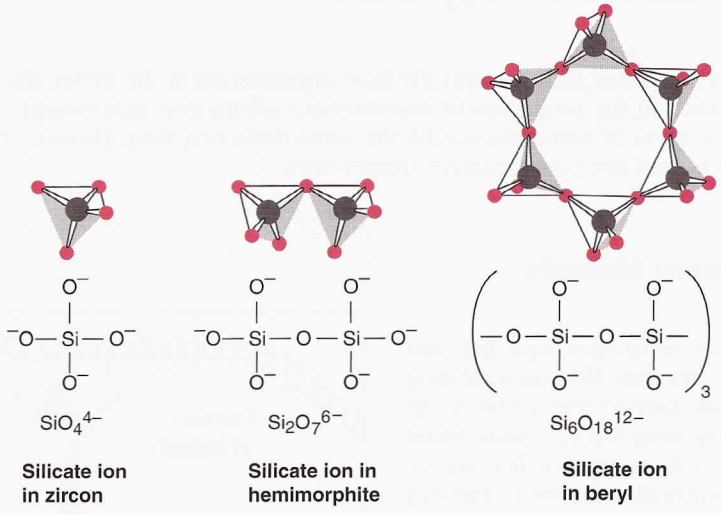

Figure 14.17 Structures of the silicate anions in some minerals.

The product reacts with itself to form water and a silicone chain molecule called a *poly(dimethyl siloxane):*

$$n(CH_3)_2Si(OH)_2 \longrightarrow \left[-O-Si(CH_3)_2-\right]_n + nH_2O$$

Silicones have properties of both plastics and minerals. The organic groups give them the flexibility and weak intermolecular forces between chains that are characteristic of a plastic, while the O—Si—O backbone confers the thermal stability and nonflammability of a mineral. In the Gallery on the following pages, note the structural parallels between silicates and silicones.

Diagonal Relationships: Boron and Silicon

The final diagonal relationship that we consider occurs between the metalloids boron and silicon. Both of these elements exhibit the electrical properties of a semiconductor (Section 12.6). Both B and Si and their mineral oxoanions—borates and silicates—occur in extended covalent networks. Both boric acid [$B(OH)_3$] and silicic acid [$Si(OH)_4$] are weakly acidic solids that occur as layers held together by widespread H bonding. Their hydrides—the compact boranes and the extended silanes—are both flammable, low-melting compounds that act as reducing agents.

Looking Backward and Forward: Groups 3A(13), 4A(14), and 5A(15)

Standing in Group 4A(14), we look back at Group 3A(13) as the transition from the *s* block of metals to the *p* block of mostly metalloids and nonmetals (Figure 14.18). Major changes in physical behavior occur moving across a period from metals to covalent networks. Changes in chemical behavior occur as well, as cations give way to covalent tetrahedra. Looking ahead to Group 5A(15), we note the more frequent occurrence of covalent bonding and (as electronegativity increases) the expanded valence shells of nonmetals, as well as the first appearance of monatomic anions.

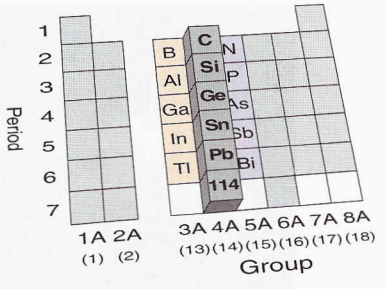

Figure 14.18 Standing in Group 4A(14), looking backward to 3A(13) and forward to 5A(15).

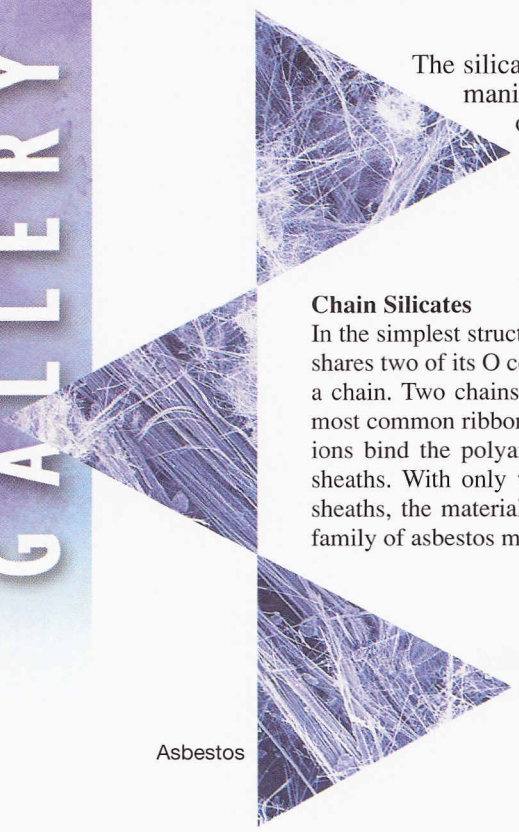
GALLERY

Silicate Minerals and Silicone Polymers

The silicates and silicones show beautifully how organization at the molecular level manifests itself in the properties of macroscopic substances. Interestingly, both of these types of materials exhibit the same three structural classes: chains, sheets, and three-dimensional frameworks.

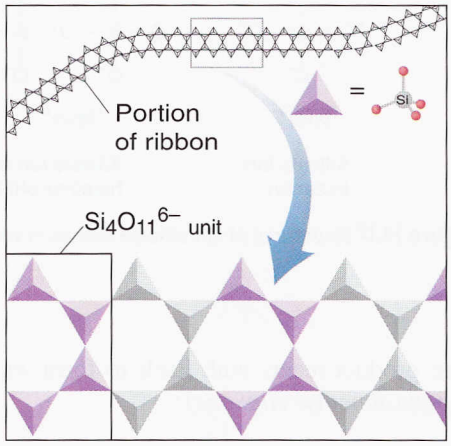


Asbestos

Silicate Minerals

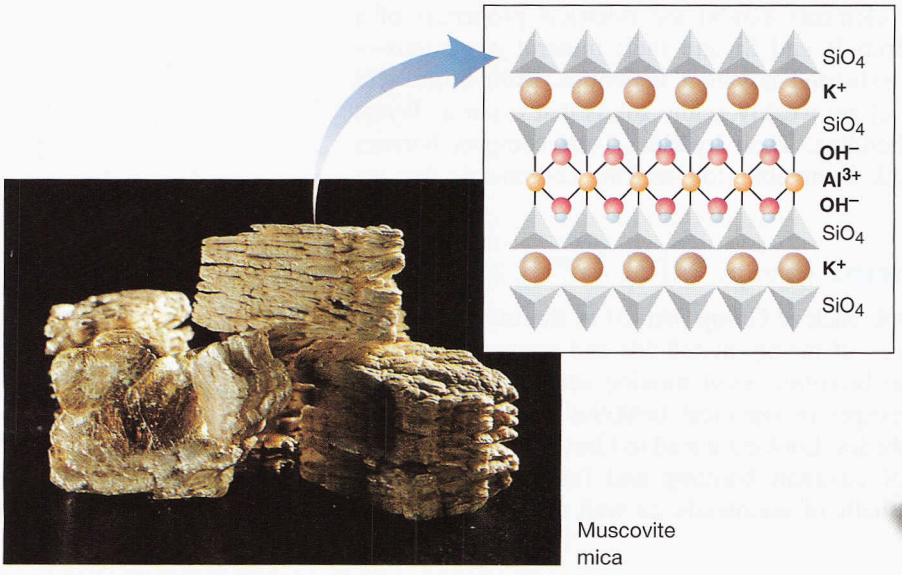
Chain Silicates

In the simplest structural class of silicates, each SiO_4 unit shares two of its O corners with other SiO_4 units, forming a chain. Two chains can link laterally into a ribbon; the most common ribbon has repeating $Si_4O_{11}^{6-}$ units. Metal ions bind the polyanionic ribbons together into neutral sheaths. With only weak intermolecular forces between sheaths, the material occurs in fibrous strands, as in the family of asbestos minerals.



Sheet (Layer) Silicates

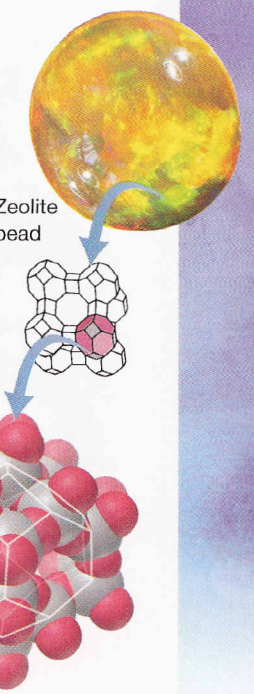
In the next structural class of silicates, each SiO_4 unit shares three of its four O corners with other SiO_4 units to form a sheet; double sheets arise when the fourth O is shared with another sheet. In talc, the softest mineral, the sheets interact through weak forces, so talcum powder feels slippery. If Al substitutes for some Si, or if $Al(OH)_3$ layers interleave with silicate sheets, an aluminosilicate results, such as the clay kaolinite. Different substitutions for Si and/or interlayers of other ions give the micas. In muscovite mica, ions lie between aluminosilicate double layers. Mica flakes when the ionic attractions are overcome.

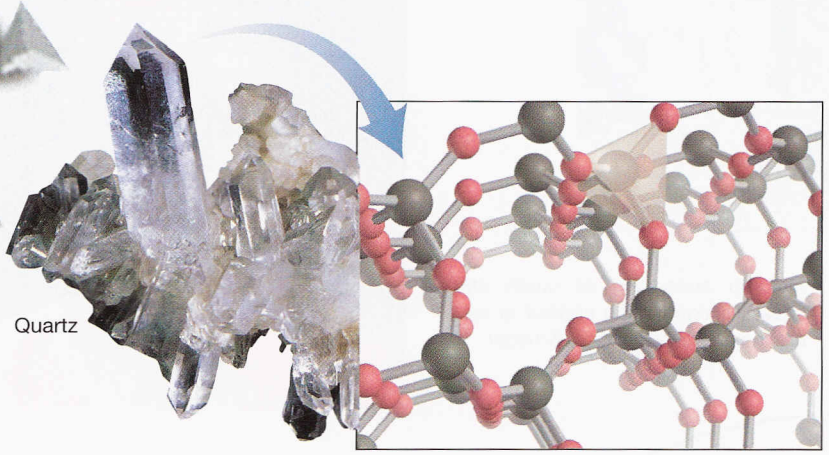


Muscovite
mica

Framework Silicates

In the final structural class of silicates, SiO_4 units share all four O corners to give a three-dimensional framework silicate, such as silica (SiO_2), which occurs most often as α-quartz. Some of silica's 12 crystalline forms exist as semiprecious gems. Feldspars, which comprise 60% of Earth's crust, result when some Si in a framework silicate is replaced by Al; granite consists of microcrystals of feldspar, mica, and quartz. Eons of weathering convert feldspars into clays. Zeolites have open frameworks of polyhedra that give rise to minute tunnels. Synthetic zeolites are made with cavities of specific sizes to trap particular molecules; they are used to dry gas mixtures, separate hydrocarbons, and prepare catalysts.

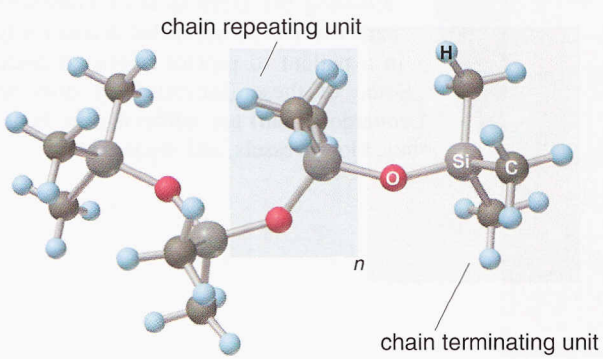




Silicone Polymers

Polymer Chemistry

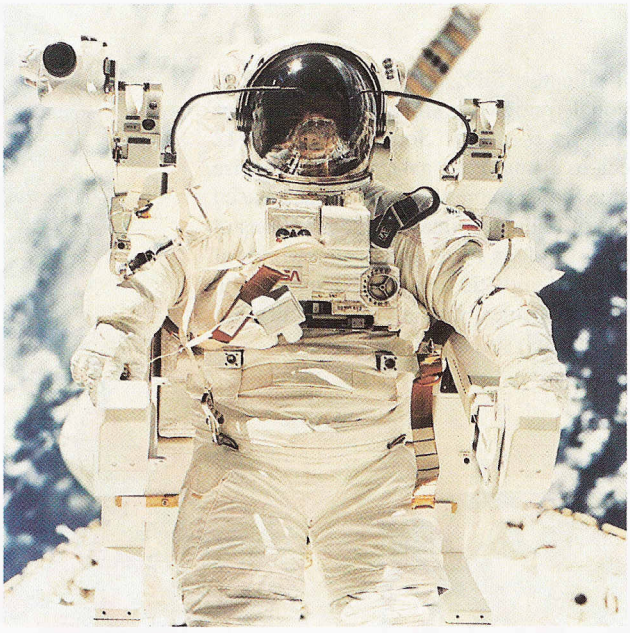
The design, synthesis, and production of polymers form one of the largest branches of modern chemical science. Nearly half of all industrial chemists and chemical engineers are involved in this pursuit. A major branch of polymer chemistry is devoted to exploring the properties and countless uses of silicones.



Chain Silicones: Oils and Greases

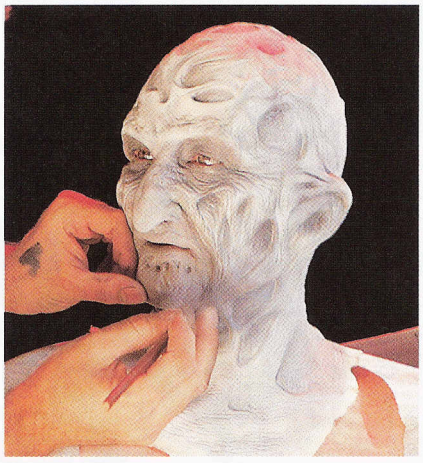
The simplest structural class of silicones consists of the poly(dimethyl siloxane) chain, in which each $(CH_3)_2Si(OH)_2$ unit uses both OH groups to link to two others. A chain-terminating compound with a third organic group, such as $(CH_3)_3SiOH$, is added to control chain length. These polymers are unreactive, oily liquids with high viscosity and low surface tension. They are used as hydraulic oils and lubricants, as antifoaming agents for frying potato chips, and as components of suntan oil, car polish, digestive aids, and makeup.

(continued)

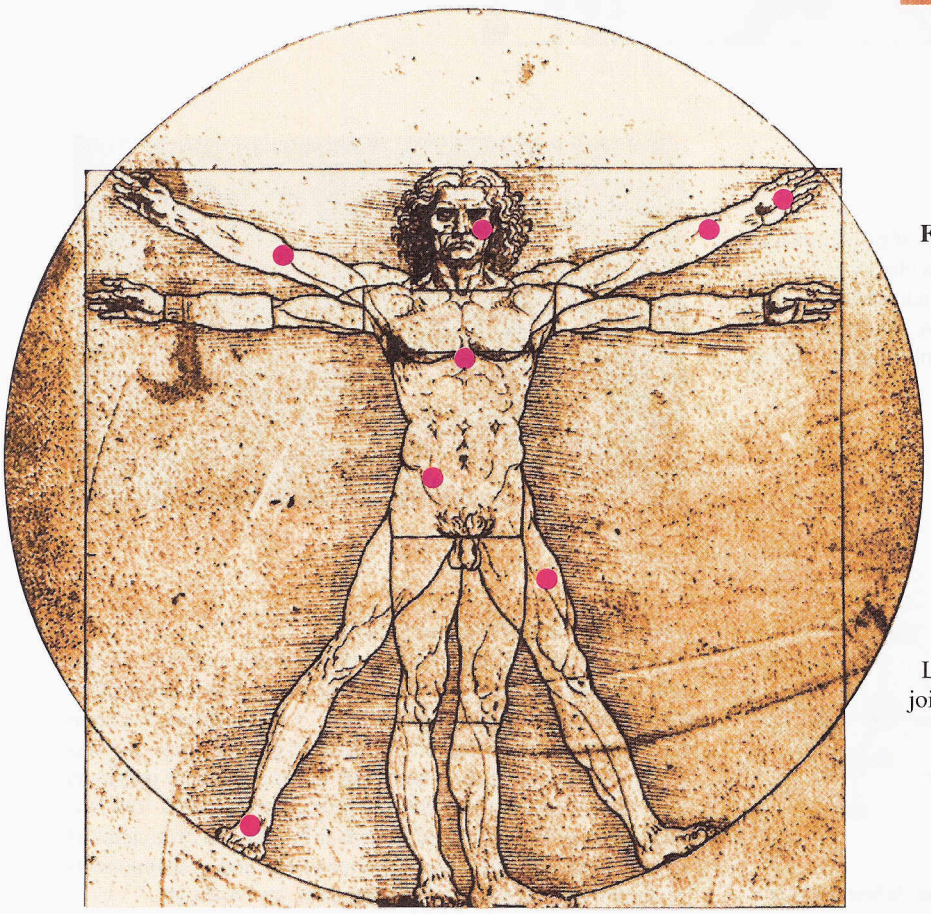


Sheet Silicones: Elastomers

In the next class of silicones, the third OH group of an added bridging compound, such as $CH_3Si(OH)_3$, reacts to condense chains laterally into gummy sheets that are made into elastomers (rubbers), which are flexible, elastic, and stable from −100°C to 250°C. These are used in gaskets, rollers, cable insulation, space suits, contact lenses, and dentures.



Makeup consisting of chain and sheet silicones being applied to create the character Freddie Krueger



Framework Silicones: Resins

In the final structural class of silicones, reactions that free OH groups, while substituting larger organic groups for some CH_3 groups, interlink sheets to produce strong, thermally stable resins. These are used as insulating laminates on printed circuit boards and as nonstick coatings on cookware. Sheet and framework silicones have revolutionized modern surgical practice by allowing the fabrication of numerous parts that can be implanted permanently in a patient to replace damaged ones. Some of these (indicated by dots on Leonardo's man) are artificial skin, bone, joints, blood vessels, and organ parts.

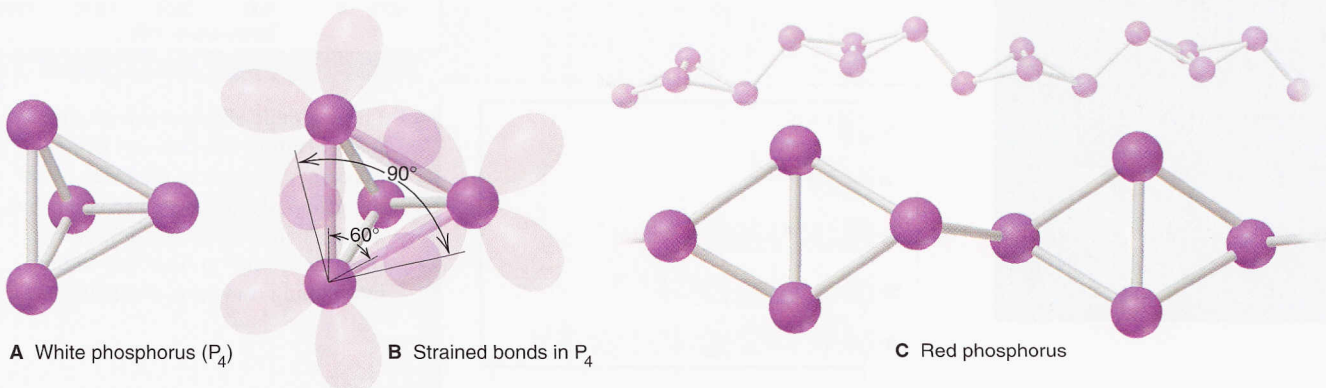
14.7 GROUP 5A(15): THE NITROGEN FAMILY

The first two elements of Group 5A(15), gaseous nonmetallic nitrogen (N) and solid nonmetallic phosphorus (P), will occupy most of our attention. The industrial and environmental significance of their compounds is matched only by their importance in the structures and functions of biomolecules. Below these nonmetals are two metalloids, arsenic (As) and antimony (Sb), followed by the sole metal, bismuth (Bi), the last nonradioactive element in the periodic table. The Group 5A(15) Family Portrait (pp. 584 and 585) provides an overview.

What Accounts for the Wide Range of Physical Behavior in Group 5A(15)?

Group 5A(15) displays the widest range of physical behavior we've seen so far because of large changes in bonding and intermolecular forces. Nitrogen occurs as a gas consisting of N_2 molecules, which interact through such weak dispersion forces that the element *boils* more than 200°C below room temperature. Elemental phosphorus exists most commonly as tetrahedral P_4 molecules. However, because P is heavier and more polarizable than N, stronger dispersion forces are present, and the element melts about 25°C above room temperature. Arsenic consists of extended, puckered sheets in which each As atom is covalently bonded to three others and forms nonbonding interactions with three nearest neighbors in adjacent sheets. This arrangement gives As the highest melting point in the group. A similar covalent network for Sb gives it a much higher melting point than the next member of the group, Bi, which has metallic bonding.

Phosphorus has several allotropes. The white and red forms have very different properties because of the way the atoms are linked. The highly reactive white form is prepared as a gas and condensed to a whitish, waxy solid under cold water to prevent it from igniting in air. It consists of tetrahedral molecules of four P atoms bonded *to each other,* with no atom in the center (Figure 14.19A). Each P atom uses its half-filled 3*p* orbitals to bond to the other three. Whereas the 3*p* orbitals of an isolated P atom lie 90° apart, the bond angles in P_4 are 60°. With the smaller angle comes poor orbital overlap and a P—P bond strength only about 80% that of a normal P—P bond (Figure 14.19B). Weaker bonds break more easily, contributing to the white allotrope's high reactivity. Heating the white form in the absence of air breaks one of the P—P bonds in each tetrahedron, and those 3*p* orbitals overlap with others to form the chains of P_4 units that make up the red form (Figure 14.19C). The individual molecules of white P make it highly reactive, low melting (44.1°C), and soluble in nonpolar solvents; the chains of red P make it much less reactive, high melting (~600°C), and insoluble.



A White phosphorus (P_4) B Strained bonds in P_4 C Red phosphorus

Figure 14.19 Two allotropes of phosphorus. A, White phosphorus exists as individual P_4 molecules, with the P—P bonds forming the edges of a tetrahedron. **B,** The reactivity of P_4 is due in part to the bond strain that arises from the 60° bond angle. Note how overlap of the 3*p* orbitals is decreased because they do not meet directly end to end (overlap is shown here for only three of the P—P bonds), which makes the bonds easier to break. **C,** In red phosphorus, one of the P—P bonds of the white form has broken and links the P_4 units together into long chains. Lone pairs (not shown) reside in *s* orbitals in both allotropes.

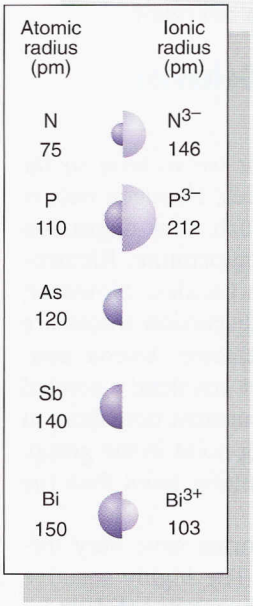
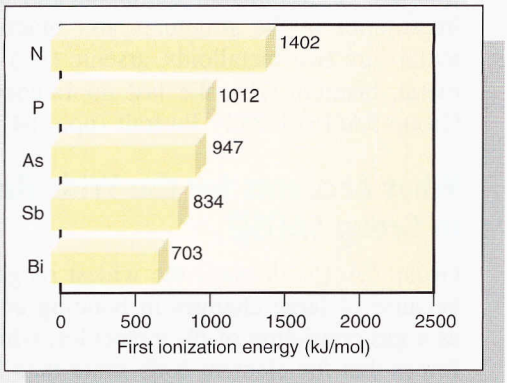
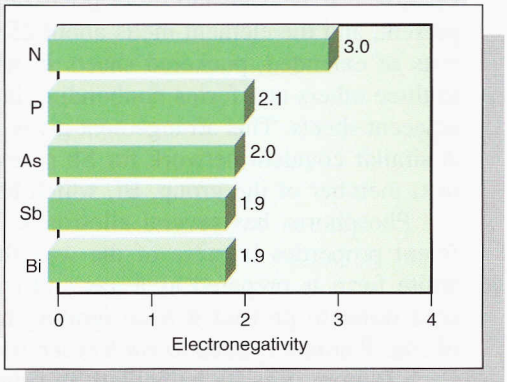
Atomic Properties



Group electron configuration is ns^2np^3. The *np* sublevel is half-filled, with each *p* orbital containing one electron. The number of oxidation states decreases down the group, and the lower (+3) state becomes more common.

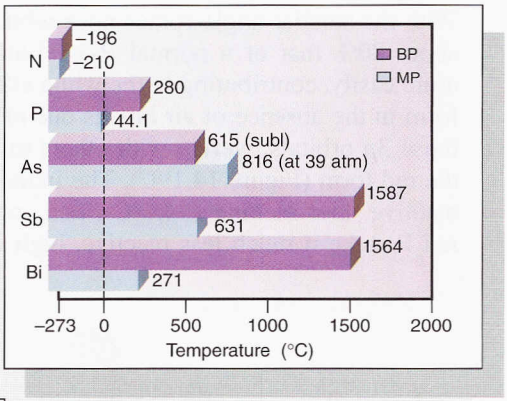
Atomic properties follow generally expected trends. The large (~50%) increase in size from N to P correlates with the much lower IE and EN of P.

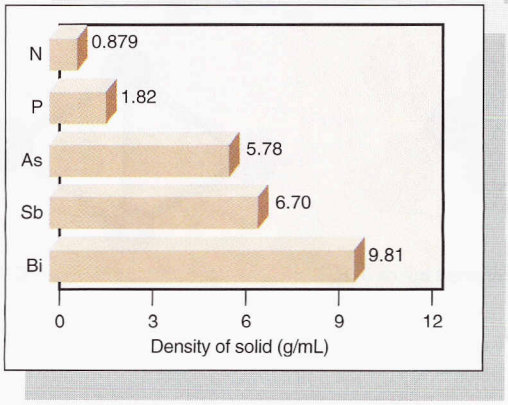




Physical Properties

Physical properties reflect the change from individual molecules (N, P) to network covalent solid (As, Sb) to metal (Bi). Thus, melting points increase and then decrease.





Large atomic size and low atomic mass result in low density. Because mass increases more than size down the group, the density of the elements as solids increases. The dramatic increase from P to As is due to the intervening transition elements.

Some Reactions and Compounds

Important Reactions

General group behavior is shown in reactions 1 to 3, whereas phosphorus chemistry is the theme in reactions 4 and 5.

1. Nitrogen is "fixed" industrially in the Haber process:

$$N_2(g) + 3H_2(g) \rightleftharpoons 2NH_3(g)$$

Further reactions convert NH_3 to NO, NO_2, and HNO_3 (*Highlights of Nitrogen Chemistry*). Hydrides of some other group members are formed from reaction in water (or with H_3O^+) of a metal phosphide, arsenide, and so forth:

$$Ca_3P_2(s) + 6H_2O(l) \longrightarrow 2PH_3(g) + 3Ca(OH)_2(aq)$$

2. Halides are formed by direct combination of the elements:

$$2E(s) + 3X_2 \longrightarrow 2EX_3 \quad (E = \text{all except N})$$

$$EX_3 + X_2 \longrightarrow EX_5 \quad (E = \text{all except N and Bi with X = F and Cl, but no } BiCl_5;\ E = P \text{ for } X = Br)$$

3. Oxoacids are formed from the halides in a reaction with water that is common to many nonmetal halides:

$$EX_3 + 3H_2O(l) \longrightarrow H_3EO_3(aq) + 3HX(aq) \quad (E = \text{all except N})$$

$$EX_5 + 4H_2O(l) \longrightarrow H_3EO_4(aq) + 5HX(aq) \quad (E = \text{all except N and Bi})$$

Note that the oxidation number of E does *not* change.

4. Phosphate ions are dehydrated to form polyphosphates:

$$3NaH_2PO_4(s) \longrightarrow Na_3P_3O_9(s) + 3H_2O(g)$$

5. When P_4 reacts in basic solution, its oxidation number both decreases *and* increases (disproportionation):

$$P_4(s) + 3OH^-(aq) + 3H_2O(l) \longrightarrow PH_3(g) + 3H_2PO_2^-(aq)$$

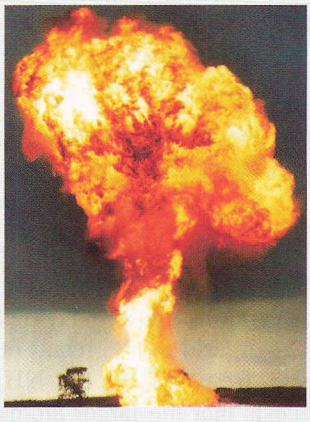
Analogous reactions are typical of many nonmetals, such as S_8 and X_2 (halogens).

Important Compounds

1. Ammonia, NH_3. First substance formed when atmospheric N_2 is used to make N-containing compounds. Annual multimillion-ton production for use in fertilizers, explosives, rayon, and polymers such as nylon, urea-formaldehyde resins, and acrylics.

2. Hydrazine, N_2H_4 (*margin note, p. 586*).

3. Nitric oxide (NO), nitrogen dioxide (NO_2), and nitric acid (HNO_3). Oxides are intermediates in HNO_3 production. This acid is used in fertilizer manufacture, nylon production, metal etching, and the explosives industry (*Highlights of Nitrogen Chemistry*).



Detonation of explosives

4. Amino acids, $H_3N^+—CH(R)—COO^-$ (R = one of 20 different organic groups). Occur in every organism, both free and linked together into proteins. Essential to the growth and function of all cells. Synthetic amino acids are used as dietary supplements.

5. Phosphorus trichloride, PCl_3. Used to form many organic phosphorus compounds, including oil and fuel additives, plasticizers, flame retardants, and insecticides. Also used to make PCl_5, $POCl_3$, and other important P-containing compounds.

6. Tetraphosphorus decaoxide (P_4O_{10}) and phosphoric acid (H_3PO_4) (*Highlights of Phosphorus Chemistry*).

7. Sodium tripolyphosphate, $Na_5P_3O_{10}$. As a water-softening agent (Calgon), it combines with hard-water Mg^{2+} and Ca^{2+} ions, preventing them from reacting with soap anions, and thus improving cleaning action. Its use has been curtailed in the United States because it pollutes lakes and streams by causing excessive algal growth (*see photo*).

Algal growth in polluted lake

8. Adenosine triphosphate (ATP) and other biophosphates. ATP acts to transfer chemical energy in the cell; it is necessary for all biological processes requiring energy. Phosphate groups also occur in sugars, fats, proteins, and nucleic acids.

9. Bismuth subsalicylate, $BiO(C_7H_5O_3)$. The active ingredient in Pepto-Bismol (*see photo*), a widely used remedy for diarrhea and nausea. (The pink color is not due to this white compound.)

What Patterns Appear in the Chemical Behavior of Group 5A(15)?

The same general pattern of chemical behavior that we discussed for Group 4A(14) appears again in this group, reflected in the change from nonmetallic N to metallic Bi. The overwhelming majority of Group 5A(15) compounds have *covalent bonds*. Whereas N can form no more than four bonds, the next three members can expand their valence shells by using empty *d* orbitals.

For a 5A element to form an ion with a noble gas electron configuration, it must *gain* three electrons, the last two in endothermic steps. Nevertheless, the enormous lattice energy released when such highly charged anions attract cations drives their formation. However, the 3− anion of N occurs only in compounds with active metals, such as Li_3N and Mg_3N_2 (and that of P may occur in Na_3P). Metallic Bi forms mostly covalent compounds but exists as a cation in a few compounds, such as BiF_3 and $Bi(NO_3)_3{\cdot}5H_2O$, through *loss* of its three valence *p* electrons.

Again, as we move down this group, we see the patterns first seen in Groups 3A and 4A. Fewer oxidation states occur, with the lower state becoming more prominent: N exhibits every state possible for a 5A element, from +5 to −3; only the +5 and +3 states are common for P, As, and Sb; and +3 is the only common state of Bi. The oxides change from acidic to amphoteric to basic, reflecting the increase in the metallic character of the elements. In addition, the lower oxide of an element is more basic than the higher oxide, reflecting the greater ionic character of the E-to-O bonding in the lower oxide.

All the Group 5A(15) elements form gaseous hydrides of formula EH_3. Except for NH_3, these are extremely reactive and poisonous and are synthesized by reaction of a metal phosphide, arsenide, and so forth, which acts as a strong base in water or aqueous acid. For example,

$$Ca_3As_2(s) + 6H_2O(l) \longrightarrow 2AsH_3(g) + 3Ca(OH)_2(aq)$$

Ammonia is made industrially by direct combination of the elements at high pressure and moderately high temperature:

$$N_2(g) + 3H_2(g) \rightleftharpoons 2NH_3(g)$$

Molecular properties of the Group 5A(15) hydrides reveal some interesting bonding and structural patterns:

- Despite its much lower molar mass, NH_3 melts and boils at higher temperatures than the other 5A hydrides as a result of *H bonding*.
- Bond angles decrease from 107.3° for NH_3 to around 90° for the other hydrides, which suggests that the larger atoms use unhybridized *p* orbitals.
- E—H bond lengths increase down the group, so bond strength and thermal stability decrease: AsH_3 decomposes at 250°C, SbH_3 at 20°C, and BiH_3 at −45°C.

We'll see these features—H bonding for the smallest member, change in bond angles, change in bond energies—in the hydrides of Group 6A(16) as well.

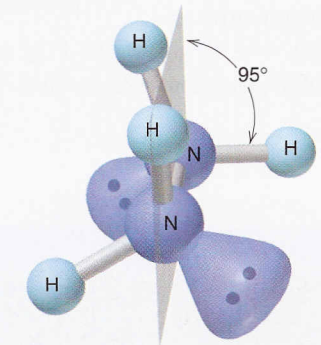
The Group 5A(15) elements all form trihalides (EX_3). All except nitrogen form pentafluorides (EF_5), but only a few other pentahalides (PCl_5, PBr_5, $AsCl_5$, and $SbCl_5$) are known. Nitrogen cannot form pentahalides because it cannot expand its valence shell. Most trihalides are prepared by direct combination:

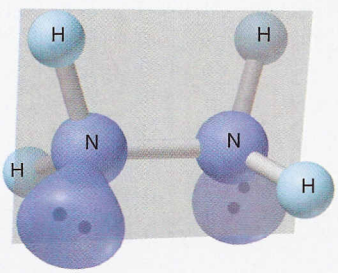
$$P_4(s) + 6Cl_2(g) \longrightarrow 4PCl_3(l)$$

The pentahalides form with excess halogen:

$$PCl_3(l) + Cl_2(g) \longrightarrow PCl_5(s)$$

As with the hydrides, the thermal stability of the halides decreases as the E—X bond becomes longer. Among the nitrogen halides, for example, NF_3 is a stable, rather unreactive gas. NCl_3 is explosive and reacts rapidly with water. (The chemist who first prepared it lost three fingers and an eye!) NBr_3 can only be made below −87°C. NI_3 has never been prepared, but an ammoniated product ($NI_3{\cdot}NH_3$) explodes at the slightest touch.





Hydrazine, Nitrogen's Other Hydride

Aside from NH_3, the most important Group 5A(15) hydride is hydrazine, N_2H_4. Like NH_3, it is a weak base, forming $N_2H_5^+$ and $N_2H_6^{2+}$ ions with acids. Hydrazine is also used to make antituberculin drugs, plant growth regulators, and fungicides, and organic hydrazine derivatives are used in rocket and missile fuels. We might expect the lone pairs in the molecule to lie opposite each other and give a symmetrical structure with no dipole moment. However, repulsions between each lone pair and the bonding pairs on the other atom force the lone pairs to lie below the N—N bond (see model), resulting in a large dipole moment (μ = 1.85 D in the gas phase). A similar arrangement occurs in hydrogen peroxide (H_2O_2), the analogous hydride of oxygen.

In an aqueous reaction pattern *typical of many nonmetal halides,* each 5A halide reacts with water to yield the hydrogen halide and the oxoacid, in which E has the *same* oxidation number as it had in the original halide. For example, PX_5 (O.N. of P = +5) produces phosphoric acid (O.N. of P = +5) and HX:

$$PCl_5(s) + 4H_2O(l) \longrightarrow H_3PO_4(l) + 5HCl(g)$$

Highlights of Nitrogen Chemistry

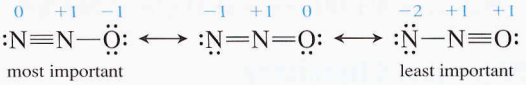
Surely the most striking highlight of nitrogen chemistry is the inertness of N_2 itself. Nearly four-fifths of the atmosphere consists of N_2, and the other fifth is nearly all O_2, a very strong oxidizing agent. Nevertheless, the searing temperature of a lightning bolt is required for significant amounts of atmospheric nitrogen oxides to form. Thus, even though N_2 is inert at moderate temperatures, it reacts at high temperatures with H_2, Li, Group 2A(2) members, B, Al, C, Si, Ge, O_2, and many transition elements. In fact, nearly every element in the periodic table forms bonds to N. Here we focus on the oxides and the oxoacids and their salts.

Nitrogen Oxides Nitrogen is remarkable for having six stable oxides, each with a *positive* heat of formation because of the great strength of the N≡N bond (BE = 945 kJ/mol). Their structures and some properties are shown in Table 14.3. Unlike the hydrides and halides of nitrogen, the oxides are planar. Nitrogen displays all its positive oxidation states in these compounds, and in N_2O and N_2O_3, the two N atoms have different states.

Table 14.3 Structures and Properties of the Nitrogen Oxides

Formula	Name	Space-filling Model	Lewis Structure	Oxidation State of N	ΔH_f^0 (kJ/mol) at 298 K	Comment
N_2O	Dinitrogen monoxide (dinitrogen oxide; nitrous oxide)		:N≡N—Ö:	+1 (0, +2)	82.0	Colorless gas; used as dental anesthetic ("laughing gas") and aerosol propellant
NO	Nitrogen monoxide (nitrogen oxide; nitric oxide)		:N=Ö:	+2	90.3	Colorless, paramagnetic gas; biochemical messenger; air pollutant
N_2O_3	Dinitrogen trioxide			+3 (+2, +4)	83.7	Reddish brown gas (reversibly dissociates to NO and NO_2)
NO_2	Nitrogen dioxide			+4	33.2	Orange-brown, paramagnetic gas formed during HNO_3 manufacture; poisonous air pollutant
N_2O_4	Dinitrogen tetraoxide			+4	9.16	Colorless to yellow liquid (reversibly dissociates to NO_2)
N_2O_5	Dinitrogen pentaoxide			+5	11.3	Colorless, volatile solid consisting of NO_2^+ and NO_3^-; gas consists of N_2O_5 molecules

Dinitrogen monoxide (N_2O; also called dinitrogen oxide or nitrous oxide) is the dental anesthetic "laughing gas" and the propellant in canned whipped cream. It is a linear molecule with an electronic structure best described by three resonance forms (note formal charges; see Problem 10.87):



Nitrogen monoxide (NO; also called nitrogen oxide or nitric oxide) is an odd-electron molecule with a vital biochemical function. In Section 11.3, we used MO theory to explain its bonding. The commercial preparation of NO through the oxidation of ammonia occurs as a first step in the production of nitric acid:

$$4NH_3(g) + 5O_2(g) \longrightarrow 4NO(g) + 6H_2O(g)$$

Nitrogen monoxide is also produced whenever air is heated to high temperatures, as in a car engine or a lightning storm:

$$N_2(g) + O_2(g) \xrightarrow{\text{high } T} 2NO(g)$$

Heating converts NO to two other oxides:

$$3NO(g) \xrightarrow{\Delta} N_2O(g) + NO_2(g)$$

This type of redox reaction is called a **disproportionation.** It occurs when a substance *acts as both an oxidizing and a reducing agent in a reaction.* In the process, an atom with an intermediate oxidation state in the reactant occurs in the products in both lower and higher states: the oxidation state of N in NO (+2) is intermediate between that in N_2O (+1) and that in NO_2 (+4).

Nitrogen dioxide (NO_2), a brown poisonous gas, forms to a small extent when NO reacts with additional oxygen:

$$2NO(g) + O_2(g) \rightleftharpoons 2NO_2(g)$$

Like NO, NO_2 is also an odd-electron molecule, but the electron is more localized on the N atom. Thus, NO_2 dimerizes reversibly to dinitrogen tetraoxide:

$$O_2N\cdot(g) + \cdot NO_2(g) \rightleftharpoons O_2N{-}NO_2(g) \quad (\text{or } N_2O_4)$$

Thunderstorms form NO and NO_2 and carry them down to the soil, where they act as natural fertilizers. In urban traffic, however, their formation leads to *photochemical smog* (Figure 14.20). During the morning commute, NO forms in car and truck (especially diesel) engines. It is then oxidized to NO_2 by free radicals ($RO_2\cdot$), which form by oxidation of unburned hydrocarbons in gasoline fumes. As the Sun climbs later in the day, radiant energy breaks down some NO_2:

$$NO_2(g) \xrightarrow{\text{sunlight}} NO(g) + O(g)$$

The O atoms collide with O_2 molecules and form ozone, O_3, a powerful oxidizing agent that damages synthetic rubber, plastics, and plant and animal tissue:

$$O_2(g) + O(g) \longrightarrow O_3(g)$$

A complex series of reactions involving NO, NO_2, O_3, unburned gasoline, and various free-radical species forms ***peroxyacylnitrates*** (PANs), a group of potent nose and eye irritants. The outcome of this fascinating atmospheric chemistry is choking, brown smog.

Nitrogen Oxoacids and Oxoanions The two common nitrogen oxoacids are nitric acid and nitrous acid (Figure 14.21). The first two steps in the *Ostwald process* for the production of nitric acid—the oxidations of NH_3 to NO and of NO to NO_2—have been shown. The final step is a disproportionation, as the oxidation numbers show:

$$\overset{+4}{3NO_2(g)} + H_2O(l) \longrightarrow \overset{+5}{2HNO_3(aq)} + \overset{+2}{NO(g)}$$

The NO is recycled to make more NO_2.

Nitric Oxide: A Biochemical Surprise
The tiny inorganic free radical NO is a remarkable player in an enormous range of biochemical systems. NO is biosynthesized in animal species from barnacles to humans. In the late 1980s and early 1990s, it was shown to play various roles in neurotransmission, blood clotting, blood pressure, and the destruction of cancer cells. The list of effects is now much longer and includes the harmful and beneficial ones of the NO-derived species NO_2, N_2O_3, $ONOO^-$, and HNO. Living systems are full of surprises!

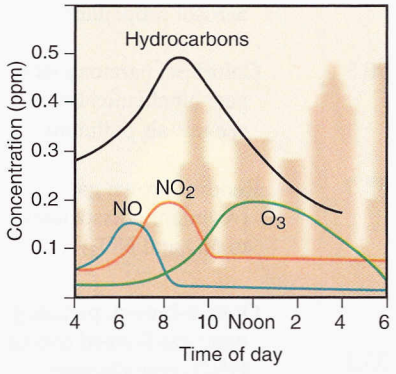


Figure 14.20 The formation of photochemical smog. Localized atmospheric concentrations of the precursor components of smog change during the day. In early morning traffic, exhaust from motor vehicles raises NO and hydrocarbon levels, followed by increases in NO_2 as NO is oxidized by free radicals. Ozone peaks later, as NO_2 breaks down in stronger sunlight and releases O atoms that react with O_2. By midafternoon, all the components for the production of peroxyacylnitrates (PANs) are present, and photochemical smog results.

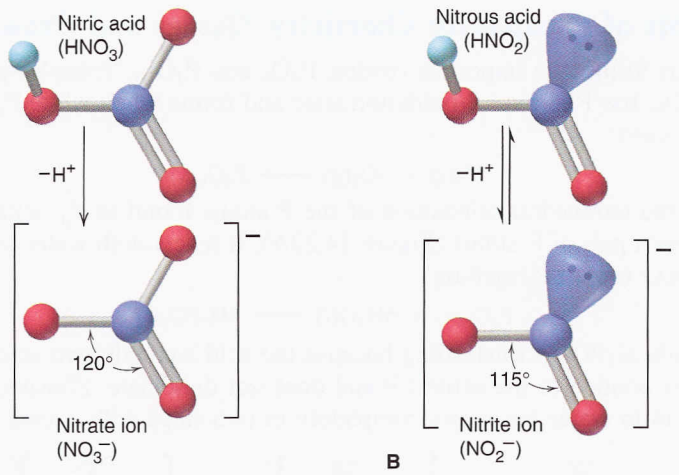

Figure 14.21 The structures of nitric and nitrous acids and their oxoanions. A, Nitric acid loses a proton (H^+) to form the trigonal planar nitrate ion (one of three resonance forms is shown). **B,** Nitrous acid, a much weaker acid, forms the planar nitrite ion (one of two resonance forms is shown). Note the effect of nitrogen's lone pair (the lone pairs of the oxygens are not shown) in reducing the ideal 120° bond angle to 115°.

In nitric acid, as in all oxoacids, *the acidic H is attached to one of the O atoms*. In the laboratory, nitric acid is used as a strong oxidizing acid. The products of its reactions with metals vary with the metal's reactivity and the acid's concentration. In the following examples, notice from the net ionic equations that *the NO_3^- ion is the oxidizing agent*. Nitrate ion that is not reduced is a spectator ion and does not appear in the net ionic equations.

- With an active metal, such as Al, and dilute acid, N is reduced from the +5 state all the way to the −3 state in the ammonium ion, NH_4^+:

$$8Al(s) + 30HNO_3(aq;\ 1\ M) \longrightarrow 8Al(NO_3)_3(aq) + 3NH_4NO_3(aq) + 9H_2O(l)$$

$$8Al(s) + 30H^+(aq) + 3NO_3^-(aq) \longrightarrow 8Al^{3+}(aq) + 3NH_4^+(aq) + 9H_2O(l)$$

- With a less reactive metal, such as Cu, and more concentrated acid, N is reduced to the +2 state in NO:

$$3Cu(s) + 8HNO_3(aq;\ 3\ to\ 6\ M) \longrightarrow 3Cu(NO_3)_2(aq) + 4H_2O(l) + 2NO(g)$$

$$3Cu(s) + 8H^+(aq) + 2NO_3^-(aq) \longrightarrow 3Cu^{2+}(aq) + 4H_2O(l) + 2NO(g)$$

- With still more concentrated acid, N is reduced only to the +4 state in NO_2:

$$Cu(s) + 4HNO_3(aq;\ 12\ M) \longrightarrow Cu(NO_3)_2(aq) + 2H_2O(l) + 2NO_2(g)$$

$$Cu(s) + 4H^+(aq) + 2NO_3^-(aq) \longrightarrow Cu^{2+}(aq) + 2H_2O(l) + 2NO_2(g)$$

Nitrates form when HNO_3 reacts with metals or with their hydroxides, oxides, or carbonates. *All nitrates are soluble in water.*

Nitrous acid, HNO_2, a much weaker acid than HNO_3, forms when metal nitrites are treated with a strong acid:

$$NaNO_2(aq) + HCl(aq) \longrightarrow HNO_2(aq) + NaCl(aq)$$

These two acids reveal a *general pattern in relative acid strength among oxoacids:* the more O atoms bonded to the central nonmetal, the stronger the acid. Thus, HNO_3 is stronger than HNO_2. The O atoms pull electron density from the N atom, which in turn pulls electron density from the O of the O—H bond, facilitating the release of the H^+ ion. The O atoms also act to stabilize the resulting oxoanion by delocalizing its negative charge. The same pattern occurs in the oxoacids of sulfur and the halogens; we'll discuss the pattern quantitatively in Chapter 18.

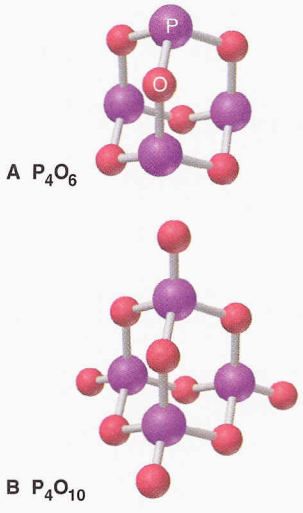

Figure 14.22 Important oxides of phosphorus. A, P_4O_6. **B,** P_4O_{10}.

Highlights of Phosphorus Chemistry: Oxides and Oxoacids

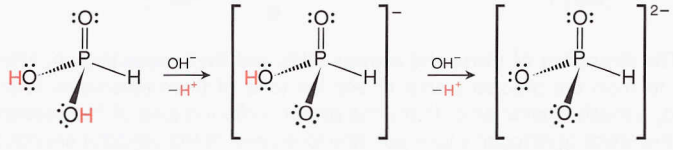
Phosphorus forms two important oxides, P_4O_6 and P_4O_{10}. Tetraphosphorus hexaoxide, P_4O_6, has P in its +3 oxidation state and forms when white P_4 reacts with limited oxygen:

$$P_4(s) + 3O_2(g) \longrightarrow P_4O_6(s)$$

P_4O_6 has the tetrahedral orientation of the P atoms found in P_4, with an O atom between each pair of P atoms (Figure 14.22A). It reacts with water to form phosphor*ous* acid (note the spelling):

$$P_4O_6(s) + 6H_2O(l) \longrightarrow 4H_3PO_3(l)$$

The formula H_3PO_3 is misleading because the acid has only two acidic H atoms; the third is bonded to the central P and does not dissociate. Phosphorous acid is a weak acid in water but reacts completely in two steps with excess strong base:



Salts of phosphorous acid contain the phosphite ion, HPO_3^{2-}.

In tetraphosphorus decaoxide, P_4O_{10}, P is in the +5 oxidation state. Commonly known as "phosphorus pentoxide" from the empirical formula (P_2O_5), it forms when P_4 burns in excess O_2:

$$P_4(s) + 5O_2(g) \longrightarrow P_4O_{10}(s)$$

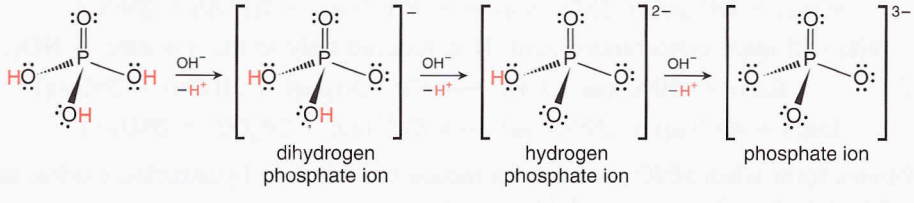
Its structure can be viewed as that of P_4O_6 with another O atom bonded to each of the four corner P atoms (Figure 14.22B). P_4O_{10} is a powerful drying agent and, in a vigorous exothermic reaction with water, forms phosphoric acid (H_3PO_4), one of the "top-10" most important compounds in chemical manufacturing:

$$P_4O_{10}(s) + 6H_2O(l) \longrightarrow 4H_3PO_4(l)$$

The presence of many H bonds makes pure H_3PO_4 syrupy, more than 75 times as viscous as water. The laboratory-grade concentrated acid is an 85% by mass aqueous solution. H_3PO_4 is a weak triprotic acid; in water, it loses one proton in the following equilibrium reaction:

$$H_3PO_4(l) + H_2O(l) \rightleftharpoons H_2PO_4^-(aq) + H_3O^+(aq)$$

In excess strong base, however, the three protons dissociate completely in three steps to give the three phosphate oxoanions:



Phosphoric acid has a central role in fertilizer production, and it is also used as a polishing agent for aluminum car trim and as an additive in soft drinks to give a touch of tartness. The various phosphate salts have numerous essential applications.

Polyphosphates are formed by heating hydrogen phosphates, which lose water as they form P—O—P linkages. This type of reaction, in which an H_2O molecule is lost for every pair of OH groups that join, is called a **dehydration-condensation;** it occurs frequently in the formation of polyoxoanion chains and other polymeric structures, both synthetic and natural. For example, sodium diphosphate, $Na_4P_2O_7$, is prepared by heating sodium hydrogen phosphate:

$$2Na_2HPO_4(s) \xrightarrow{\Delta} Na_4P_2O_7(s) + H_2O(g)$$

The Countless Uses of Phosphates

Phosphates have an amazing array of applications in home and industry. Na_3PO_4 is a paint stripper and grease remover and is still used in cleaning powders in other countries. Na_2HPO_4 is a laxative ingredient and is used to adjust the acidity of boiler water. The potassium salt K_3PO_4 is used to stabilize latex for synthetic rubber, and K_2HPO_4 is a radiator corrosion inhibitor. Ammonium phosphates are used as fertilizers and as flame retardants on curtains and paper costumes. Calcium phosphates are used in baking powders and toothpastes, as mineral supplements in livestock feed, and (on the hundred-million-ton scale) as fertilizers throughout the world.

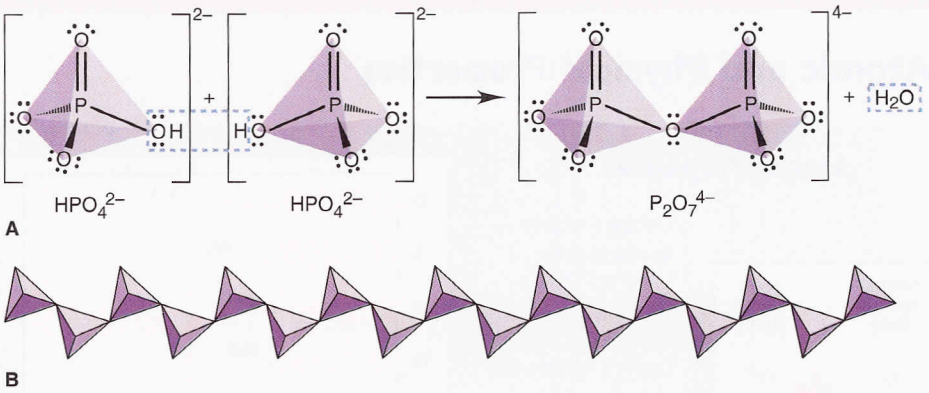


Figure 14.23 The diphosphate ion and polyphosphates. A, When two hydrogen phosphate ions undergo a dehydration-condensation reaction, they lose a water molecule and join through a shared O atom to form a diphosphate ion. **B,** Polyphosphates are chains of many such tetrahedral PO_4 units. Chain shapes depend on the orientation of the individual units. Note the similarity to silicate chains (see the Gallery, p. 580).

The diphosphate ion, $P_2O_7^{4-}$, the smallest of the polyphosphates, consists of two PO_4 units linked through a common oxygen corner (Figure 14.23A). Its reaction with water, the reverse of the previous reaction, generates heat:

$$P_2O_7^{4-}(aq) + H_2O(l) \longrightarrow 2HPO_4^{-}(aq) + heat$$

A similar process is put to vital use by organisms, when a third PO_4 unit linked to diphosphate creates the triphosphate grouping, part of the all-important high-energy biomolecule adenosine triphosphate (ATP). In Chapters 20 and 21, we discuss the central role of ATP in biological energy production. Extended polyphosphate chains consist of many tetrahedral PO_4 units (Figure 14.23B) and are structurally similar to silicate chains. As a final look at the chemical versatility of phosphorus, consider some of its numerous important compounds with sulfur and with nitrogen.

Match Heads, Bug Sprays, and O-Rings

Phosphorus forms many sulfides and nitrides. P_4S_3 is used in "strike-anywhere" match heads, and P_4S_{10} is used in the manufacture of organophosphorus pesticides, such as malathion. Polyphosphazenes have properties similar to those of silicones. Indeed, the $—(R_2)P{=}N—$ unit is isoelectronic with the silicone unit, $—(R_2)Si—O—$. Sheets, films, fibers, and foams of polyphosphazene are water repellent, flame resistant, solvent resistant, and flexible at low temperatures—perfect for the gaskets and O-rings in spacecraft and polar vehicles.

14.8 GROUP 6A(16): THE OXYGEN FAMILY

The first two members of this family—gaseous nonmetallic oxygen (O) and solid nonmetallic sulfur (S)—are among the most important elements in industry, the environment, and living things. Two metalloids, selenium (Se) and tellurium (Te), appear below them, then comes the lone metal, radioactive polonium (Po), and newly synthesized element 116 ends the group. The Group 6A(16) Family Portrait (pp. 592 and 593) displays the features of these elements.

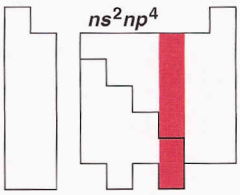
How Do the Oxygen and Nitrogen Families Compare Physically?

Group 6A(16) resembles Group 5A(15) in many respects, so let's look at some common themes. The pattern of physical properties we saw in Group 5A appears again in this group. Like nitrogen, oxygen occurs as a low-boiling diatomic gas. Like phosphorus, sulfur occurs as a polyatomic molecular solid. Like arsenic, selenium commonly occurs as a gray metalloid. Like antimony, tellurium is slightly more metallic than the preceding group member but still displays network covalent bonding. Finally, like bismuth, polonium has a metallic crystal structure. As we expect by comparison with the Group 5A elements, electrical conductivities increase steadily down Group 6A as bonding changes from individual molecules (insulators) to metalloid networks (semiconductors) to a metallic solid (conductor).

Group 6A(16): The Oxygen Family

Key Atomic and Physical Properties

KEY
Atomic No.
Symbol
Atomic mass
Valence e⁻ configuration
Common oxidation states



GROUP 6A(16)

8 **O** 16.00 $2s^22p^4$ (−1, **−2**)	
16 **S** 32.07 $3s^23p^4$ (**−2, +6,** +4, +2)	34 **Se** 78.96 $4s^24p^4$ (−2, +6, **+4,** +2)	52 **Te** 127.6 $5s^25p^4$ (**−2, +6,** **+4,** +2)	84 **Po** (209) $6s^26p^4$ (**+4,** +2)	
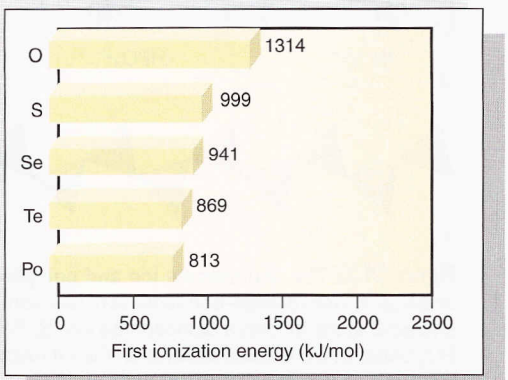
116 (292) $7s^27p^4$	No sample available

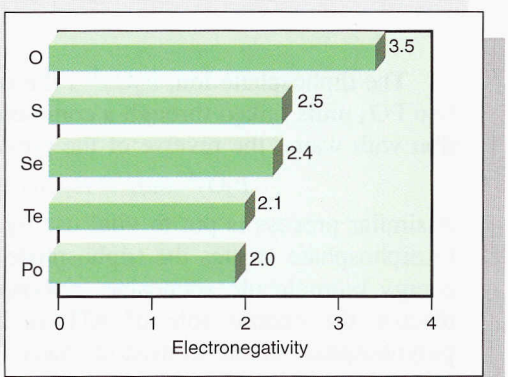
Atomic Properties

Atomic radius (pm)		Ionic radius (pm)
O 73		O^{2-} 140
S 103		S^{2-} 184
Se 119		Se^{2-} 198
Te 142		
Po 168		Po^{4+} 94

Group electron configuration is ns^2np^4. As in Groups 3A(13) and 5A(15), a lower (+4) oxidation state becomes more common down the group.

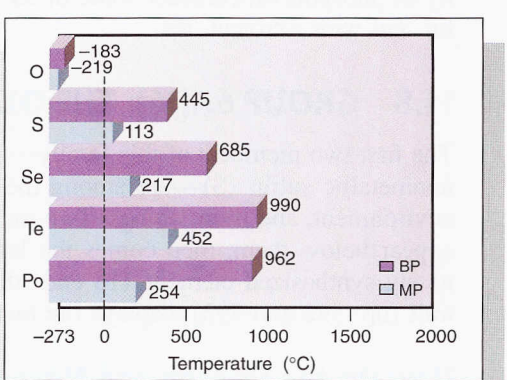
Down the group, atomic and ionic size increase, and IE and EN decrease.

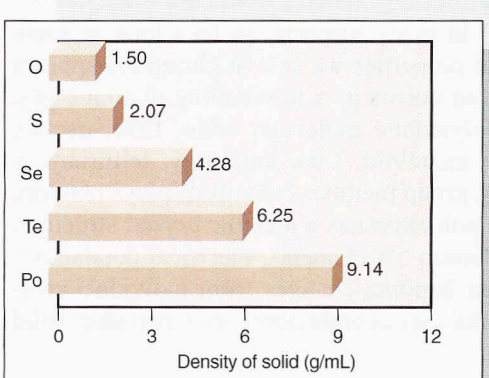




Physical Properties

Melting points increase through Te, which has covalent bonding, and then decrease for Po, which has metallic bonding.





Densities of the elements as solids increase steadily.

Some Reactions and Compounds

Important Reactions

Halogenation and oxidation of the elements (E) appear in reactions 1 and 2, and sulfur chemistry in reactions 3 and 4.

1. Halides are formed by direct combination:

$$E(s) + X_2(g) \longrightarrow \text{various halides} \quad (E = S, Se, Te; X = F, Cl)$$

2. The other elements in the group are oxidized by O_2:

$$E(s) + O_2(g) \longrightarrow EO_2 \quad (E = S, Se, Te, Po)$$

SO_2 is oxidized further, and the product is used in the final step of H_2SO_4 manufacture (*Highlights of Sulfur Chemistry*):

$$2SO_2(g) + O_2(g) \longrightarrow 2SO_3(g)$$

3. Sulfur is recovered when hydrogen sulfide is oxidized:

$$8H_2S(g) + 4O_2(g) \longrightarrow S_8(s) + 8H_2O(g)$$

This reaction is used to obtain sulfur when natural deposits are not available.

4. The thiosulfate ion is formed when an alkali metal sulfite reacts with sulfur, as in the preparation of "hypo," photographer's developing solution:

$$S_8(s) + 8Na_2SO_3(aq) \longrightarrow 8Na_2S_2O_3(aq)$$

Important Compounds

1. Water, H_2O. The single most important compound on Earth (*Section 12.5*).

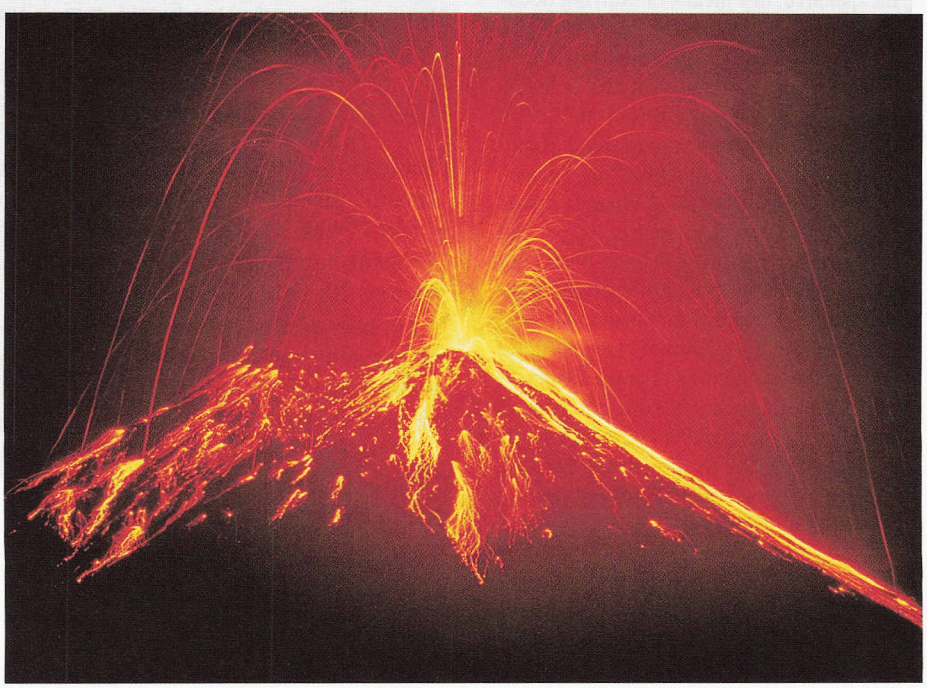
2. Hydrogen peroxide, H_2O_2. Used as an oxidizing agent, disinfectant, and bleach, and in the production of peroxy compounds for polymerization (*margin note, p. 595*).

3. Hydrogen sulfide, H_2S. Vile-smelling toxic gas formed during anaerobic decomposition of plant and animal matter, in volcanoes, and in deep-sea thermal vents. Used as a source of sulfur and in the manufacture of paper. Atmospheric traces cause silver to tarnish through formation of black Ag_2S (*see photo*).

4. Sulfur dioxide, SO_2. Colorless, choking gas formed in volcanoes (*see photo*) or whenever an S-containing material (coal, oil, metal sulfide ores, and so on) is burned. More than 90% of SO_2 produced is used to make sulfuric acid. Also used as a fumigant and a preservative of fruit, syrups, and wine. As a reducing agent, removes excess Cl_2 from industrial wastewater, removes O_2 from petroleum handling tanks, and prepares ClO_2 for bleaching paper. Atmospheric pollutant in acid rain.

5. Sulfur trioxide (SO_3) and sulfuric acid (H_2SO_4). SO_3, formed from SO_2 over a K_2O/V_2O_5 catalyst, is then converted to H_2SO_4. The acid is the cheapest strong acid and is so widely used in industry that its production level is an indicator of a nation's economic strength. It is a strong dehydrating agent that removes water from any organic source (*Highlights of Sulfur Chemistry*).

6. Sulfur hexafluoride, SF_6. Extremely inert gas used as an electrical insulator.



Allotropism is more common in Group 6A(16) than in Group 5A(15). Oxygen has two allotropes: life-giving dioxygen (O_2), and poisonous triatomic ozone (O_3). Oxygen gas is colorless, odorless, paramagnetic, and thermally stable. In contrast, ozone gas is bluish, has a pungent odor, is diamagnetic, and decomposes in heat and especially in ultraviolet (UV) light:

$$2O_3(g) \xrightarrow{UV} 3O_2(g)$$

This ability to absorb high-energy photons makes stratospheric ozone vital to life. A thinning of the ozone layer, observed above the North Pole and especially the South Pole, means that more UV light will reach Earth's surface, with potentially hazardous effects. (We'll discuss the chemical causes of ozone depletion in Chapter 16.)

Sulfur is the allotrope "champion" of the periodic table, with more than 10 forms. The S atom's ability to bond to other S atoms creates numerous rings and chains, with S—S bond lengths that range from 180 pm to 260 pm and bond angles from 90° to 180°. At room temperature, the sulfur molecule is a crown-shaped ring of eight atoms, called *cyclo-*S_8 (Figure 14.24). The most stable allotrope is orthorhombic α-S_8, which consists entirely of these molecules; all other S allotropes eventually revert to this one.

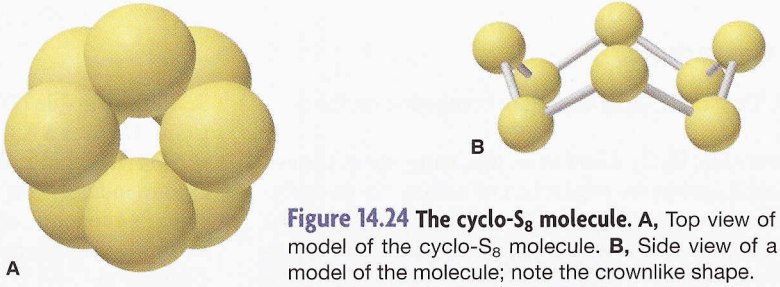


Figure 14.24 The cyclo-S_8 molecule. A, Top view of a space-filling model of the cyclo-S_8 molecule. **B,** Side view of a ball-and-stick model of the molecule; note the crownlike shape.

Selenium also has several allotropes, some consisting of crown-shaped Se_8 molecules. Gray Se is composed of layers of helical chains. Its electrical conductivity in visible light revolutionized the photocopying industry. When molten glass, cadmium sulfide, and gray Se are mixed and heated in the absence of air, a ruby-red glass forms, which you see whenever you stop at a traffic light.

Selenium and Xerography Photocopying was invented in the 1940s as a rapid, inexpensive, dry means of copying documents (*xerography,* Greek "dry writing"). It is based on the ability of Se to conduct a current when illuminated. A film of amorphous Se is deposited on an aluminum drum and electrostatically charged. Exposure to a document produces an "image" of low and high positive charges corresponding to the document's bright and dark areas. Negatively charged black, dry ink (toner) particles are attracted to the regions of high charge more than to those of low charge. This pattern of black particles is transferred electrostatically to paper, and the particles are fused to the paper's surface by heat or solvent. Excess toner is removed from the Se film, the charges are "erased" by exposure to light, and the film is ready for the next page.

How Do the Oxygen and Nitrogen Families Compare Chemically?

Changes in chemical behavior in Group 6A(16) are also similar to those in the previous group. Even though O and S occur as anions much more often than do N and P, like N and P, they bond covalently with almost every other nonmetal. Covalent bonds appear in the compounds of Se and Te (as in those of As and Sb), whereas Po behaves like a metal (as does Bi) in some of its saltlike compounds. In contrast to nitrogen, oxygen has few common oxidation states, but the earlier pattern returns with the other members: the +6, +4, and −2 states occur most often, with the lower positive (+4) state becoming more common in Te and Po [as the lower positive (+3) state does in Sb and Bi].

The range in atomic properties is wider in this group than in Group 5A(15) because of oxygen's high EN (3.5) and great oxidizing strength, second only to that of fluorine. As in 5A and earlier groups, the behavior of the Period 2 element stands out. In fact, aside from a similar outer electron configuration, the larger

members of Group 6A behave very little like oxygen: they are much less electronegative, form anions much less often (S^{2-} occurs with active metals), and their hydrides exhibit no H bonding.

Except for O, all the 6A elements form foul-smelling, poisonous, gaseous hydrides (H_2E) on treatment with acid of the metal sulfide, selenide, and so forth. For example,

$$FeSe(s) + 2HCl(aq) \longrightarrow H_2Se(g) + FeCl_2(aq)$$

Hydrogen sulfide also forms naturally in swamps from the breakdown of organic matter. It is as toxic as HCN, and even worse, it anesthetizes your olfactory nerves, so that as its concentration increases, you smell it less! The other hydrides are about 100 times *more* toxic.

In their bonding and thermal stability, these Group 6A hydrides have several features in common with those of Group 5A:

- Only water can form H bonds, so it melts and boils much higher than the other H_2E compounds (see Figure 12.14, p. 440). (Oxygen's other hydride, H_2O_2, is also extensively H bonded.)
- Bond angles drop from the nearly tetrahedral value for H_2O (104.5°) to around 90° for the larger 6A hydrides, suggesting that the central atom uses unhybridized *p* orbitals.
- E—H bond length increases (bond energy decreases) down the group. Thus, H_2Te decomposes above 0°C, and H_2Po can be made only in extreme cold because thermal energy from the radioactive Po decomposes it. Another result of longer (weaker) bonds is that the 6A hydrides are acids in water, and their acidity increases from H_2S to H_2Po.

Except for O, the Group 6A elements form a wide range of halides, whose structure and reactivity patterns depend on the *sizes of the central atom and the surrounding halogens:*

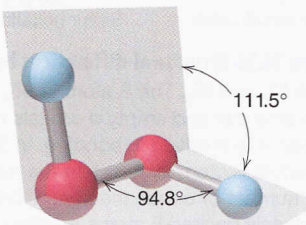
- Sulfur forms many fluorides, a few chlorides, one bromide, but no stable iodides.
- As the central atom becomes larger, the halides become more stable. Thus, tetrachlorides and tetrabromides of Se, Te, and Po are known, as are tetraiodides of Te and Po. Hexafluorides are known only for S, Se, and Te.

The inverse relationship between bond length and bond strength that we've seen previously does not account for this pattern. Rather, it is based on the effect of electron repulsions due to crowding of lone pairs and halogen (X) atoms around the central Group 6A atom. With S, the larger X atoms would be too crowded, which explains why sulfur iodides do not occur. With increasing size of E, and therefore increasing length of E—X bonds, however, lone pairs and X atoms do not crowd each other as much, and a greater number of stable halides form.

Two sulfur fluorides illustrate clearly how crowding and orbital availability affect reactivity. Sulfur tetrafluoride (SF_4) is extremely reactive. It forms SO_2 and HF when exposed to moisture and is commonly used to fluorinate many compounds:

$$3SF_4(g) + 4BCl_3(g) \longrightarrow 4BF_3(g) + 3SCl_2(l) + 3Cl_2(g)$$

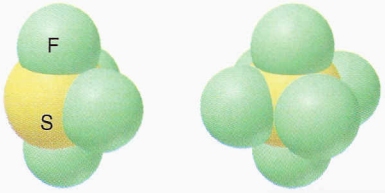
In contrast, sulfur hexafluoride (SF_6) is almost as inert as a noble gas! It is odorless, tasteless, nonflammable, nontoxic, and insoluble. Hot metals, boiling HCl, molten KOH, and high-pressure steam have no effect on it. It is used as an insulating gas in high-voltage generators, withstanding over 10^6 volts across electrodes only 50 mm apart. A look at the structures of these two fluorides provides



Hydrogen Peroxide: Hydrazine's Cousin In addition to water, oxygen forms another hydride, called hydrogen peroxide, H_2O_2 (HO—OH). Like hydrazine ($H_2N—NH_2$), the related hydride of nitrogen, hydrogen peroxide has a skewed molecular shape. It is a colorless liquid with a high density, viscosity, and boiling point because of extensive H bonding. In peroxides, O has the −1 oxidation state, midway between that in O_2 (zero) and that in oxides (−2); thus, H_2O_2 readily disproportionates:

$$H_2O_2(l) \longrightarrow H_2O(l) + \tfrac{1}{2}O_2(g)$$

Aside from the familiar use of H_2O_2 as a hair bleach and disinfectant, more than 70% of the half-million tons produced each year are used to bleach paper pulp, textiles, straw, and leather and to make other chemicals. H_2O_2 is also used in tertiary sewage treatment (Chemical Connections, p. 530) to oxidize foul-smelling effluents and restore O_2 to wastewater.



SF_4 Sulfur tetrafluoride SF_6 Sulfur hexafluoride

Figure 14.25 Structural differences between SF_4 and SF_6. The S atom in SF_4 has a lone pair and empty *d* orbitals that can become involved in bonding. In SF_6, the central S atom already has the maximum number of bonds that it can form, and closely packed F atoms envelop it, rendering SF_6 chemically inert.

the key to these astounding differences (Figure 14.25). Sulfur in SF_4 can form bonds to another atom either by donating its lone electron pair or by accepting a lone pair into one of its empty *d* orbitals. On the other hand, the central S atom in SF_6 has no lone pair, and the six F atoms around it form an octahedral sheath that blocks chemical attack.

Highlights of Oxygen Chemistry: Range of Oxide Properties

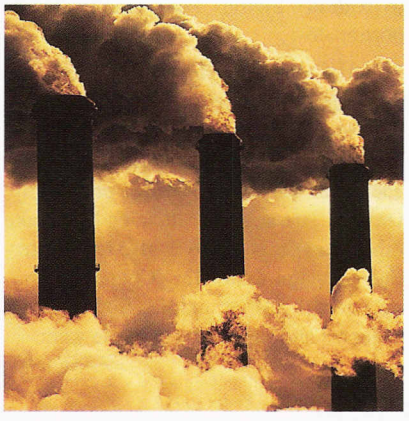
Oxygen is the most abundant element on Earth's surface, occurring both as the free element and in innumerable oxides, silicates, carbonates, and phosphates, as well as in water. Virtually all free O_2 has a biological origin, having been formed for billions of years by photosynthetic algae and multicellular plants in an overall equation that looks deceptively simple:

$$nH_2O(l) + nCO_2(g) \xrightarrow{\text{light}} nO_2(g) + (CH_2O)_n \text{ (carbohydrates)}$$

The reverse process occurs during combustion and respiration. Through these O_2-forming and O_2-utilizing processes, the 1.5×10^9 km^3 of water on Earth is, on average, used and remade every 2 million years!

Every element (except He, Ne, and Ar) forms at least one oxide, many by direct combination. A broad spectrum of properties characterizes these compounds. Some oxides are gases that condense at very low temperatures, such as CO (bp = −192°C); others are solids that melt at extremely high temperatures, such as BeO (mp = 2530°C). Oxides cover the full range of conductivity: insulators (MgO), semiconductors (NiO), conductors (ReO_3), and superconductors ($YBa_2Cu_3O_7$). Some oxides have endothermic heats of formation (ΔH_f^0 of NO = +90.3 kJ/mol), whereas other oxides have exothermic ones (ΔH_f^0 of CO_2 = −393.5 kJ/mol). They may be thermally stable (CaO) or unstable (HgO), as well as chemically reactive (Li_2O) or inert (Fe_2O_3).

Given this vast range of behavior, another useful way to classify element oxides is by their acid-base properties (see Interchapter, Topic 4). The oxides of Group 6A(16) exhibit expected trends in acidity, with SO_3 the most acidic and PoO_2 the most basic.



Acid from the Sky Awareness of SO_2 as a major air pollutant is now widespread. Even though enormous amounts of SO_2 form during volcanic and other geothermal activity, they are dwarfed by the amounts emitted from human sources: coal-burning power plants, petroleum refineries, and metal-ore smelters. In the atmosphere, SO_2 undergoes several reaction steps to form sulfuric acid, which falls in rain, snow, and dust on animals, plants, buildings, and lakes. The destructive effects of acid precipitation are being intensively studied, and remedial action is intensifying (Chapter 19).

Highlights of Sulfur Chemistry: Oxides, Oxoacids, and Sulfides

Like phosphorus, sulfur forms two important oxides, sulfur dioxide (SO_2) and sulfur trioxide (SO_3). Sulfur is in its +4 oxidation state in SO_2, a colorless, choking gas that forms whenever S, H_2S, or a metal sulfide burns in air:

$$2H_2S(g) + 3O_2(g) \longrightarrow 2H_2O(g) + 2SO_2(g)$$
$$4FeS_2(s) + 11O_2(g) \longrightarrow 2Fe_2O_3(s) + 8SO_2(g)$$

Most SO_2 is used to produce sulfuric acid.

In water, sulfur dioxide forms sulfurous acid, which exists in equilibrium with hydrated SO_2 rather than as isolable H_2SO_3 molecules:

$$SO_2(aq) + H_2O(l) \rightleftharpoons [H_2SO_3(aq)] \rightleftharpoons H^+(aq) + HSO_3^-(aq)$$

(Similarly, carbonic acid occurs in equilibrium with hydrated CO_2 and cannot be isolated as H_2CO_3 molecules.) Sulfurous acid is weak and has two acidic protons, forming the hydrogen sulfite (bisulfite, HSO_3^-) and sulfite (SO_3^{2-}) ions with strong base. Because the S in SO_3^{2-} is in the +4 state and is easily oxidized to the +6 state, sulfites are good reducing agents and are used to preserve foods and wine by eliminating undesirable products of air oxidation.

En route to sulfuric acid, SO_2 is first oxidized to SO_3 (S in the +6 state) by heating in O_2 over a catalyst:

$$SO_2(g) + \tfrac{1}{2}O_2(g) \underset{}{\overset{V_2O_5/K_2O \text{ catalyst}}{\rightleftharpoons}} SO_3(g)$$

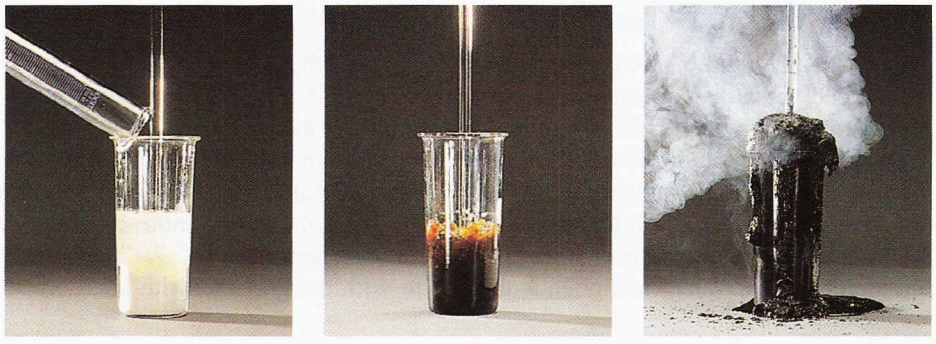


Figure 14.26 The dehydration of carbohydrates by sulfuric acid. The protons of concentrated H_2SO_4 combine exothermically with water, dehydrating many organic materials. When table sugar is treated with sulfuric acid, the components of water are removed from the carbohydrate molecules $(CH_2O)_n$. Steam forms, and the remaining carbon expands to a porous mass.

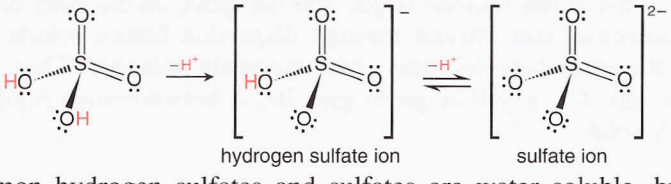
(We discuss how catalysts work in Chapter 16 and how H_2SO_4 is produced in Chapter 22.) The SO_3 is absorbed into concentrated H_2SO_4 and treated with additional H_2O:

$$SO_3(\text{in concentrated } H_2SO_4) + H_2O(l) \longrightarrow H_2SO_4(l)$$

With more than 40 million tons produced each year in the United States alone, H_2SO_4 ranks first among all industrial chemicals. Fertilizer production, metal, pigment, and textile processing, and soap and detergent manufacturing are just a few of the major industries that depend on sulfuric acid.

Concentrated laboratory-grade sulfuric acid is a viscous, colorless liquid that is 98% H_2SO_4 by mass. Like other strong acids, H_2SO_4 dissociates completely in water, forming the hydrogen sulfate (or bisulfate) ion, a much weaker acid:



Most common hydrogen sulfates and sulfates are water soluble, but those of Group 2A(2) members (except $MgSO_4$), Pb^{2+}, and Hg_2^{2+} are not.

Concentrated sulfuric acid is an excellent dehydrating agent. Its loosely held proton transfers to water in a highly exothermic formation of hydronium (H_3O^+) ions. This process can occur even when the reacting substance contains no free water. For example, H_2SO_4 dehydrates wood, natural fibers, and many other organic substances by removing the components of water from the molecular structure, leaving behind a carbonaceous mass (Figure 14.26).

Thiosulfuric acid ($H_2S_2O_3$) is a structural analog of sulfuric acid in which a second S substitutes for one of the O atoms (*thio-* means "containing sulfur in place of oxygen"). The thiosulfate ion ($S_2O_3^{2-}$) is an important reducing agent in chemical analysis. However, its largest commercial use is in photography, where sodium thiosulfate pentahydrate ($Na_2S_2O_3 \cdot 5H_2O$), known as "hypo," is involved in fixing the image (Section 23.3).

Many metals combine directly with S to form *metal sulfides*. Indeed, naturally occurring sulfides are ores, which are mined for the extraction of many metals, including copper, zinc, lead, and silver. Aside from the sulfides of Groups 1A(1) and 2A(2), most metal sulfides do not have discrete S^{2-} ions. Several transition metals, such as chromium, iron, and nickel, form covalent, alloy-like, nonstoichiometric compounds with S, such as $Cr_{0.88}S$ or $Fe_{0.86}S$. Some important minerals contain S_2^{2-} ions; an example is iron pyrite, or "fool's gold" (FeS_2) (Figure 14.27). We discuss the metallurgy of ores in Chapter 22.

Figure 14.27 A common sulfide mineral. Pyrite (FeS_2), or fool's gold, is a beautiful but relatively cheap mineral that contains the S_2^{2-} ion, but no gold.

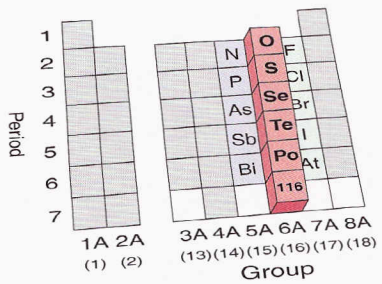


Figure 14.28 Standing in Group 6A(16), looking backward to Group 5A(15) and forward to Group 7A(17).

Looking Backward and Forward: Groups 5A(15), 6A(16), and 7A(17)

Groups 5A(15) and 6A(16) are very similar in their physical and chemical trends and in the versatility of phosphorus and sulfur (Figure 14.28). Their greatest difference is the sluggish behavior of N_2 compared with the striking reactivity of O_2. In both groups, metallic character appears only in the largest members. From here on, metals and even metalloids are left behind: all Group 7A(17) elements are reactive nonmetals. Anion formation, which was rare in 5A and more common in 6A, is one of the dominant features of 7A. Another feature of the 7A elements is the number of covalent compounds they form with oxygen *and* with each other.

14.9 GROUP 7A(17): THE HALOGENS

Our last chance to view elements of great reactivity occurs in Group 7A(17). The halogens begin with fluorine (F), the strongest electron "grabber" of all. Chlorine (Cl), bromine (Br), and iodine (I) also form compounds with most elements, and even extremely rare astatine (At) is thought to be reactive. The key features of Group 7A(17) are presented in the Family Portrait on pages 600 and 601.

What Accounts for the Regular Changes in the Halogens' Physical Properties?

Like the alkali metals at the other end of the periodic table, the halogens display regular trends in their physical properties. However, whereas melting and boiling points and heats of fusion and vaporization *decrease* down Group 1A(1), these properties *increase* down Group 7A(17) (see the Interchapter, Topic 6). The reason for these opposite trends is the different type of bonding in the elements. The alkali metals consist of atoms held together by metallic bonding, which *decreases* in strength as the atoms become larger. The halogens, on the other hand, exist as diatomic molecules that interact through dispersion forces, which *increase* in strength as the atoms become larger and more easily polarized. Thus, F_2 is a very pale yellow gas, Cl_2 a yellow-green gas, Br_2 a brown-orange liquid, and I_2 a purple-black solid.

Why Are the Halogens So Reactive?

The Group 7A(17) elements react with most metals and nonmetals to form many ionic and covalent compounds: metal and nonmetal halides, halogen oxides, and oxoacids. The reason for halogen reactivity is the same as that for alkali metal reactivity—an electron configuration one electron away from that of a noble gas. Whereas a 1A metal atom must *lose* one electron to attain a filled outer level, *a 7A nonmetal atom must gain one electron to fill its outer level.* It accomplishes this filling in either of two ways:

1. Gaining an electron from a metal atom, thus forming a negative ion as the metal forms a positive one
2. Sharing an electron pair with a nonmetal atom, thus forming a covalent bond

Down the group, reactivity reflects the decrease in electronegativity: F_2 is the most reactive and I_2 the least. The exceptional reactivity of elemental F_2 is also related to the weakness of the F—F bond. Because F is small, the bond is short; however, the lone pairs on each F atom repel those on the other, which weakens the bond (Figure 14.29). As a result of these factors, F_2 reacts with every element (except He, Ne, and Ar), in many cases, explosively.

The halogens display the largest range in electronegativity of any group, but all are electronegative enough to behave as nonmetals. They act as *oxidizing*

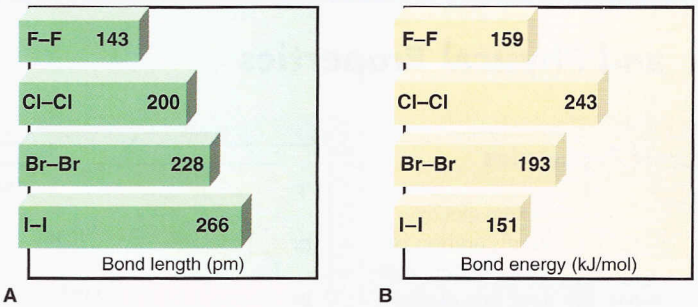

Figure 14.29 Bond energies and bond lengths of the halogens. A, In keeping with the increase in atomic size down the group, bond lengths increase steadily. **B,** The halogens show a general decrease in bond energy as bond length increases. However, F_2 deviates from this trend because its small, close, electron-rich atoms repel each other, thereby lowering its bond energy.

agents in the majority of their reactions, and halogens higher in the group can oxidize halide ions lower down:

$$F_2(g) + 2X^-(aq) \longrightarrow 2F^-(aq) + X_2(aq) \quad (X = Cl, Br, I)$$

Thus, the oxidizing ability of X_2 *decreases* down the group: the lower the EN, the less strongly each X atom pulls electrons. Similarly, the reducing ability of X^- *increases* down the group: the larger the ion, the more easily it gives up its electron (Figure 14.30).

The halogens undergo some important aqueous redox chemistry. Fluorine is such a powerful oxidizing agent that it tears water apart, oxidizing the O to produce O_2, some O_3, and HFO (hypofluorous acid). The other halogens undergo disproportionations (note the oxidation numbers):

$$\overset{0}{X_2} + H_2O(l) \rightleftharpoons \overset{-1}{HX}(aq) + \overset{+1}{HXO}(aq) \quad (X = Cl, Br, I)$$

At equilibrium, very little product is present unless excess OH^- ion is added, which reacts with the HX and HXO and drives the reaction to completion:

$$X_2 + 2OH^-(aq) \longrightarrow X^-(aq) + XO^-(aq) + H_2O(l)$$

When X is Cl, the product mixture acts as a bleach: household bleach is a dilute solution of sodium hypochlorite (NaClO). Heating causes XO^- to disproportionate further, creating oxoanions with X in a higher oxidation state:

$$\overset{+1}{3XO^-}(aq) \xrightarrow{\Delta} \overset{-1}{2X^-}(aq) + \overset{+5}{XO_3^-}(aq)$$

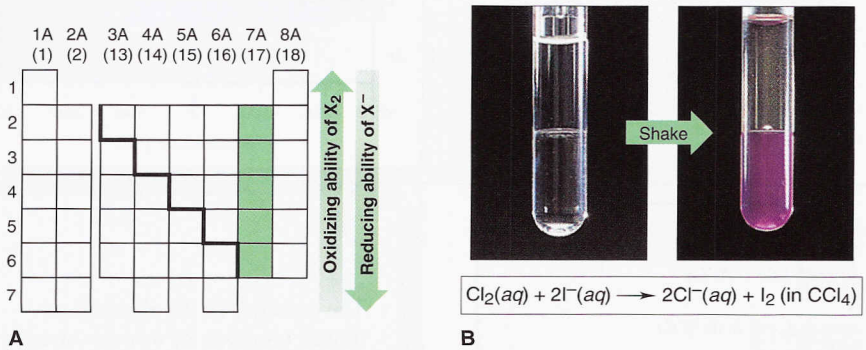

Figure 14.30 The relative oxidizing ability of the halogens. A, Halogen redox behavior is based on atomic properties such as electron affinity, ionic charge density, and electronegativity. A halogen (X_2) higher in the group can oxidize a halide ion (X^-) lower down. **B,** As an example, when aqueous Cl_2 is added to a solution of I^- (*top layer*), it oxidizes the I^- to I_2, which dissolves in the CCl_4 solvent (*bottom layer*) to give a purple solution.

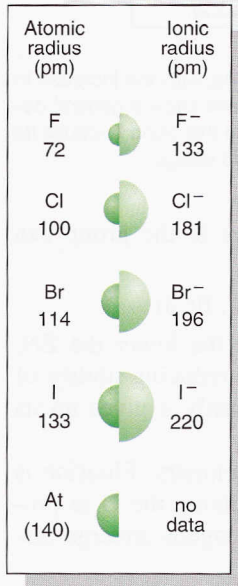
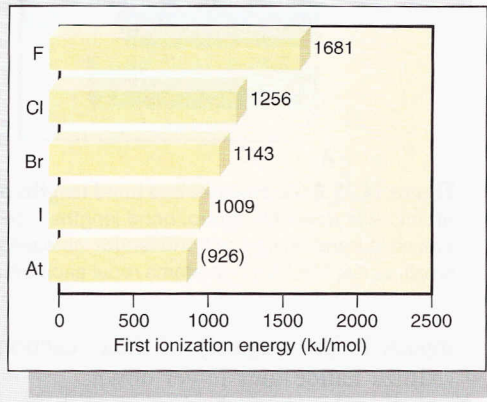
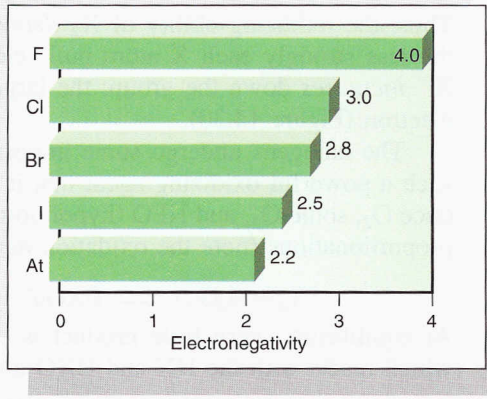
Atomic Properties



Group electron configuration is ns^2np^5; elements lack one electron to complete their outer level. The −1 oxidation state is the most common for all members. Except for F, the halogens exhibit all odd-numbered states (+7 through −1).

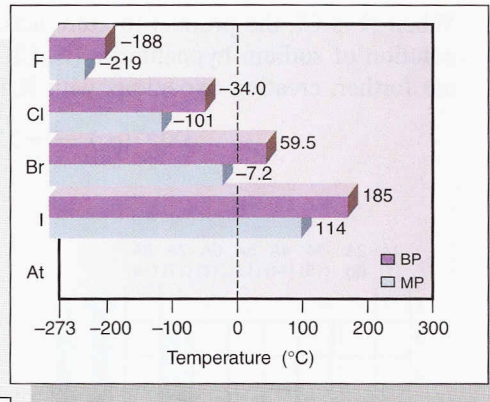
Down the group, atomic and ionic size increase steadily, as IE and EN decrease.

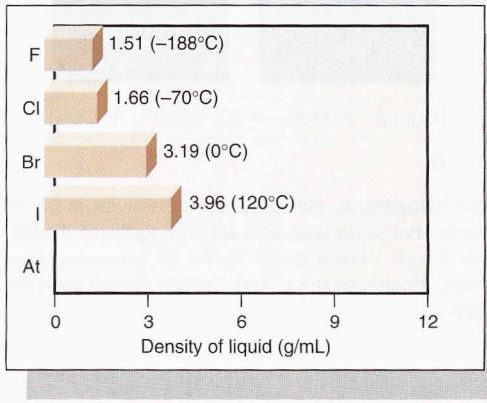




Physical Properties

Down the group, melting and boiling points increase smoothly as a result of stronger dispersion forces between heavier molecules.





The densities of the elements as liquids (at given T) increase steadily with molar mass.

Some Reactions and Compounds

Important Reactions

Oxidizing strength and aqueous redox chemistry of the halogens are shown in reactions 1 and 2, and industrial processes involving fluorine in reactions 3 and 4.

1. The halogens (X_2) oxidize many metals and nonmetals. The reaction with hydrogen, although not used commercially for HX production (except for high-purity HCl), is characteristic of these strong oxidizing agents:

$$X_2 + H_2(g) \longrightarrow 2HX(g)$$

2. The halogens disproportionate in water:

$$X_2 + H_2O(l) \rightleftharpoons HX(aq) + HXO(aq) \qquad (X = Cl, Br, I)$$

In aqueous base, the reaction goes to completion to form hypohalites (*see text*) and, at higher temperatures, halates; for example:

$$3Cl_2(g) + 6OH^-(aq) \xrightarrow{\Delta} ClO_3^-(aq) + 5Cl^-(aq) + 3H_2O(l)$$

3. F_2 is produced electrolytically at moderate temperature:

$$2HF \text{ (as a soln of KF in HF)} \xrightarrow[90°C]{\text{electrolysis}} H_2(g) + F_2(g)$$

A major use of F_2 is in the preparation of UF_6 for nuclear fuel.

4. Glass (amorphous silica) is etched with HF:

$$SiO_2(s) + 6HF(g) \longrightarrow H_2SiF_6(aq) + 2H_2O(l)$$

Space shuttle

Important Compounds

Fluorite

1. Fluorspar (fluorite), CaF_2. Widely distributed mineral used as a flux in steelmaking and in the production of HF (*see photo*).

2. Hydrogen fluoride, HF. Colorless, extremely toxic gas used to make F_2, organic fluorine compounds, and polymers. Also used in aluminum manufacture and in glass etching (*margin note, p. 602*).

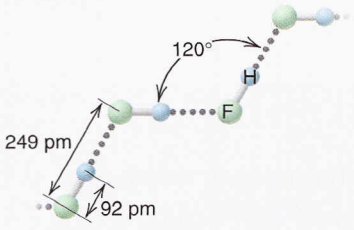
3. Hydrogen chloride, HCl. Extremely water-soluble gas that forms hydrochloric acid, which occurs naturally in the stomach fluids of mammals (humans produce 1.5 L of 0.1 *M* HCl daily) and in volcanic gases (from reaction of H_2O and sea salt). Made by reaction of NaCl and H_2SO_4 and as a by-product of plastics (PVC) production. Used in the "pickling" of steel (removal of adhering oxides) and in the production of syrups, rayon, and plastic.

4. Sodium hypochlorite, NaClO, and calcium hypochlorite, $Ca(ClO)_2$. Oxidizing agents used to bleach wood pulp and textiles and to disinfect swimming pools, foods, and sewage (also used to disinfect the Apollo 11 on return from the Moon). Household bleach is 5.25% NaClO by mass in water.

5. Ammonium perchlorate, NH_4ClO_4. Strong oxidizing agent used in the space shuttle program (*see photo*).

6. Potassium iodide, KI. Most common soluble iodide. Added to table salt to prevent thyroid disease (goiter). Used in chemical analysis because it is easily oxidized to I_2, which provides a colored end point.

7. Polychlorinated biphenyls, PCBs. Mixture of chlorinated organic compounds used as nonflammable insulating liquids in electrical transformers. Production discontinued because of persistence in the environment, where they become concentrated in the tissues of fish, birds, and mammals, and cause reproductive disturbances and possibly cancer.



HF: Unusual Structure, Familiar Uses
At room temperature, all the hydrogen halides except HF are diatomic gases. As a result of its extensive H bonding, gaseous HF exists as short chains or rings of formula $(HF)_6$; liquid HF boils at 19.5°C, more than 50 degrees higher than even the much heavier HI; and solid HF exists as an H-bonded polymer. HF has many uses, including the synthesis of cryolite (Na_3AlF_6) for aluminum production, of fluorocarbons for refrigeration, and of NaF for water fluoridation. HF is also used in nuclear fuel processing and for glass etching in the manufacture of lightbulbs, transistors, and TV tubes.

Highlights of Halogen Chemistry

In this section, we examine the compounds the halogens form with hydrogen and with each other, as well as their oxides, oxoanions, and oxoacids.

The Hydrogen Halides The halogens form gaseous hydrogen halides (HX) through direct combination with H_2 or through the action of a concentrated acid on the metal halide (a nonoxidizing acid is used for HBr and HI):

$$CaF_2(s) + H_2SO_4(l) \longrightarrow CaSO_4(s) + 2HF(g)$$
$$3NaBr(s) + H_3PO_4(l) \longrightarrow Na_3PO_4(s) + 3HBr(g)$$

Commercially, most HCl is formed as a by-product in the chlorination of hydrocarbons for plastics production:

$$CH_2{=}CH_2(g) + Cl_2(g) \longrightarrow ClCH_2CH_2Cl(l) \xrightarrow{500°C} \underset{\text{vinyl chloride}}{CH_2{=}CHCl(g)} + HCl(g)$$

In this case, the vinyl chloride reacts in a separate process to form poly(vinyl chloride), or PVC, a polymer used extensively in modern plumbing pipes.

In water, gaseous HX molecules form a *hydrohalic acid*. Only HF, with its relatively short, strong bond, forms a weak acid:

$$HF(g) + H_2O(l) \rightleftharpoons H_3O^+(aq) + F^-(aq)$$

The others dissociate completely to form the stoichiometric amount of H_3O^+ ions:

$$HBr(g) + H_2O(l) \longrightarrow H_3O^+(aq) + Br^-(aq)$$

(We saw reactions similar to these in Chapter 4. They involve transfer of a proton from acid to H_2O and are classified as *Brønsted-Lowry acid-base reactions*. In Chapter 18, we discuss them thoroughly and examine the relation between bond length and acidity of the larger HX molecules.)

Interhalogen Compounds: The "Halogen Halides" Halogens react exothermically with one another to form many **interhalogen compounds.** The simplest are diatomic molecules, such as ClF or BrCl. Every binary combination of the four common halogens is known. The more electronegative halogen is in the −1 oxidation state, and the less electronegative is in the +1 state. Interhalogens of general formula XY_n (n = 3, 5, 7) form when the larger members of the group (X) use d orbitals to expand their valence shells. In every case, the central atom has the *lower electronegativity* and a positive oxidation state.

The commercially useful interhalogens are powerful *fluorinating agents*, some of which react with metals, nonmetals, and oxides—even wood and asbestos:

$$Sn(s) + ClF_3(l) \longrightarrow SnF_2(s) + ClF(g)$$
$$P_4(s) + 5ClF_3(l) \longrightarrow 4PF_3(g) + 3ClF(g) + Cl_2(g)$$
$$2B_2O_3(s) + 4BrF_3(l) \longrightarrow 4BF_3(g) + 2Br_2(l) + 3O_2(g)$$

Their reactions with water are nearly explosive and yield HF and *the oxoacid in which the central halogen has the same oxidation state*. For example,

$$3H_2O(l) + \overset{+5}{BrF_5}(l) \longrightarrow 5HF(g) + \overset{+5}{HBrO_3}(aq)$$

The Oddness and Evenness of Oxidation States In Topic 5 of the Interchapter, we saw that odd-numbered groups exhibit odd-numbered oxidation states and even-numbered groups exhibit even-numbered states. The reason for this general behavior is that *almost all stable molecules have paired electrons*, either as bonding or lone pairs. Therefore, *when bonds form or break, two electrons are involved, so the oxidation state changes by 2.*

Consider the interhalogens. Four general formulas are XY, XY_3, XY_5, and XY_7; examples are shown in Figure 14.31. With Y in the −1 state, X must be in the +1, +3, +5, and +7 state, respectively. The −1 state arises when Y fills its valence level; the +7 state arises when the central halogen (X) is completely

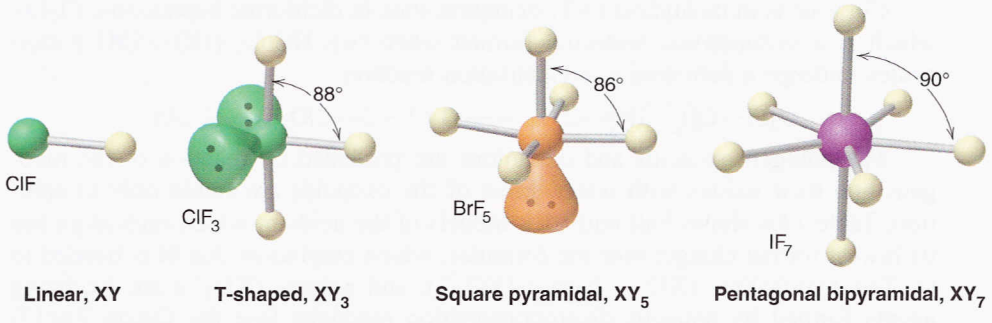


Figure 14.31 Molecular shapes of the main types of interhalogen compounds.

oxidized, that is, when all seven valence electrons have shifted away from it to the more electronegative Y atoms around it.

Let's examine the iodine fluorides to see why the oxidation states jump by two units. When I_2 reacts with F_2, IF forms (note the oxidation number of I):

$$I_2 + F_2 \longrightarrow \overset{+1}{2IF}$$

In IF_3, I uses *two* more valence electrons to form *two* more bonds:

$$\overset{+1}{IF} + F_2 \longrightarrow \overset{+3}{IF_3}$$

Otherwise, an unstable lone-electron species containing two fluorines would form. With more fluorine, another jump of two units occurs and the pentafluoride forms:

$$\overset{+3}{IF_3} + F_2 \longrightarrow \overset{+5}{IF_5}$$

With still more fluorine, the heptafluoride forms:

$$\overset{+5}{IF_5} + F_2 \longrightarrow \overset{+7}{IF_7}$$

An element in an even-numbered group, such as sulfur in Group 6A(16), shows the same tendency for its compounds to have paired electrons. Elemental sulfur (oxidation number, O.N. = 0) gains or shares two electrons to complete its shell (O.N. = −2). It uses two electrons to react with fluorine, for example, and form SF_2 (O.N. = +2), two more electrons for SF_4 (O.N. = +4), and two more for SF_6 (O.N. = +6). Thus, an element with one even state typically has all even states, and an element with one odd state typically has all odd states. To reiterate the main point, *successive oxidation states differ by two units because stable molecules have electrons in pairs around their atoms.*

Halogen Oxides, Oxoacids, and Oxoanions The Group 7A(17) elements form many oxides that are *powerful oxidizing agents and acids in water.* Dichlorine monoxide (Cl_2O) and especially chlorine dioxide (ClO_2) are used to bleach paper (Figure 14.32). ClO_2 is unstable to heat and shock, so it is prepared on site, and more than 100,000 tons are used annually:

$$2NaClO_3(s) + SO_2(g) + H_2SO_4(aq) \longrightarrow 2ClO_2(g) + 2NaHSO_4(aq)$$

The dioxide has an unpaired electron and Cl in the unusual +4 oxidation state.

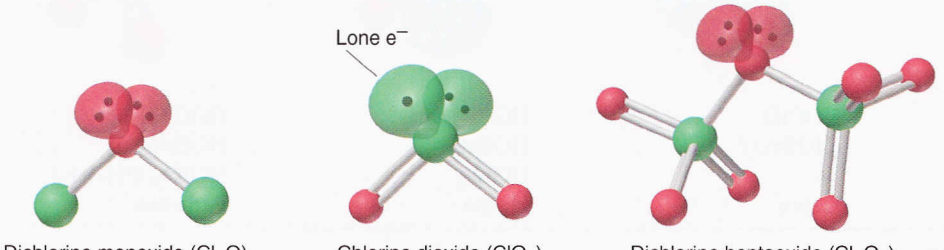

Figure 14.32 Chlorine oxides. Dichlorine monoxide and chlorine dioxide are bent molecules; note the lone electron in ClO_2. Dichlorine heptaoxide can be viewed as two ClO_4 tetrahedra joined through an O corner. (Each ball-and-stick model shows the structure in which each atom has its lowest formal charge. Lone pairs are shown on the central atoms only.)

Chlorine is in its highest (+7) oxidation state in dichlorine heptaoxide, Cl_2O_7, which is a symmetrical molecule formed when two $HClO_4$ ($HO—ClO_3$) molecules undergo a dehydration-condensation reaction:

$$O_3Cl—O\boxed{H + HO}—ClO_3 \longrightarrow O_3Cl—O—ClO_3(l) + H_2O(l)$$

The halogen oxoacids and oxoanions are produced by reaction of the halogens and their oxides with water. Most of the oxoacids are stable only in solution. Table 14.4 shows ball-and-stick models of the acids in which each atom has its lowest formal charge; note the formulas, which emphasize that H is bonded to O. The hypohalites (XO^-), halites (XO_2^-), and halates (XO_3^-) are oxidizing agents formed by aqueous disproportionation reactions [see the Group 7A(17) Family Portrait, reaction 2]. You may have heated solid alkali chlorates in the laboratory to form small amounts of O_2:

$$2MClO_3(s) \xrightarrow{\Delta} 2MCl(s) + 3O_2(g)$$

Potassium chlorate is the oxidizer in "safety" matches.

Pyrotechnic Perchlorates Thousands of tons of perchlorates are made each year for use in explosives and fireworks. The white flash of a fireworks display are caused by $KClO_4$ reacting with powdered sulfur and aluminum. At rock concerts and other theatrical productions, mixtures of $KClO_4$ and Mg are often used for special effects.

Several perhalates are also strong oxidizing agents. Ammonium perchlorate, prepared from sodium perchlorate, is the oxidizing agent for the aluminum powder in the solid-fuel booster rocket of the space shuttle; each launch uses more than 700 tons of NH_4ClO_4:

$$10Al(s) + 6NH_4ClO_4(s) \longrightarrow 4Al_2O_3(s) + 12H_2O(g) + 3N_2(g) + 2AlCl_3(g)$$

The relative strengths of the halogen oxoacids depend on two factors:

1. *Electronegativity of the halogen.* Among oxoacids with the halogen in the same oxidation state, such as the halic acids, HXO_3 (or $HOXO_2$), acid strength decreases as the halogen's EN decreases:

$$HOClO_2 > HOBrO_2 > HOIO_2$$

The more electronegative the halogen, the more electron density it removes from the O—H bond, and the more easily the proton is lost.

2. *Oxidation state of the halogen.* Among oxoacids of a given halogen, such as chlorine, acid strength decreases as the oxidation state of the halogen decreases:

$$HOClO_3 > HOClO_2 > HOClO > HOCl$$

The higher the oxidation state (number of attached O atoms) of the halogen, the more electron density it pulls from the O—H bond. We consider these trends quantitatively in Chapter 18.

Table 14.4 The Known Halogen Oxoacids*

Central Atom	Hypohalous Acid (HOX)	Halous Acid (HOXO)	Halic Acid ($HOXO_2$)	Perhalic Acid ($HOXO_3$)
				Fluorine	HOF	—	—	—
Chlorine	HOCl	HOClO	$HOClO_2$	$HOClO_3$
Bromine	HOBr	(HOBrO)?	$HOBrO_2$	$HOBrO_3$
Iodine	HOI	—	$HOIO_2$	$HOIO_3$, $(HO)_5IO$
Oxoanion	Hypohalite	Halite	Halate	Perhalate

*Lone pairs are shown only on the halogen atom.

14.10 GROUP 8A(18): THE NOBLE GASES

The last main group consists of individual atoms too "noble" to interact with others. The Group 8A(18) elements display regular trends in physical properties and very low, if any, reactivity. The group consists of helium (He), the second most abundant element in the universe, neon (Ne) and argon (Ar), krypton (Kr) and xenon (Xe), the only members for which compounds have been well studied, and finally, radioactive radon (Rn). The noble gases make up about 1% by volume of the atmosphere, primarily due to the high abundance of Ar. Their properties appear in the Group 8A(18) Family Portrait on page 606.

How Can Noble Gases Form Compounds?

Lying at the far right side of the periodic table, the Group 8A(18) elements consist of individual atoms with filled outer levels and the smallest radii in their periods: even Li, the smallest alkali metal (152 pm), is bigger than Rn, the largest noble gas (140 pm). These elements come as close to behaving as ideal gases as any other substances. Only at very low temperatures do they condense and solidify. In fact, He is the only substance that does *not* solidify by a reduction in temperature alone; it requires an increase in pressure as well. Helium has the lowest melting point known (−272.2°C at 25 atm), only one degree above 0 K (−273.15°C), and it boils only about three degrees higher. Weak dispersion forces hold these elements in condensed states, with melting and boiling points that increase, as expected, with molar mass.

Ever since their discovery in the late 19th century, these elements had been considered, and even formerly named, the "inert" gases. Atomic theory and, more important, all experiments had supported this idea. Then, in 1962, all this changed when the first noble gas compound was prepared. How, with filled outer levels and extremely high ionization energies, *can* noble gases react?

The discovery of noble gas reactivity is a classic example of clear thinking in the face of an unexpected event. At the time, a young inorganic chemist named Neil Bartlett was studying platinum fluorides, known to be strong oxidizing agents. When he accidentally exposed PtF_6 to air, its deep-red color lightened slightly, and analysis showed that the PtF_6 had oxidized O_2 to form the ionic compound $[O_2]^+[PtF_6]^-$. Knowing that the ionization energy of the oxygen molecule ($O_2 \longrightarrow O_2^+ + e^-$; IE = 1175 kJ/mol) is very close to IE_1 of xenon (1170 kJ/mol), Bartlett reasoned that PtF_6 might be able to oxidize xenon. Shortly thereafter, he prepared $XePtF_6$, an orange-yellow solid. Within a few months, the white crystalline XeF_2 and XeF_4 (Figure 14.33) were also prepared. In addition to its +2 and +4 oxidation states, Xe has the +6 state in several compounds, such as XeF_6, and the +8 state in the unstable oxide, XeO_4. A few compounds of Kr have also been made. The xenon fluorides react rapidly in water to form HF and various other products, including different xenon compounds.

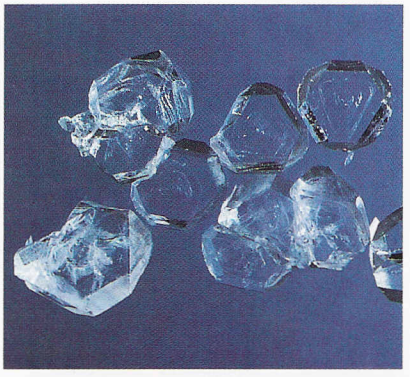

Figure 14.33 **Crystals of xenon tetrafluoride (XeF_4).**

Looking Backward and Forward: Groups 7A(17), 8A(18), and 1A(1)

With the disappearance of metallic behavior, the Group 7A(17) elements form a host of anions, covalent oxides, and oxoanions, which change oxidation states readily in a rich aqueous chemistry. The vigorous reactivity of the halogens is in stark contrast to the inertness of their 8A neighbors. Filled outer levels render the noble gas atoms largely inert, despite a limited ability to react with the most electronegative elements, fluorine and oxygen. The least reactive family in the periodic table stands between the two most reactive: the halogens, which need one more electron to fill their outer level, and the alkali metals, which need one fewer (Figure 14.34). As you know, atomic, physical, and chemical properties change dramatically from Group 8A(18) to Group 1A(1).

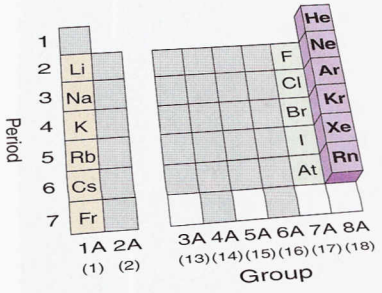

Figure 14.34 **Standing in Group 8A(18), looking backward at the halogens, Group 7A(17), and ahead to the alkali metals, Group 1A(1).**

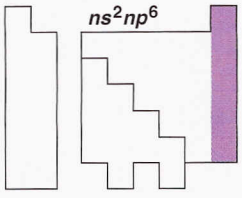
Group 8A(18): The Noble Gases

Key Atomic and Physical Properties

KEY
Atomic No.
Symbol
Atomic mass
Valence e^- configuration
Common oxidation states



GROUP 8A(18)

2 **He** 4.003 $1s^2$ **(none)**	10 **Ne** 20.18 $2s^22p^6$ **(none)**	18 **Ar** 39.95 $3s^23p^6$ **(none)**	36 **Kr** 83.80 $4s^24p^6$ **(+2)**	54 **Xe** 131.3 $5s^25p^6$ **(+8, +6, +4, +2)**	86 **Rn** (222) $6s^26p^6$ **(+2)**	
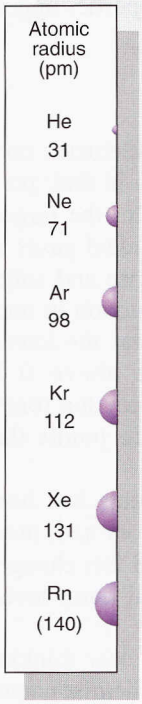
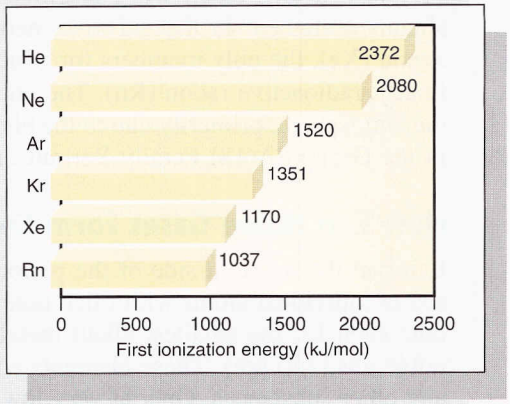
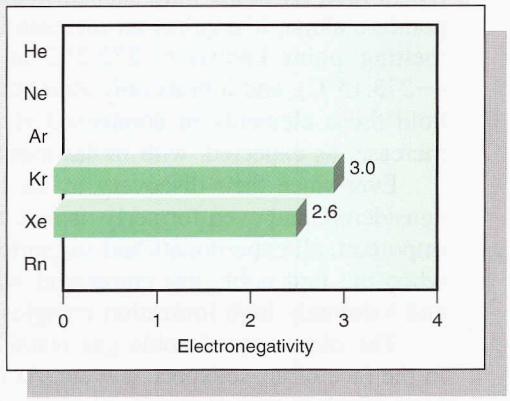
Atomic Properties



Group electron configuration is $1s^2$ for He and ns^2np^6 for the others. The valence shell is filled. Only Kr and Xe (and perhaps Rn) are known to form compounds. The more reactive Xe exhibits all even oxidation states (+2 to +8).

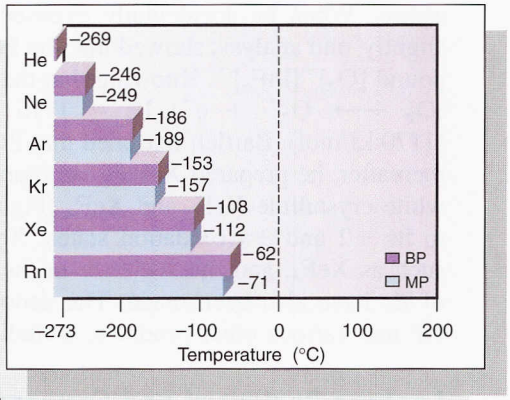


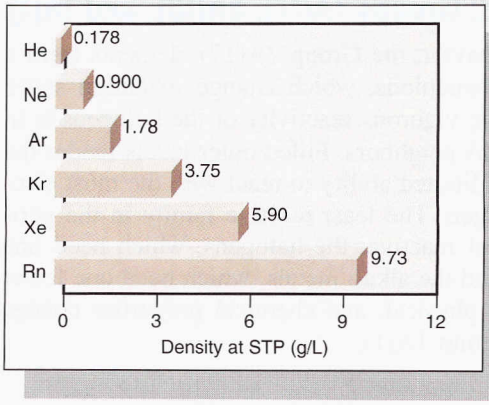
This group contains the smallest atoms with the highest IEs in their periods. Down the group, atomic size increases and IE decreases steadily. (EN values are given only for Kr and Xe.)



Physical Properties

Melting and boiling points of these gaseous elements are extremely low but increase down the group because of stronger dispersion forces. Note the extremely small liquid ranges.





Densities (at STP) increase steadily, as expected.

Chapter Perspective

Our excursion through the bonding and reactivity patterns of the elements has come full circle, but we've only been able to touch on some of the most important features. Clearly, the properties of the atoms and the resultant physical and chemical behaviors of the elements are magnificent testimony to nature's diversity. In Chapter 15, we continue with our theme of macroscopic behavior emerging from atomic properties in an investigation of the marvelously complex organic compounds of carbon. In Chapter 22, we revisit the most important main-group elements to see how they occur in nature and how we isolate and use them.

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section numbers appear in parentheses.

Understand These Concepts

Note: Many characteristic reactions appear in the "Important Reactions" section of each group's Family Portrait.

1. How hydrogen is similar to, yet different from, alkali metals and halogens; the differences between ionic, covalent, and metallic hydrides (Section 14.1)
2. Key horizontal trends in atomic properties, types of bonding, oxide acid-base properties, and redox behavior as the elements change from metals to nonmetals (Section 14.2)
3. How the ns^1 configuration accounts for the physical and chemical properties of the alkali metals (Section 14.3)
4. How small atomic size and limited number of valence orbitals account for the anomalous behavior of the Period 2 member of each group (see each section for details)
5. How the ns^2 configuration accounts for the key differences between Groups 1A(1) and 2A(2) (Section 14.4)
6. The basis of the three important diagonal relationships (Li/Mg, Be/Al, B/Si) (Sections 14.4 to 14.6)
7. How the presence of inner $(n-1)d$ electrons affects properties in Group 3A(13) (Section 14.5)
8. Patterns among larger members of Groups 3A(13) to 6A(16): two common oxidation states (inert-pair effect), lower state more important down the group, and more basic lower oxide (Sections 14.5 to 14.8)
9. How boron attains an octet of electrons (Section 14.5)
10. The effect of bonding on the physical behavior of Groups 4A(14) to 6A(16) (Sections 14.6 to 14.8)
11. Allotropism in carbon, phosphorus, and sulfur (Sections 14.6 to 14.8)
12. How atomic properties lead to catenation and multiple bonds in organic compounds (Section 14.6)
13. Structures and properties of the silicates and silicones (Section 14.6)
14. Patterns of behavior among hydrides and halides of Groups 5A(15) and 6A(16) (Sections 14.7 and 14.8)
15. The meaning of disproportionation (Section 14.7) and its importance in halogen aqueous chemistry (Section 14.9)
16. Structure and chemistry of the nitrogen oxides and oxoacids (Section 14.7)
17. Structure and chemistry of the phosphorus oxides and oxoacids (Section 14.7)
18. Dehydration-condensation reactions and polyphosphate structures (Section 14.7)
19. Structure and chemistry of the sulfur oxides and oxoacids (Section 14.8)
20. How the ns^2np^5 configuration accounts for halogen reactivity with metals (Section 14.9)
21. Why the oxidation states of an element change by two units (Section 14.9)
22. Structure and chemistry of the halogen oxides and oxoacids (Section 14.9)
23. How the ns^2np^6 configuration accounts for the relative inertness of the noble gases (Section 14.10)

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

Note: This set begins with problems based on material from the Interchapter.

Interchapter Review

Concept Review Questions

14.1 (a) Define the four atomic properties that are reviewed in the Interchapter.
(b) To what do the three parts of the electron configuration ($nl^{\#}$) correlate?
(c) Which part of the electron configuration is primarily associated with the size of the atom?
(d) What is the major distinction between the outer electron configurations within a group and those within a period?
(e) What correlation, if any, exists between the group number and the number of valence electrons?

14.2 (a) What trends, if any, exist for Z_{eff} across a period and down a group?
(b) How does Z_{eff} influence atomic size, IE_1, and EN across a period?

14.3 Iodine monochloride and elemental bromine have nearly the same molar mass and liquid density but very different boiling points.
(a) What molecular property is primarily responsible for this difference in boiling point? What atomic property gives rise to it? Explain.
(b) Which substance has a higher boiling point? Why?

14.4 How does the trend in atomic size differ from the trend in ionization energy? Explain.

14.5 How are bond energy, bond length, and reactivity related for similar compounds?

14.6 How are covalent and metallic bonding similar? How are they different?

14.7 If the leftmost element in a period combined with each of the others in the period, how would the type of bonding change from left to right? Explain in terms of atomic properties.

14.8 Why is rotation about the bond axis possible for single-bonded atoms but not double-bonded atoms?

14.9 Explain the horizontal irregularity in size of the most common ions of Period 3 elements.

14.10 Would you expect S^{2-} to be larger or smaller than Cl^-? Would you expect Mg^{2+} to be larger or smaller than Na^+? Explain.

14.11 (a) How does the type of bonding in element oxides correlate with the electronegativity of the elements?
(b) How does the acid-base behavior of element oxides correlate with the electronegativity of the elements?

14.12 (a) How does the metallic character of an element correlate with the *acidity* of its oxide?
(b) What trends, if any, exist in oxide *basicity* across a period and down a group?

14.13 How are atomic size, IE_1, and EN related to redox behavior of the elements in Groups 1A(1), 2A(2), 6A(16), and 7A(17)?

14.14 How do the physical properties of a network covalent solid and a molecular covalent solid differ? Why?

Skill-Building Exercises *(grouped in similar pairs)*

14.15 Rank the following elements in order of *increasing*
(a) atomic size: Ba, Mg, Sr
(b) IE_1: P, Na, Al
(c) EN: Br, Cl, Se
(d) number of valence electrons: Bi, Ga, Sn

14.16 Rank the following elements in order of *decreasing*
(a) atomic size: N, Si, P
(b) IE_1: Kr, K, Ar
(c) EN: In, Rb, I
(d) number of valence electrons: Sb, S, Cs

14.17 Which of the following pairs react to form *ionic* compounds: (a) Cl and Br; (b) Na and Br; (c) P and Se; (d) H and Ba?

14.18 Which of the following pairs react to form *covalent* compounds: (a) Be and C; (b) Sr and O; (c) Ca and Cl; (d) P and F?

14.19 Draw a Lewis structure for a compound with a bond order of 2 throughout the molecule.

14.20 Draw a Lewis structure for a polyatomic ion with a fractional bond order throughout the molecule.

14.21 Rank the following in order of *increasing* bond length: $SiCl_4$, CF_4, $GeBr_4$.

14.22 Rank the following in order of *decreasing* bond energy: NF_3, NI_3, NCl_3.

14.23 Rank the following in order of *increasing* radius:
(a) O^{2-}, F^-, Na^+ (b) S^{2-}, P^{3-}, Cl^-

14.24 Rank the following in order of *decreasing* radius:
(a) Ca^{2+}, K^+, Ga^{3+} (b) Br^-, Sr^{2+}, Rb^+

14.25 Rank O^-, O^{2-}, and O in order of *increasing* size.

14.26 Rank Tl^{3+}, Tl, and Tl^+ in order of *decreasing* size.

14.27 Which member of each pair gives the more *basic* solution in water: (a) CaO or SO_3; (b) BeO or BaO; (c) CO_2 or SO_2; (d) P_4O_{10} or K_2O? For the pair in part (a), write an equation for the dissolving of each oxide to support your answer.

14.28 Which member of each pair gives the more *acidic* solution in water: (a) CO_2 or SrO; (b) SnO or SnO_2; (c) Cl_2O or Na_2O; (d) SO_2 or MgO? For the pair in part (a), write an equation for the dissolving of each oxide to support your answer.

14.29 Which member of each pair has more *covalent* character in its bonds: (a) LiCl or KCl; (b) $AlCl_3$ or PCl_3; (c) NCl_3 or $AsCl_3$?

14.30 Which member of each pair has more *ionic* character in its bonds: (a) BeF_2 or CaF_2; (b) PbF_2 or PbF_4; (c) GeF_4 or PF_3?

14.31 Rank the following in order of *increasing*
(a) Melting point: Na, Si, Ar (b) ΔH_{fus}: Rb, Cs, Li

14.32 Rank the following in order of *decreasing*
(a) Boiling point: O_2, Br_2, As(*s*) (b) ΔH_{vap}: Cl_2, Ar, I_2

Hydrogen, the Simplest Atom

Concept Review Questions

14.33 Hydrogen has only one proton, but its IE_1 is much greater than that of lithium, which has three protons. Explain.

14.34 Sketch a periodic table, and label the areas containing elements that give rise to the three types of hydrides.

Skill-Building Exercises *(grouped in similar pairs)*

14.35 Draw Lewis structures for the following compounds, and predict which member of each pair will form hydrogen bonds:
(a) NF_3 or NH_3 (b) CH_3OCH_3 or CH_3CH_2OH

14.36 Draw Lewis structures for the following compounds, and predict which member of each pair will form hydrogen bonds:
(a) NH_3 or AsH_3 (b) CH_4 or H_2O

14.37 Complete and balance the following equations:
(a) An active metal reacting with acid,

$$Al(s) + HCl(aq) \longrightarrow$$

(b) A saltlike (alkali metal) hydride reacting with water,

$$LiH(s) + H_2O(l) \longrightarrow$$

14.38 Complete and balance the following equations:
(a) A saltlike (alkaline earth metal) hydride reacting with water,

$$CaH_2(s) + H_2O(l) \longrightarrow$$

(b) Reduction of a metal halide by hydrogen to form a metal,

$$PdCl_2(aq) + H_2(g) \longrightarrow$$

Problems in Context

14.39 Compounds such as $NaBH_4$, $Al(BH_4)_3$, and $LiAlH_4$ are complex hydrides used as reducing agents in many syntheses.
(a) Give the oxidation state of each element in these compounds.
(b) Write a Lewis structure for the polyatomic anion in $NaBH_4$, and predict its shape.

14.40 Unlike the F^- ion, which has an ionic radius close to 133 pm in all alkali metal fluorides, the ionic radius of H^- varies from 137 pm in LiH to 152 pm in CsH. Suggest an explanation for the large variability in the size of H^- but not F^-.

Trends Across the Periodic Table

Concept Review Questions

14.41 How does the maximum oxidation number vary across a period in the main groups? Is the pattern in Period 2 different?

14.42 What correlation, if any, exists for the Period 2 elements between group number and the number of covalent bonds the element typically forms? How is the correlation different for elements in Periods 3 to 6?

14.43 Each of the chemically active Period 2 elements forms stable compounds that have bonds to fluorine.
(a) What are the names and formulas of these compounds?
(b) Does ΔEN increase or decrease left to right?
(c) Does percent ionic character increase or decrease left to right?
(d) Draw Lewis structures for these compounds.

14.44 Period 6 is unusual in several ways.
(a) It is the longest period in the table. How many elements belong to Period 6? How many metals?
(b) It contains no metalloids. Where is the metal/nonmetal boundary in Period 6?

14.45 An element forms an oxide, E_2O_3, and a fluoride, EF_3.
(a) Of which two groups might E be a member?
(b) How does the group to which E belongs affect the properties of the oxide and the fluoride?

14.46 Fluorine lies between oxygen and neon in Period 2. Whereas atomic sizes and ionization energies of these three elements change smoothly, their electronegativities display a dramatic change. What is this change, and how do their electron configurations explain it?

Group 1A(1): The Alkali Metals

Concept Review Questions

14.47 Lithium salts are often much less soluble in water than the corresponding salts of other alkali metals. For example, at 18°C, the concentration of a saturated LiF solution is 1.0×10^{-2} *M*, whereas that of a saturated KF solution is 1.6 *M*. How would you explain this behavior?

14.48 The alkali metals play virtually the same general chemical role in all their reactions.
(a) What is this role?
(b) How is it based on atomic properties?
(c) Using sodium, write two balanced equations that illustrate this role.

14.49 How do atomic properties account for the low densities of the Group 1A(1) elements?

Skill-Building Exercises *(grouped in similar pairs)*

14.50 Each of the following properties shows regular trends in Group 1A(1). Predict whether each increases or decreases *down* the group: (a) density; (b) ionic size; (c) E—E bond energy; (d) IE_1; (e) magnitude of ΔH_{hydr} of E^+ ion.

14.51 Each of the following properties shows regular trends in Group 1A(1). Predict whether each increases or decreases *up* the group: (a) melting point; (b) E—E bond length; (c) hardness; (d) molar volume; (e) lattice energy of EBr.

14.52 Write a balanced equation for the formation from its elements of sodium peroxide, an industrial bleach.

14.53 Write a balanced equation for the formation of rubidium bromide through a reaction of a strong acid and a strong base.

Problems in Context

14.54 Although the alkali metal halides can be prepared directly from the elements, the far less expensive industrial route is treatment of the carbonate or hydroxide with aqueous hydrohalic acid (HX) followed by recrystallization. Balance the reaction between potassium carbonate and aqueous hydriodic acid.

14.55 Lithium forms several useful organolithium compounds. Calculate the mass percent of Li in the following:
(a) Lithium stearate ($C_{17}H_{35}COOLi$), a water-resistant grease used in cars because it does not harden at cold temperatures
(b) Butyllithium (LiC_4H_9), a reagent in organic syntheses

Group 2A(2): The Alkaline Earth Metals

Concept Review Questions

14.56 How do Groups 1A(1) and 2A(2) compare with respect to reaction of the metals with water?

14.57 Alkaline earth metals are involved in two key diagonal relationships in the periodic table. (a) Give the two pairs of elements in these diagonal relationships. (b) For each pair, cite two similarities that demonstrate the relationship. (c) Why are the members of each pair so similar in behavior?

14.58 The melting points of alkaline earth metals are many times higher than those of the alkali metals. Explain this difference on the basis of atomic properties. Name three other physical properties for which Group 2A(2) metals have higher values than the corresponding 1A(1) metals.

Skill-Building Exercises *(grouped in similar pairs)*

14.59 Write a balanced equation for each reaction:
(a) "Slaking" of lime (treatment with water)
(b) Combustion of calcium in air

14.60 Write a balanced equation for each reaction:
(a) Thermal decomposition of witherite (barium carbonate)
(b) Neutralization of stomach acid (HCl) by milk of magnesia (magnesium hydroxide)

Problems in Context

14.61 Lime (CaO) is one of the most abundantly produced chemicals in the world. Write balanced equations for
(a) The preparation of lime from natural sources
(b) The use of slaked lime to remove SO_2 from flue gases
(c) The reaction of lime with arsenic acid (H_3AsO_4) to manufacture the insecticide calcium arsenate
(d) The regeneration of NaOH in the paper industry by reaction of lime with aqueous sodium carbonate

14.62 In some reactions, Be behaves like a typical alkaline earth metal; in others, it does not. Complete and balance the following equations:
(a) $BeO(s) + H_2O(l) \longrightarrow$
(b) $BeCl_2(l) + Cl^-(l;$ from molten NaCl$) \longrightarrow$
In which reaction does Be behave like the other Group 2A(2) members?

Group 3A(13): The Boron Family

Concept Review Questions

14.63 How do the transition metals in Period 4 affect the pattern of ionization energies in Group 3A(13)? How does this pattern compare with that in Group 3B(3)?

14.64 How do the acidities of aqueous solutions of Tl_2O and Tl_2O_3 compare with each other? Explain.

14.65 Despite the expected decrease in atomic size, there is an unexpected drop in the first ionization energy between Groups 2A(2) and 3A(13) in Periods 2 through 4. Explain this pattern in terms of electron configurations and orbital energies.

14.66 Many compounds of Group 3A(13) elements have chemical behavior that reflects an electron deficiency.
(a) What is the meaning of *electron deficiency?*
(b) Give two reactions that illustrate this behavior.

14.67 Boron's chemistry is not typical of its group.
(a) Cite three ways in which boron and its compounds differ significantly from the other 3A(13) members and their compounds.
(b) What is the reason for these differences?

Skill-Building Exercises *(grouped in similar pairs)*

14.68 Rank the following oxides in order of increasing aqueous *acidity:* Ga_2O_3, Al_2O_3, In_2O_3.

14.69 Rank the following hydroxides in order of increasing aqueous *basicity:* $Al(OH)_3$, $B(OH)_3$, $In(OH)_3$.

14.70 Thallium forms the compound TlI_3. What is the apparent oxidation state of Tl in this compound? Given that the anion is I_3^-, what is the actual oxidation state of Tl? Draw the shape of the anion, giving its VSEPR class and bond angles. Propose a reason why the compound does not exist as $(Tl^{3+})(I^-)_3$.

14.71 Very stable dihalides of the Group 3A(13) metals are known. What is the apparent oxidation state of Ga in $GaCl_2$? Given that $GaCl_2$ consists of a Ga^+ cation and a $GaCl_4^-$ anion, what are the actual oxidation states of Ga? Draw the shape of the anion, giving its VSEPR class and bond angles.

Problems in Context

14.72 Give the name and symbol or formula of a Group 3A(13) element or compound that fits each description or use:
(a) Component of heat-resistant (Pyrex-type) glass
(b) Manufacture of high-speed computer chips
(c) Largest temperature range for liquid state of an element
(d) Elementary substance with three-center, two-electron bonds
(e) Metal protected from oxidation by adherent oxide coat
(f) Mild antibacterial agent (e.g., for eye infections)
(g) Toxic metal that lies between two other toxic metals

14.73 Indium (In) reacts with HCl to form a diamagnetic solid with the formula $InCl_2$.
(a) Write condensed electron configurations for In, In^+, In^{2+}, and In^{3+}.
(b) Which of these species is (are) diamagnetic and which paramagnetic?
(c) What is the apparent oxidation state of In in $InCl_2$?
(d) Given your answers to parts (b) and (c), explain how $InCl_2$ can be diamagnetic.

14.74 Use VSEPR theory to draw structures, with ideal bond angles, for boric acid and the anion it forms in reaction with water.

14.75 Boron nitride (BN) has a structure similar to graphite, but is a white insulator rather than a black conductor. It is synthesized by heating diboron trioxide with ammonia at about 1000°C.
(a) Write a balanced equation for the formation of BN; water forms also.
(b) Calculate ΔH^0_{rxn} for the production of BN (ΔH^0_f of BN is −254 kJ/mol).
(c) Boron is obtained from the mineral borax, $Na_2B_4O_7 \cdot 10H_2O$. How much borax is needed to produce 1.0 kg of BN, assuming 72% yield?

Group 4A(14): The Carbon Family

Concept Review Questions

14.76 How does the basicity of SnO_2 in water compare with that of CO_2? Explain.

14.77 Nearly every compound of silicon has the element in the +4 oxidation state. In contrast, most compounds of lead have the element in the +2 state.
(a) What general observation do these facts illustrate?
(b) Explain in terms of atomic and molecular properties.
(c) Give an analogous example from Group 3A(13).

14.78 The sum of IE_1 through IE_4 for Group 4A(14) elements shows a decrease from C to Si, a slight increase from Si to Ge, a decrease from Ge to Sn, and an increase from Sn to Pb.
(a) What is the expected trend for ionization energy down a group?
(b) Suggest a reason for the deviations from the expected trend.
(c) Which group might show even greater deviations?

14.79 Give explanations for the large drops in melting point from C to Si and from Ge to Sn.

14.80 What is an allotrope? Name two Group 4A(14) elements that exhibit allotropism, and name two of their allotropes.

14.81 Even though EN values vary relatively little down Group 4A(14), the elements change from nonmetal to metal. Explain.

14.82 How do atomic properties account for the enormous number of carbon compounds? Why don't other Group 4A(14) elements behave similarly?

Skill-Building Exercises *(grouped in similar pairs)*

14.83 Draw a Lewis structure for
(a) The cyclic silicate ion $Si_4O_{12}^{8-}$
(b) A cyclic hydrocarbon with formula C_4H_8

14.84 Draw a Lewis structure for
(a) The cyclic silicate ion $Si_6O_{18}^{12-}$
(b) A cyclic hydrocarbon with formula C_6H_{12}

14.85 Show three units of a linear silicone polymer made from $(CH_3)_2Si(OH)_2$ with some $(CH_3)_3SiOH$ added to end the chain.

14.86 Show two chains of three units each of a sheet silicone polymer made from $(CH_3)_2Si(OH)_2$ with $CH_3Si(OH)_3$ added to crosslink the chains.

Problems in Context

14.87 Zeolite A, $Na_{12}[(AlO_2)_{12}(SiO_2)_{12}]\cdot 27H_2O$, is used to soften water by replacing Ca^{2+} and Mg^{2+} with Na^+. A source of hard water is 4.5×10^{-3} *M* Ca^{2+} and 9.2×10^{-4} *M* Mg^{2+}, and a pipe delivers 25,000 L of this hard water per day. What mass (in kg) of zeolite A is needed to soften a week's supply of the water? (Assume zeolite A loses its capacity to exchange ions when 85 mol % of its Na^+ has been lost.)

14.88 Give the name and symbol or formula of a Group 4A(14) element or compound that fits each description or use:
(a) Hardest known substance
(b) Medicinal antacid
(c) Atmospheric gas implicated in the greenhouse effect
(d) Waterproofing polymer based on silicon
(e) Synthetic abrasive composed entirely of Group 4A elements
(f) Product formed when coke burns in a limited supply of air
(g) Toxic metal found in plumbing and paints

14.89 One similarity between B and Si is the explosive combustion of their hydrides in air. Write balanced equations for the combustion of B_2H_6 and of Si_4H_{10}.

Group 5A(15): The Nitrogen Family

Concept Review Questions

14.90 Which Group 5A(15) elements form trihalides? Pentahalides? Explain.

14.91 As you move down Group 5A(15), the melting points of the elements increase and then decrease. Explain.

14.92 (a) What is the range of oxidation states shown by the elements of Group 5A(15) as you move down the group? (b) How does this range illustrate the general rule for the range of oxidation states in groups on the right side of the periodic table?

14.93 Bismuth(V) compounds are such powerful oxidizing agents that they have not been prepared in pure form. How is this fact consistent with the location of Bi in the periodic table?

14.94 Rank the following oxides in order of increasing acidity in water: Sb_2O_3, Bi_2O_3, P_4O_{10}, Sb_2O_5.

Skill-Building Exercises *(grouped in similar pairs)*

14.95 Assuming acid strength relates directly to electronegativity of the central atom, rank H_3PO_4, HNO_3, and H_3AsO_4 in order of *increasing* acid strength.

14.96 Assuming acid strength relates directly to number of O atoms bonded to the central atom, rank $H_2N_2O_2$ [or $(HON)_2$]; HNO_3 (or $HONO_2$); and HNO_2 (or HONO) in order of *decreasing* acid strength.

14.97 Complete and balance the following:
(a) $As(s)$ + excess $O_2(g)$ ⟶
(b) $Bi(s)$ + excess $F_2(g)$ ⟶
(c) $Ca_3As_2(s) + H_2O(l)$ ⟶

14.98 Complete and balance the following:
(a) Excess $Sb(s) + Br_2(l)$ ⟶
(b) $HNO_3(aq) + MgCO_3(s)$ ⟶
(c) $K_2HPO_4(s) \xrightarrow{\Delta}$

14.99 Complete and balance the following:
(a) $N_2(g) + Al(s) \xrightarrow{\Delta}$
(b) $PF_5(g) + H_2O(l)$ ⟶

14.100 Complete and balance the following:
(a) $AsCl_3(l) + H_2O(l)$ ⟶
(b) $Sb_2O_3(s) + NaOH(aq)$ ⟶

14.101 Based on the relative sizes of F and Cl, predict the structure of PF_2Cl_3.

14.102 Use the VSEPR model to predict the structure of the cyclic ion $P_3O_9^{3-}$.

Problems in Context

14.103 The pentafluorides of the larger members of Group 5A(15) have been prepared, but N can have only eight electrons. A claim has been made that, at low temperatures, a compound with the empirical formula NF_5 forms. Draw a possible Lewis structure for this compound. (*Hint:* NF_5 is ionic.)

14.104 Give the name and symbol or formula of a Group 5A(15) element or compound that fits each description or use:
(a) Hydride produced at multimillion-ton level
(b) Element(s) essential in plant nutrition
(c) Hydride used to manufacture rocket propellants and drugs
(d) Odd-electron molecule (two examples)
(e) Amphoteric hydroxide with a 5A element in its +3 state
(f) Phosphorus-containing water softener
(g) Element that is an electrical conductor

14.105 In addition to those in Table 14.3, other less stable nitrogen oxides exist. Draw a Lewis structure for each of the following:
(a) N_2O_2, a dimer of nitrogen monoxide with an N—N bond
(b) N_2O_2, a dimer of nitrogen monoxide with no N—N bond
(c) N_2O_3 with no N—N bond
(d) NO^+ and NO_3^-, products of the ionization of liquid N_2O_4

14.106 Nitrous oxide (N_2O), the "laughing gas" used as an anesthetic by dentists, is made by thermal decomposition of solid NH_4NO_3. Write a balanced equation for this reaction. What are the oxidation states of N in NH_4NO_3 and in N_2O?

14.107 Write balanced equations for the thermal decomposition of potassium nitrate (O_2 is also formed in both cases): (a) at low temperature to the nitrite; (b) at high temperature to the metal oxide and nitrogen.

Group 6A(16): The Oxygen Family

Concept Review Questions

14.108 Rank the following in order of increasing electrical conductivity, and explain your ranking: Po, S, Se.

14.109 The oxygen and nitrogen families have some obvious similarities and differences.
(a) State two general physical similarities between Group 5A(15) and 6A(16) elements.
(b) State two general chemical similarities between Group 5A(15) and 6A(16) elements.
(c) State two chemical similarities between P and S.
(d) State two physical similarities between N and O.
(e) State two chemical differences between N and O.

14.110 A molecular property of the Group 6A(16) hydrides changes abruptly down the group. This change has been explained in terms of a change in orbital hybridization.
(a) Between what periods does the change occur?
(b) What is the change in the molecular property?
(c) What is the change in hybridization?
(d) What other group displays a similar change?

Skill-Building Exercises *(grouped in similar pairs)*

14.111 Complete and balance the following:
(a) $NaHSO_4(aq) + NaOH(aq) \longrightarrow$
(b) $S_8(s) +$ excess $F_2(g) \longrightarrow$
(c) $FeS(s) + HCl(aq) \longrightarrow$
(d) $Te(s) + I_2(s) \longrightarrow$

14.112 Complete and balance the following:
(a) $H_2S(g) + O_2(g) \longrightarrow$
(b) $SO_3(g) + H_2O(l) \longrightarrow$
(c) $SF_4(g) + H_2O(l) \longrightarrow$
(d) $Al_2Se_3(s) + H_2O(l) \longrightarrow$

14.113 Is each oxide basic, acidic, or amphoteric in water: (a) SeO_2; (b) N_2O_3; (c) K_2O; (d) BeO; (e) BaO?

14.114 Is each oxide basic, acidic, or amphoteric in water: (a) MgO; (b) N_2O_5; (c) CaO; (d) CO_2; (e) TeO_2?

14.115 Rank the following hydrides in order of *increasing* acid strength: H_2S, H_2O, H_2Te.

14.116 Rank the following species in order of *decreasing* acid strength: H_2SO_4, H_2SO_3, HSO_3^-.

Problems in Context

14.117 Describe the physical changes observed when solid sulfur is heated from room temperature to 440°C and then poured quickly into cold water. Explain the molecular changes responsible for the macroscopic changes.

14.118 Give the name and symbol or formula of a Group 6A(16) element or compound that fits each description or use:
(a) Unreactive gas used as an electrical insulator
(b) Unstable allotrope of oxygen
(c) Oxide having sulfur in the same oxidation state as in sulfuric acid
(d) Air pollutant produced by burning sulfur-containing coal
(e) Powerful dehydrating agent
(f) Compound used in solution in the photographic process
(g) Gas in trace amounts in air that tarnishes silver

14.119 Give the oxidation state of sulfur in (a) S_8; (b) SF_4; (c) SF_6; (d) H_2S; (e) FeS_2; (f) H_2SO_4; (g) $Na_2S_2O_3 \cdot 5H_2O$.

14.120 Disulfur decafluoride is intermediate in reactivity between SF_4 and SF_6. It disproportionates at 150°C to these monosulfur fluorides. Write a balanced equation for this reaction, and give the oxidation state of S in each compound.

Group 7A(17): The Halogens

Concept Review Questions

14.121 (a) What is the physical state and color of each of the halogens at STP?
(b) Explain the change in physical state down Group 7A(17) in terms of molecular properties.

14.122 (a) What are the common oxidation states of the halogens?
(b) Give an explanation based on electron configuration for the range and values of the oxidation states of chlorine.
(c) Why is fluorine an exception to the pattern of oxidation states found for the other group members?

14.123 How many electrons does a halogen atom need to complete its octet? Give examples of the ways a Cl atom can do so.

14.124 Select the stronger bond in each pair:
(a) Cl—Cl or Br—Br
(b) Br—Br or I—I
(c) F—F or Cl—Cl. Why doesn't the F—F bond strength follow the group trend?

14.125 In addition to interhalogen compounds, many interhalogen ions exist. Would you expect interhalogen ions with a 1+ or a 1− charge to have an even or odd number of atoms? Explain.

14.126 (a) A halogen (X_2) disproportionates in base in several steps to X^- and XO_3^-. Write the overall equation for the disproportionation of Br_2 to Br^- and BrO_3^-.
(b) Write a balanced equation for the reaction of ClF_5 with aqueous base (see the reaction of BrF_5 shown on p. 602).

Skill-Building Exercises *(grouped in similar pairs)*

14.127 Complete and balance the following equations. If no reaction occurs, write NR:
(a) $Rb(s) + Br_2(l) \longrightarrow$
(b) $I_2(s) + H_2O(l) \longrightarrow$
(c) $Br_2(l) + I^-(aq) \longrightarrow$
(d) $CaF_2(s) + H_2SO_4(l) \longrightarrow$

14.128 Complete and balance the following equations. If no reaction occurs, write NR:
(a) $H_3PO_4(l) + NaI(s) \longrightarrow$
(b) $Cl_2(g) + I^-(aq) \longrightarrow$
(c) $Br_2(l) + Cl^-(aq) \longrightarrow$
(d) $ClF(g) + F_2(g) \longrightarrow$

14.129 Rank the following acids in order of *increasing* acid strength: HClO, $HClO_2$, HBrO, HIO.

14.130 Rank the following acids in order of *decreasing* acid strength: $HBrO_3$, $HBrO_4$, HIO_3, $HClO_4$.

Problems in Context

14.131 Give the name and symbol or formula of a Group 7A(17) element or compound that fits each description or use:
(a) Used in etching glass
(b) Naturally occurring source (ore) of fluorine
(c) Oxide used in bleaching paper pulp and textiles
(d) Weakest hydrohalic acid
(e) Compound used as food additive to prevent goiter (thyroid disorder)
(f) Element that is produced in the largest quantity
(g) Organic chloride used to make plastics

14.132 An industrial chemist treats solid NaCl with concentrated H_2SO_4 and obtains gaseous HCl and $NaHSO_4$. When she substitutes solid NaI for NaCl, gaseous H_2S, solid I_2, and S_8 are obtained but no HI.
(a) What type of reaction did the H_2SO_4 undergo with NaI?
(b) Why does NaI, but not NaCl, cause this type of reaction?
(c) To produce HI(g) by the reaction of NaI with an acid, how does the acid have to differ from sulfuric acid?

14.133 Rank the halogens Cl_2, Br_2, and I_2 in order of increasing oxidizing strength based on their products with metallic Re: $ReCl_6$, $ReBr_5$, ReI_4. Explain your ranking.

Group 8A(18): The Noble Gases

14.134 Which noble gas is the most abundant in the universe? In Earth's atmosphere?

14.135 What oxidation states does Xe show in its compounds?

14.136 Why do the noble gases have such low boiling points?

14.137 Explain why Xe, and to a limited extent Kr, form compounds, whereas He, Ne, and Ar do not.

14.138 (a) Why do stable xenon fluorides have an even number of F atoms? (b) Why do the ionic species XeF_3^+ and XeF_7^- have odd numbers of F atoms? (c) Predict the shape of XeF_3^+.

Comprehensive Problems

14.139 Sodium hydride is used to prepare sodium dithionate ($Na_2S_2O_4$), used in bleaching paper pulp:

$$NaH(s) + SO_2(l) \longrightarrow Na_2S_2O_4(s) + H_2(g)$$

(a) Balance the equation, and give the O.N. of each element.
(b) How many liters of hydrogen gas measured at 758 torr and −45°C can form when exactly 1 metric ton of NaH reacts with 1 metric ton of SO_2?

14.140 Given the following information,

$$H^+(g) + H_2O(g) \longrightarrow H_3O^+(g) \qquad \Delta H = -720 \text{ kJ}$$
$$H^+(g) + H_2O(l) \longrightarrow H_3O^+(aq) \qquad \Delta H = -1090 \text{ kJ}$$
$$H_2O(l) \longrightarrow H_2O(g) \qquad \Delta H = 40.7 \text{kJ}$$

calculate the heat of solution of the hydronium ion:

$$H_3O^+(g) \xrightarrow{H_2O} H_3O^+(aq)$$

14.141 The electronic transition in Na from $3p^1$ to $3s^1$ gives rise to a bright yellow-orange emission at 589.2 nm. What is the energy of this transition?

14.142 Unlike other Group 2A(2) metals, beryllium reacts like aluminum and zinc with concentrated aqueous base to release hydrogen gas and form oxoanions of formula $M(OH)_4^{n-}$. Write equations for the reactions of these three metals with NaOH.

14.143 Just as boron nitride is isoelectronic with carbon, other compounds of Groups 3A(13) and 5A(15) are isoelectronic with elements in Group 4A(14). What element is isoelectronic with (a) aluminum phosphide; (b) gallium arsenide?

14.144 Cyclopropane (C_3H_6), the smallest cyclic hydrocarbon, is reactive for the same reason white phosphorus is. Use bond properties and valence bond theory to explain its high reactivity.

14.145 Thionyl chloride ($SOCl_2$) is a sulfur oxohalide used industrially to dehydrate metal halide hydrates.
(a) Write a balanced equation for its reaction with magnesium chloride hexahydrate, in which SO_2 and HCl form along with the metal halide.
(b) Draw a Lewis structure of $SOCl_2$ with minimal formal charges.

14.146 The main reason alkali metal dihalides (MX_2) do *not* form is the high IE_2 of the metal.
(a) Why is IE_2 so high for alkali metals?
(b) The IE_2 for Cs is 2255 kJ/mol, low enough for CsF_2 to form exothermically ($\Delta H_f^0 = -125$ kJ/mol). This compound cannot be synthesized, however, because CsF forms with a much greater release of heat ($\Delta H_f^0 = -530$ kJ/mol). Thus, the breakdown of CsF_2 to CsF happens readily. Write the equation for this breakdown, and calculate the heat of reaction per mole of CsF.

14.147 Semiconductors made from elements in Groups 3A(13) and 5A(15) are typically prepared by direct reaction of the elements at high temperature. An engineer treats 32.5 g of molten gallium with 20.4 L of white phosphorus vapor at 515 K and 195 kPa. If purification losses are 7.2% by mass, how many grams of gallium phosphide will be prepared?

14.148 Two substances with empirical formula HNO are hyponitrous acid ($\mathcal{M}$ = 62.04 g/mol) and nitroxyl ($\mathcal{M}$ = 31.02 g/mol).
(a) What is the molecular formula of each species?
(b) For each species, draw the Lewis structure having the lowest formal charges. (*Hint:* Hyponitrous acid has an N=N bond.)
(c) Predict the shape around the N atoms of each species.
(d) When hyponitrous acid loses two protons, it forms the hyponitrite ion. Draw *cis* and *trans* forms of this ion.

14.149 The species CO, CN^-, and C_2^{2-} are isoelectronic.
(a) Draw their Lewis structures.
(b) Draw their MO diagrams (assume $2s$-$2p$ mixing, as in N_2), and give the bond order and electron configuration for each.

14.150 The Ostwald process is a series of three reactions used for the industrial production of nitric acid from ammonia.
(a) Write a series of balanced equations for the Ostwald process.
(b) If NO is *not* recycled, how many moles of NH_3 are consumed per mole of HNO_3 produced?
(c) In a typical industrial unit, the process is very efficient, with a 96% yield for the first step. Assuming 100% yields for the subsequent steps, what volume of nitric acid (60.% by mass; d = 1.37 g/mL) can be prepared for each cubic meter of a gas mixture that is 90.% air and 10.% NH_3 by volume at the industrial conditions of 5.0 atm and 850.°C?

14.151 Buckminsterfullerene (C_{60}) is a soccer-ball–shaped molecule with a C atom at each vertex. It has a face-centered cubic unit cell that contains 240 C atoms and a density of only 1.693 g/cm^3, less than half that of diamond. Calculate the volume and edge length of the unit cell, and suggest a reason for the low density despite the closest packing.

14.152 Perhaps surprisingly, some pure liquid interhalogens that contain fluorine have high electrical conductivity. The explanation is that one molecule transfers a fluoride ion to another molecule. Write the equation that would explain the high electrical conductivity of bromine trifluoride.

14.153 All common plant fertilizers contain nitrogen compounds. Determine the mass % of N in (a) ammonia; (b) ammonium nitrate; (c) ammonium hydrogen phosphate.

14.154 Producer gas is a fuel formed by passing air over red-hot coke (amorphous carbon). It consists of approximately 25% CO, 5.0% CO_2, and 70.% N_2 by mass. What mass of producer gas can be formed from 1.75 metric tons of coke, assuming an 87% yield?

14.155 Gaseous F_2 reacts with water to form HF and O_2. In NaOH solution, F_2 forms F^-, water, and oxygen difluoride (OF_2), a highly toxic gas and powerful oxidizing agent. The OF_2 reacts with excess OH^-, forming O_2, water, and F^-.

(a) For each reaction, write a balanced equation, give the oxidation state of O in all compounds, and identify the oxidizing and reducing agents.

(b) Draw a Lewis structure for OF_2 and predict the molecule's shape.

14.156 What is a disproportionation reaction, and which of the following fit the description?

(a) $I_2(s) + KI(aq) \longrightarrow KI_3(aq)$

(b) $2ClO_2(g) + H_2O(l) \longrightarrow HClO_3(aq) + HClO_2(aq)$

(c) $Cl_2(g) + 2NaOH(aq) \longrightarrow NaCl(aq) + NaClO(aq) + H_2O(l)$

(d) $NH_4NO_2(s) \longrightarrow N_2(g) + 2H_2O(g)$

(e) $3MnO_4^{2-}(aq) + 2H_2O(l) \longrightarrow 2MnO_4^-(aq) + MnO_2(s) + 4OH^-(aq)$

(f) $3AuCl(s) \longrightarrow AuCl_3(s) + 2Au(s)$

14.157 Explain the following observations:

(a) In reactions with Cl_2, phosphorus forms PCl_5 in addition to the expected PCl_3, but nitrogen forms only NCl_3.

(b) Carbon tetrachloride is unreactive toward water, but silicon tetrachloride reacts rapidly and completely. (To give what?)

(c) The sulfur-oxygen bond in SO_4^{2-} is shorter than expected for an S—O single bond.

(d) Chlorine forms ClF_3 and ClF_5, but ClF_4 is unknown.

14.158 Which group(s) of the periodic table is (are) described by each of the following general statements?

(a) The elements form neutral compounds of VSEPR class AX_3E.

(b) The free elements are strong oxidizing agents and form monatomic ions and oxoanions.

(c) The valence electron configuration allows the atoms to form compounds by combining with two atoms that donate one electron each.

(d) The free elements are strong reducing agents, show only one nonzero oxidation state, and form mainly ionic compounds.

(e) The elements can form stable compounds with only three bonds, but as a central atom, they can accept a pair of electrons from a fourth atom without expanding their valence shell.

(f) Only larger members of the group are chemically active.

14.159 Diiodine pentaoxide (I_2O_5) was discovered by Joseph Gay-Lussac in 1813, but its structure was unknown until 1970! Like Cl_2O_7, it can be prepared by the dehydration-condensation of the corresponding oxoacid.

(a) Name the precursor oxoacid, write a reaction for formation of the oxide, and draw a likely Lewis structure.

(b) Data show that the bonds to the terminal O are shorter than the bonds to the bridging O. Why?

(c) I_2O_5 is one of the few chemicals that can oxidize CO rapidly and completely; elemental iodine forms in the process. Write a balanced equation for this reaction.

14.160 An important starting material for the manufacture of polyphosphazenes is the cyclic molecule $(NPCl_2)_3$. The molecule has a symmetrical six-membered ring of alternating N and P atoms, with the Cl atoms bonded to the P atoms. The nitrogen-phosphorus bond length is significantly less than that expected for an N—P single bond.

(a) Draw a likely Lewis structure for the molecule.

(b) How many lone pairs of electrons do the ring atoms have?

(c) What is the order of the nitrogen-phosphorus bond?

14.161 Potassium fluotitanate (K_2TiF_6), a starting material for producing other titanium salts, is made by dissolving titanium(IV) oxide in concentrated HF, adding aqueous KF, and then heating to dryness to drive off excess HF. The impure solid is recrystallized by dissolving in hot water and then cooling to 0°C, which leaves excess KF in solution. For the reaction of 5.00 g of TiO_2, 250. mL of hot water is used to recrystallize the product. How many grams of purified K_2TiF_6 are obtained? (Solubility of K_2TiF_6 in water at 0°C is 0.60 g/100 mL.)

14.162 Bromine monofluoride (BrF) disproportionates to bromine gas and bromine tri- and pentafluorides. Use the following to find ΔH^0_{rxn} for the decomposition of BrF to its elements:

$$3BrF(g) \longrightarrow Br_2(g) + BrF_3(l) \qquad \Delta H_{rxn} = -125.3 \text{ kJ}$$

$$5BrF(g) \longrightarrow 2Br_2(g) + BrF_5(l) \qquad \Delta H_{rxn} = -166.1 \text{ kJ}$$

$$BrF_3(l) + F_2(g) \longrightarrow BrF_5(l) \qquad \Delta H_{rxn} = -158.0 \text{ kJ}$$

14.163 Account for the following facts:

(a) Ca^{2+} and Na^+ have very nearly the same radii.

(b) CaF_2 is insoluble in water, but NaF is quite soluble.

(c) Molten $BeCl_2$ is a poor electrical conductor, whereas molten $CaCl_2$ is an excellent one.

14.164 Cake alum (aluminum sulfate) is used as a *flocculating agent* in water purification. The "floc" is a gelatinous precipitate of aluminum hydroxide that carries out of solution small suspended particles and bacteria for removal by filtration.

(a) The hydroxide is formed by the reaction of the aluminum ion with water. Write the equation for this reaction.

(b) The acidity from this reaction is partially neutralized by the sulfate ion. Write an equation for this reaction.

14.165 Carbon tetrachloride is made by passing Cl_2 in the presence of a catalyst through liquid CS_2 near its boiling point. Disulfur dichloride (S_2Cl_2) also forms, in addition to the by-products SCl_2 and CCl_3SCl. How many grams of CS_2 reacted if excess Cl_2 yielded 50.0 g of CCl_4 and 0.500 g of CCl_3SCl? Is it possible to determine how much S_2Cl_2 and SCl_2 also formed? Explain.

14.166 H_2 may act as a reducing agent or an oxidizing agent, depending on the substance reacting with it. Using, in turn, sodium or chlorine as the other reactant, write balanced equations for the two reactions, and characterize the redox role of hydrogen.

14.167 P_4 is prepared by heating phosphate rock [principally $Ca_3(PO_4)_2$] with sand and coke:

$$Ca_3(PO_4)_2(s) + SiO_2(s) + C(s) \longrightarrow CaSiO_3(s) + CO(g) + P_4(g) \text{ [unbalanced]}$$

How many kilograms of phosphate rock are needed to produce 315 mol of P_4, assuming that the conversion is 90.% efficient?

14.168 Assume you can use either NH_4NO_3 or N_2H_4 as fertilizer. Which contains more moles of N per mole of compound? Which contains the higher mass of N per gram of compound?

14.169 From its formula, one might expect CO to be quite polar, but its dipole moment is actually low (0.11 D).
(a) Draw the Lewis structure for CO.
(b) Calculate the formal charges.
(c) Based on your answers to parts (a) and (b), explain why the dipole moment is so low.

14.170 In addition to Al_2Cl_6, aluminum forms other species with bridging halide ions to two aluminum atoms. One such species is the ion $Al_2Cl_7^-$. The ion is symmetrical, with a 180° Al—Cl—Al bond angle.
(a) What orbitals does Al use to bond with the Cl atoms?
(b) What is the shape around each Al?
(c) What is the hybridization of the central Cl?
(d) What do the shape and hybridization suggest about the presence of lone pairs of electrons on the central Cl?

14.171 When an alkaline earth carbonate is heated, it releases CO_2, leaving the metal oxide. The temperature at which each Group 2A carbonate yields a CO_2 partial pressure of 1 atm is

Carbonate	Temperature (°C)
$MgCO_3$	542
$CaCO_3$	882
$SrCO_3$	1155
$BaCO_3$	1360

(a) Suggest a reason for this trend.
(b) Mixtures of $CaCO_3$ and MgO are used to absorb dissolved silicates from boiler water. How would you prepare a mixture of $CaCO_3$ and MgO from dolomite, which contains $CaCO_3$ and $MgCO_3$?

14.172 The bond angles in the nitrite ion, nitrogen dioxide, and the nitronium ion (NO_2^+) are 115°, 134°, and 180°, respectively. Explain these values using Lewis structures and VSEPR theory.

14.173 A common method for producing a gaseous hydride is to treat a salt containing the anion of the volatile hydride with a strong acid.
(a) Write an equation for each of the following examples: (1) the production of HF from CaF_2; (2) the production of HCl from NaCl; (3) the production of H_2S from FeS.
(b) In some cases even a weak acid such as water will suffice if the anion of the salt has a sufficiently strong attraction for protons. An example is the production of PH_3 from Ca_3P_2 and water. Write the equation for this reaction.
(c) By analogy, predict the products and write the equation for the reaction of Al_4C_3 with water.

14.174 Chlorine trifluoride was formerly used in the production of uranium hexafluoride for the U.S. nuclear industry:

$$U(s) + 3ClF_3(l) \longrightarrow UF_6(l) + 3ClF(g)$$

How many grams of UF_6 can form from 1.00 metric ton of uranium ore that is 1.55% by mass uranium and 12.75 L of chlorine trifluoride (d = 1.88 g/mL)?

14.175 Chlorine is used to make household bleach solutions containing 5.25% (by mass) NaClO. Assuming 100% yield in the reaction producing NaClO from Cl_2, how many liters of $Cl_2(g)$ at STP will be needed to make 1000. L of bleach solution (d = 1.07 g/mL)?

14.176 The triatomic molecular ion H_3^+ was first detected and characterized by J. J. Thomson using mass spectrometry. Use the bond energy of H_2 (432 kJ/mol) and the proton affinity of H_2 ($H_2 + H^+ \longrightarrow H_3^+$; $\Delta H = -337$ kJ/mol) to calculate the heat of reaction for

$$H + H + H^+ \longrightarrow H_3^+$$

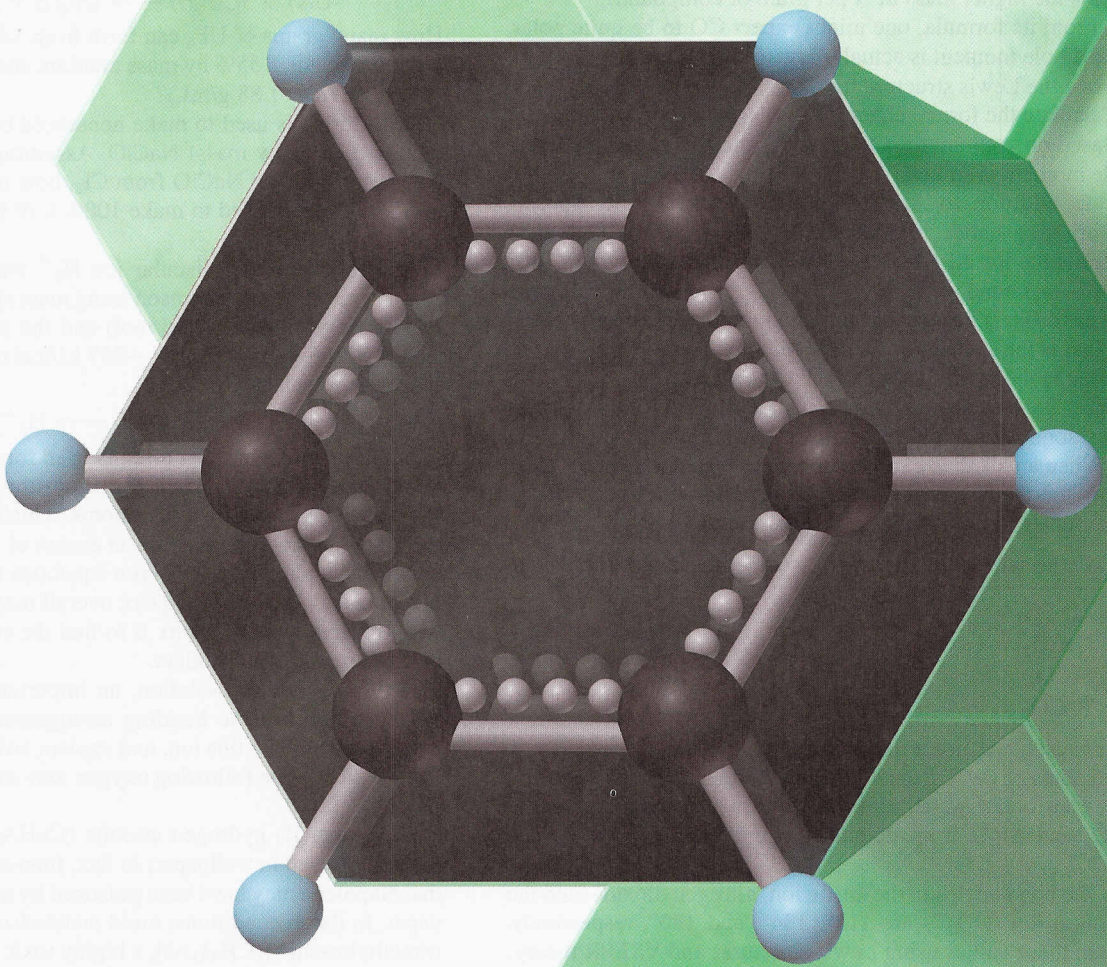
14.177 An atomic hydrogen torch is used for cutting and welding thick sheets of metal. When H_2 passes through an electric arc, the molecules decompose into atoms, which react with O_2 at the end of the torch. Temperatures in excess of 5000°C are reached, which can melt all metals. Write equations for H_2 breakdown to H atoms and for the subsequent overall reaction of the H atoms with oxygen. Use Appendix B to find the standard heat of each reaction per mole of product.

14.178 In aqueous HF solution, an important species is the ion HF_2^-, which has the bonding arrangement FHF^-. Draw the Lewis structure for this ion, and explain how it arises.

14.179 Which of the following oxygen ions are paramagnetic: O^+, O^-, O^{2-}, O^{2+}?

14.180 Copper(II) hydrogen arsenite ($CuHAsO_3$) is a green pigment once used in wallpaper; in fact, forensic evidence suggests that Napoleon may have been poisoned by arsenic from his wallpaper. In damp conditions, mold metabolizes this compound to trimethylarsenic [$(CH_3)_3As$], a highly toxic gas.
(a) Calculate the mass percent of As in each compound.
(b) How much $CuHAsO_3$ must react to reach a toxic level in a room that measures 12.35 m × 7.52 m × 2.98 m (arsenic is toxic at 0.50 mg/m^3)?

14.181 Hydrogen peroxide can act as either an oxidizing agent or a reducing agent.
(a) When H_2O_2 is treated with aqueous KI, I_2 forms. In which role is H_2O_2 acting? What is the oxygen-containing product formed?
(b) When H_2O_2 is treated with aqueous $KMnO_4$, the purple color of MnO_4^- disappears and a gas forms. In which role is H_2O_2 acting? What is the oxygen-containing product formed?



Precursor extraordinaire Benzene, almost an icon for organic compounds, is used to synthesize countless medicines, polymers, dyes, and other chemicals. Ultimately, our biochemical nature derives from our organochemical nature, which, as you'll see in this chapter, emerges from the amazing properties of the carbon atom.

Is there any chemical system more remarkable than a living cell? Through delicately controlled mechanisms, it oxidizes food for energy, maintains the concentrations of thousands of aqueous components, interacts continuously with its environment, synthesizes both simple and complex molecules, and even reproduces itself! For all our technological prowess, no human-made system even approaches the cell for sheer elegance of function.

This amazing chemical machine consumes, creates, and consists largely of *organic compounds*. Except for a few inorganic salts and ever-present water, nearly everything you put into or on your body—food, medicine, cosmetics, and clothing—consists of organic compounds. Organic fuels warm our homes, cook our meals, and power our society. Major industries are devoted to producing organic compounds, such as polymers, pharmaceuticals, and insecticides.

What *is* an organic compound? Dictionaries define it as "a compound of carbon," but that definition is too general because it includes carbonates, cyanides, carbides, cyanates, and other carbon-containing ionic compounds that most chemists classify as inorganic. Here is a more specific definition: all **organic compounds** contain carbon, nearly always bonded to other carbons and hydrogen, and often to other elements.

The word *organic* has a biological connotation arising from a major misconception that stifled research into the chemistry of living systems for many decades. In the early 19th century, many prominent thinkers believed that an unobservable spiritual energy, a "vital force," existed *within* the compounds of living things, making them impossible to synthesize and fundamentally different from compounds of the mineral world. This idea of *vitalism* was challenged in 1828, when the young German chemist Friedrich Wöhler heated ammonium cyanate, a "mineral-world" compound, and produced urea, a "living-world" compound:

$$NH_4OCN \xrightarrow{\Delta} H_2N{-}\overset{\overset{O}{\|}}{C}{-}NH_2$$

Although Wöhler did not appreciate the significance of this reaction—he was more interested in the fact that two compounds can have the same molecular formula—his experiment is considered a key event in the origin of organic chemistry. Chemists soon synthesized methane, acetic acid, acetylene, and many other organic compounds from inorganic sources. Today, we know that *the same chemical principles govern organic and inorganic systems* because the behavior of a compound arises from the properties of its elements, no matter how marvelous that behavior may be.

IN THIS CHAPTER . . . We apply the text's central theme to the enormous field of organic chemistry—how the structure and reactivity of organic molecules emerge naturally from the properties of their component atoms. First, we review the special atomic properties of carbon and see how they lead to the complex structure and reactivity of organic molecules. Next, we focus on writing and naming hydrocarbons as a prelude to naming other types of organic compounds. We classify the main types of organic reactions and apply them to various families of organic compounds. Finally, we extend these ideas to the giant molecules of commerce and life—synthetic and natural polymers.

Concepts & Skills to Review

before you study this chapter

- naming simple organic compounds; the functional-group concept (Section 2.8)
- constitutional isomerism (Section 3.2)
- ΔEN and bond polarity (Section 9.5)
- resonance structures (Section 10.1)
- VSEPR theory (Section 10.2)
- orbital hybridization (Section 11.1)
- σ and π bonding (Section 11.2)
- types of intermolecular forces and the shapes of biological macromolecules (Sections 12.3, 12.7, and 13.2)
- properties of the Period 2 elements (Section 14.2)
- properties of the Group 4A(14) elements (Section 14.6)

urea

Organic Chemistry Is Enough to Drive One Mad The vitalists did not change their beliefs overnight. Indeed, organic compounds *do* seem different from inorganic compounds because of their complex structures and compositions. Imagine the consternation of the 19th-century chemist who was accustomed to studying compounds with formulas such as $CaCO_3$, $Ba(NO_3)_2$, and $CuSO_4 \cdot 5H_2O$ and then isolated white crystals from a gallstone and found their empirical formula to be $C_{27}H_{46}O$ (cholesterol). Even Wöhler later said, "Organic chemistry . . . is enough to drive one mad. It gives me the impression of a primeval tropical forest, full of the most remarkable things, a monstrous and boundless thicket, with no way of escape, into which one may well dread to enter."

15.1 THE SPECIAL NATURE OF CARBON AND THE CHARACTERISTICS OF ORGANIC MOLECULES

Although there is nothing mystical about organic molecules, their indispensable role in biology and industry leads us to ask if carbon has some extraordinary attributes that give it a special chemical "personality." Of course, each element has its own specific properties, and carbon is no more unique than sodium,

hafnium, or any other element. But the atomic properties of carbon do give it bonding capabilities beyond those of any other element, which in turn lead to the two obvious characteristics of organic molecules—structural complexity and chemical diversity.

The Structural Complexity of Organic Molecules

Most organic molecules have much more complex structures than most inorganic molecules, and a quick review of carbon's atomic properties and bonding behavior shows why:

1. *Electron configuration, electronegativity, and covalent bonding.* Carbon's ground-state electron configuration of [He] $2s^2 2p^2$—four electrons more than He and four fewer than Ne—means that the formation of carbon ions is energetically impossible under ordinary conditions: to form a C^{4+} cation requires energy equal to the sum of IE_1 through IE_4, and a C^{4-} anion requires the sum of EA_1 through EA_4, the last three steps being endothermic. Carbon's position in the periodic table (Figure 15.1) and its electronegativity are midway between the most metallic and nonmetallic elements of Period 2: Li = 1.0, C = 2.5, F = 4.0. Therefore, *carbon shares electrons to attain a filled outer (valence) level,* bonding covalently in all its elemental forms and compounds.

2. *Bond properties, catenation, and molecular shape.* The *number* and *strength* of carbon's bonds lead to its outstanding ability to *catenate* (form chains of atoms), which allows it to form a multitude of chemically and thermally stable chain, ring, and branched compounds. Through the process of orbital hybridization (Section 11.1), *carbon forms four bonds in virtually all its compounds,* and they point in as many as four different directions. The small size of carbon allows close approach to another atom and thus greater orbital overlap, meaning that *carbon forms relatively short, strong bonds.* The C—C bond is short enough to allow side-to-side overlap of half-filled, unhybridized *p* orbitals and the formation of *multiple bonds,* which restrict rotation of attached groups (see Figure 11.13, p. 409). These features add more possibilities for the shapes of carbon compounds.

3. *Molecular stability.* Although silicon and several other elements also catenate, none can compete with carbon. Atomic and bonding properties confer three crucial differences between C and Si chains that explain why C chains are so stable and, therefore, so common:

- *Atomic size and bond strength.* As atomic size increases down Group 4A(14), bonds between identical atoms become longer and weaker. Thus, a C—C bond (347 kJ/mol) is much stronger than an Si—Si bond (226 kJ/mol).
- *Relative heats of reaction.* A C—C bond (347 kJ/mol) and a C—O bond (358 kJ/mol) have nearly the same energy, so relatively little heat is released when a C chain reacts and one bond replaces the other. In contrast, an Si—O bond (368 kJ/mol) is much stronger than an Si—Si bond (226 kJ/mol), so a large quantity of heat is released when an Si chain reacts.
- *Orbitals available for reaction.* Unlike C, Si has low-energy *d* orbitals that can be attacked (occupied) by the lone pairs of incoming reactants. Thus, for example, ethane ($CH_3—CH_3$) is stable in water and does not react in air unless sparked, whereas disilane ($SiH_3—SiH_3$) breaks down in water and ignites spontaneously in air.

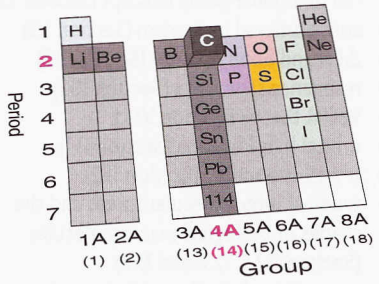

Figure 15.1 The position of carbon in the periodic table. Lying at the center of Period 2, carbon has an intermediate electronegativity (EN), and its position at the top of Group 4A(14) means it is relatively small. Other elements common in organic compounds are H, N, O, P, S, and the halogens.

The Chemical Diversity of Organic Molecules

In addition to their elaborate geometries, organic compounds are noted for their sheer number and diverse chemical behavior. Look in any compendium of known

compounds, such as the *CRC Handbook of Chemistry and Physics,* and you'll find that the number of organic compounds dwarfs the number of inorganic compounds of all the other elements combined! Several million organic compounds are known, and thousands more are discovered or synthesized each year.

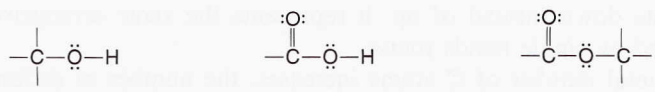
This incredible diversity is also founded on atomic and bonding behavior and is due to three interrelated factors:

1. *Bonding to heteroatoms.* Many organic compounds contain **heteroatoms,** atoms other than C or H. The most common heteroatoms are N and O, but S, P, and the halogens often occur, and organic compounds with other elements are known as well. To get an idea of the diversity arising from the presence of a heteroatom, look at Figure 15.2, which shows that 23 different molecular structures are produced by various arrangements of four C atoms singly bonded to each other, the necessary number of H atoms, and just one O atom (either singly or doubly bonded).

2. *Electron density and reactivity.* Most reactions start—that is, a new bond begins to form—*when a region of high electron density on one molecule meets a region of low electron density on another.* These regions may be due to the presence of a multiple bond or to the partial charges that occur in carbon-heteroatom bonds. For example, consider four bonds that are commonly found in organic molecules:

- *The C—C bond.* When C is singly bonded to itself, as it is in portions of nearly every organic molecule, the EN values are equal and the bond is nonpolar. Therefore, in general, *C—C bonds are unreactive.*
- *The C—H bond.* This bond, which also occurs in nearly every organic molecule, is very nearly nonpolar because it is short (109 pm) and the EN values of H (2.1) and C (2.5) are close. Thus, *C—H bonds are largely unreactive* as well.
- *The C—O bond.* In contrast to the previous two bonds, this bond, which occurs in many types of organic molecules, is highly polar ($\Delta EN = 1.0$), with the O end of the bond electron rich and the C end electron poor. As a result of this imbalance in electron density, *the C—O bond is reactive* and, given appropriate conditions, a reaction will occur there.
- *Bonds to other heteroatoms.* Even when a carbon-heteroatom bond has a small ΔEN, such as that for C—Br ($\Delta EN = 0.3$), or none at all, as for C—S ($\Delta EN = 0$), heteroatoms like these are large, and so their bonds to carbon are long, weak, and thus reactive.

3. *Nature of functional groups.* One of the most important ideas in organic chemistry is that of the **functional group,** a specific combination of bonded atoms that reacts in a *characteristic* way, no matter what molecule it occurs in (we mentioned this idea briefly in Section 2.8). In nearly every case, *the reaction of an organic compound takes place at the functional group.* In fact, as you'll see, we often substitute a general symbol for the remainder of the molecule because it usually stays the same while the functional group reacts. Functional groups vary from carbon-carbon multiple bonds to several combinations of carbon-heteroatom bonds, and each has its own pattern of reactivity. A particular bond may be a functional group itself or *part* of one or more functional groups. For example, the C—O bond occurs in four functional groups. We will discuss the reactivity of three of these groups in this chapter:



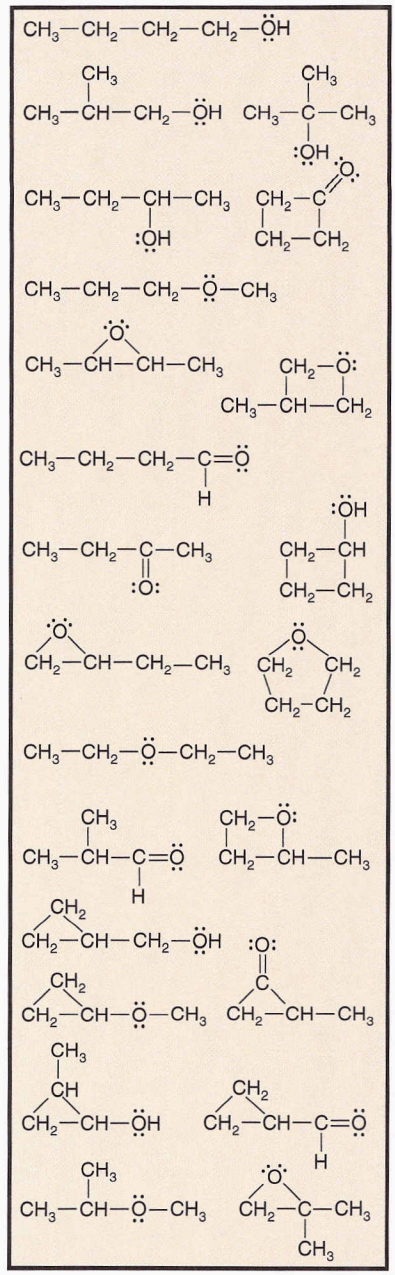


Figure 15.2 The chemical diversity of organic compounds. Different arrangements of chains, branches, rings, and heteroatoms give rise to many structures. There are 23 different compounds possible from just four C atoms joined by single bonds, one O atom, and the necessary H atoms.

SECTION SUMMARY

The structural complexity of organic compounds arises from carbon's small size, intermediate EN, four valence electrons, ability to form multiple bonds, and absence of *d* orbitals in the valence level. These factors lead to chains, branches, and rings of C atoms joined by strong, chemically resistant bonds that point in as many as four directions from each C. The chemical diversity of organic compounds arises from carbon's ability to bond to many other elements, including O and N, which creates polar bonds and greater reactivity. These factors lead to compounds that contain functional groups, specific portions of molecules that react in characteristic ways.

15.2 THE STRUCTURES AND CLASSES OF HYDROCARBONS

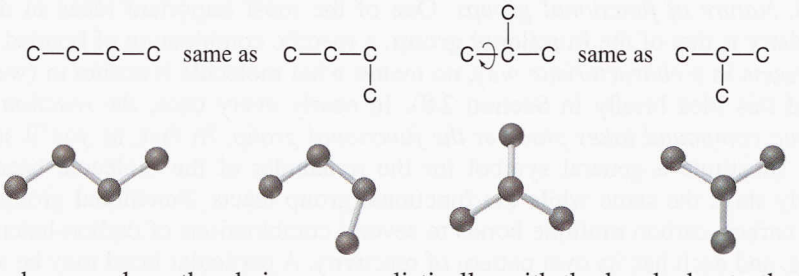
A fanciful, anatomical analogy can be made between an organic molecule and an animal. The carbon-carbon bonds form the skeleton, with the longest continual chain the backbone and any branches the limbs. Covering the skeleton is a skin of hydrogen atoms, with functional groups protruding at specific locations, like chemical fingers ready to grab an incoming reactant.

In this section, we "dissect" one group of compounds down to their skeletons and see how to name and draw them. **Hydrocarbons,** the simplest type of organic compound, are a large group of substances containing only H and C atoms. Some common fuels, such as natural gas and gasoline, are hydrocarbon mixtures. Hydrocarbons are also important *feedstocks,* precursor reactants used to make other compounds. Ethylene, acetylene, and benzene, for example, are feedstocks for hundreds of other substances.

Carbon Skeletons and Hydrogen Skins

Let's begin by examining the possible bonding arrangements of C atoms only (we'll leave off the H atoms at first) in simple skeletons without multiple bonds or rings. To distinguish different arrangements, focus on the *sequence* of C atoms (that is, the successive linkages of one to another) and keep in mind that *groups joined by single (sigma) bonds are relatively free to rotate* (Section 11.2).

Structures with one, two, or three carbons can be arranged in only one way. Whether you draw three C atoms in a line or with a bend, the *sequence* is the same. Four C atoms, however, have two possible arrangements—a four-C chain or a three-C chain with a one-C branch at the central C:



Even when we show the chain more realistically, with the bends due to the tetrahedral shape around the C atoms (as in the ball-and-stick models) the situation is the same. Notice that if the branch is added to either end of the three-C chain, it is simply a bend in a four-C chain, *not* a different arrangement. Similarly, if the branch points down instead of up, it represents the same arrangement because groups joined by single bonds rotate.

As the total number of C atoms increases, the number of different arrangements increases as well. Five C atoms have 3 possible arrangements; 6 C atoms can be arranged in 5 ways, 7 C atoms in 9 ways, 10 C atoms in 75 ways, and

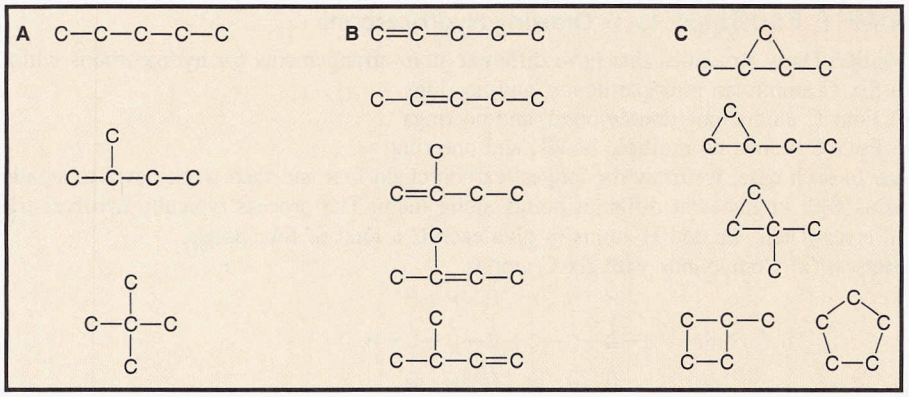


Figure 15.3 Some five-carbon skeletons. A, Three five-C skeletons are possible with only single bonds. **B,** Five more skeletons are possible with one C=C bond present. **C,** Five more skeletons are possible with one ring present. Even more would be possible with a ring *and* a double bond.

20 C atoms in more than 300,000 ways! If we include multiple bonds and rings, the number of arrangements increases further. For example, including one C=C bond in the five-C skeletons creates 5 more arrangements, and including one ring creates 5 more (Figure 15.3).

When determining the number of different skeletons for a given number of C atoms, remember that

- Each C atom can form a *maximum* of four single bonds, or two single and one double bond, or one single and one triple bond.
- The *arrangement* of C atoms determines the skeleton, so a straight chain and a bent chain represent the same skeleton.
- Groups joined by single bonds can *rotate,* so a branch pointing down is the same as one pointing up. (Recall that a double bond restricts rotation.)

If we put a hydrogen "skin" on a carbon skeleton, we obtain a hydrocarbon. Figure 15.4 shows that the skeleton has the correct number of H atoms when each C has four bonds. Sample Problem 15.1 provides practice drawing hydrocarbons.

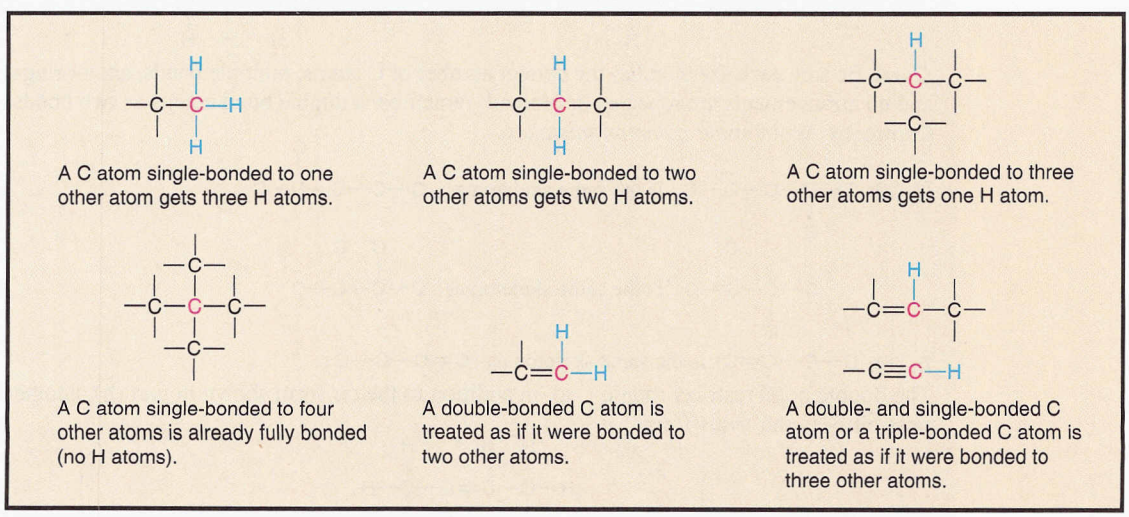

Figure 15.4 Adding the H-atom skin to the C-atom skeleton. In a hydrocarbon molecule, each carbon atom bonds to as many hydrogen atoms as needed to give the carbon a total of four bonds.

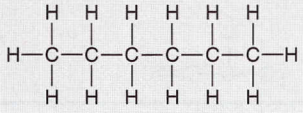
SAMPLE PROBLEM 15.1 Drawing Hydrocarbons

Problem Draw structures that have different atom arrangements for hydrocarbons with:
(a) Six C atoms, no multiple bonds, and no rings
(b) Four C atoms, one double bond, and no rings
(c) Four C atoms, no multiple bonds, and one ring

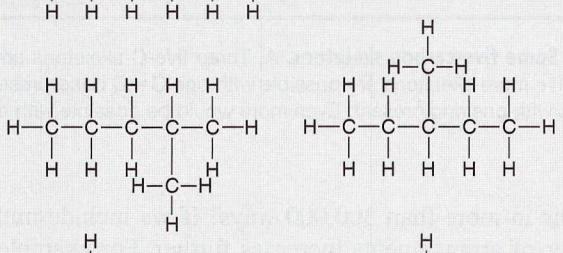
Plan In each case, we draw the longest carbon chain first and then work down to smaller chains with branches at different points along them. The process typically involves trial and error. Then, we add H atoms to give each C a total of four bonds.

Solution **(a)** Compounds with six C atoms:

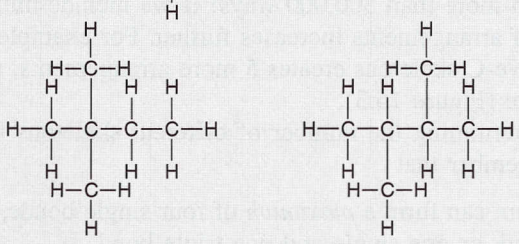
6-C chain:



5-C chains:

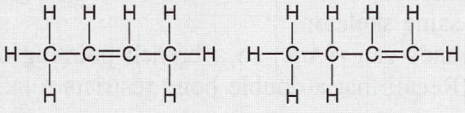


4-C chains:

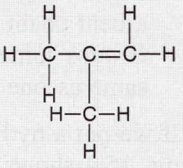


(b) Compounds with four C atoms and one double bond:

4-C chains:

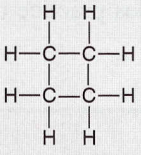


3-C chain:

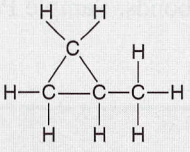


(c) Compounds with four C atoms and one ring:

4-C ring:



3-C ring:

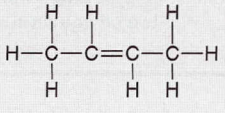


Check Be sure each skeleton has the correct number of C atoms, multiple bonds, and/or rings, and no arrangements are repeated or omitted; remember a double bond counts as two bonds.

Comment Avoid some *common mistakes:*

In (a):  is the same skeleton as 
 is the same skeleton as 
In (b): is the same skeleton as

The double bond restricts rotation, so, in addition to the *cis* form shown in part (b), another possibility is the *trans* form:



(We discuss *cis-trans* isomers fully later in this section.)

Too many bonds to one C in 
In (c): Too many bonds to one C in 
FOLLOW-UP PROBLEM 15.1 Draw all hydrocarbons that have different atom arrangements with:
(a) Seven C atoms, no multiple bonds, and no rings (nine arrangements)
(b) Five C atoms, one triple bond, and no rings (three arrangements)

Hydrocarbons can be classified into four main groups. In the remainder of this section, we examine some structural features and physical properties of each group. Later, we discuss the chemical behavior of the hydrocarbons.

Alkanes: Hydrocarbons with Only Single Bonds

A hydrocarbon that contains only single bonds is an **alkane** (general formula $\mathbf{C_nH_{2n+2}}$, where n is a positive integer). For example, if $n = 5$, the formula is $C_5H_{[(2\times5)+2]}$, or C_5H_{12}. The alkanes comprise a **homologous series,** one in which each member differs from the next by a $—CH_2—$ (methylene) group. In an alkane, each C is sp^3 hybridized. Because each C is bonded to the *maximum number of other atoms* (C or H), alkanes are referred to as **saturated hydrocarbons.**

Naming Alkanes You learned how to name simple alkanes in Section 2.8. Here we discuss general rules for naming any alkane and, by extension, other organic compounds as well. The key point is that *each chain, branch, or ring has a name based on the* ***number*** *of C atoms*. The name of a compound has three portions:

PREFIX + ROOT + SUFFIX

- *Root:* The root tells the number of C atoms in the longest *continuous* chain in the molecule. The roots for the ten smallest alkanes are shown in Table 15.1. Recall that there are special roots for compounds of one to four C atoms; roots of longer chains are based on Greek numbers.
- *Prefix:* Each prefix identifies a *group attached to the main chain* and the number of the carbon to which it is attached. Prefixes identifying hydrocarbon branches are the same as root names (Table 15.1) but have *-yl* as their ending. Each prefix is placed *before* the root.
- *Suffix:* The suffix tells the *type of organic compound* the molecule represents; that is, it identifies the key functional group the molecule possesses. The suffix is placed *after* the root.

For example, in the name 2-methylbutane, *2-methyl-* is the prefix (a one-carbon branch is attached to C-2 of the main chain), *-but-* is the root (the main chain has four C atoms), and *-ane* is the suffix (the compound is an alkane).

To obtain the systematic name of a compound,

1. Name the longest chain (root).
2. Add the compound type (suffix).
3. Name any branches (prefix).

Table 15.1 Numerical Roots for Carbon Chains and Branches

Roots	Number of C Atoms
meth-	1
eth-	2
prop-	3
but-	4

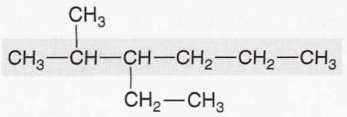
hex-	6
hept-	7
oct-	8
non-	9
dec-	10

Table 15.2 Rules for Naming an Organic Compound

1. Naming the longest chain (root)
   (a) Find the longest *continuous* chain of C atoms.
   (b) Select the root that corresponds to the number of C atoms in this chain.

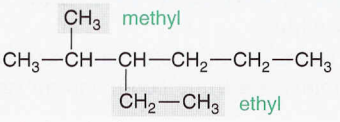


6 carbons ⟹ hex-

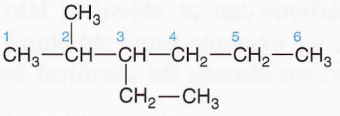
2. Naming the compound type (suffix)
   (a) For alkanes, add the suffix *-ane* to the chain root. (Other suffixes appear in Table 15.5 with their functional group and compound type.)
   (b) If the chain forms a ring, the name is preceded by *cyclo-*.

hex- + -ane ⟹ hexane

3. Naming the branches (prefixes) (If the compound has no branches, the name consists of the root and suffix.)
   (a) Each branch name consists of a subroot (number of C atoms) and the ending *-yl* to signify that it is not part of the main chain.
   (b) Branch names precede the chain name. When two or more branches are present, their names appear in *alphabetical* order.
   (c) To specify where the branch occurs along the chain, number the main-chain C atoms consecutively, starting at the end *closer* to a branch, to achieve the *lowest* numbers for the branches. Precede each branch name with the number of the main-chain C to which that branch is attached.



ethylmethylhexane



3-ethyl-2-methylhexane

Table 15.2 presents the rules for naming any organic compound and applies them to an alkane component of gasoline. Other organic compounds are named with a variety of other prefixes and suffixes (see Table 15.5, p. 639). In addition to *systematic* names, we'll also note important *common* names still in use.

Depicting Alkanes with Formulas and Models Chemists have several ways to depict organic compounds. Expanded, condensed, and carbon-skeleton formulas are easy to draw; ball-and-stick and space-filling models show the actual shapes.

The *expanded formula* shows each atom and bond. One type of *condensed formula* groups each C atom with its H atoms. *Carbon-skeleton formulas* show only carbon-carbon bonds and appear as zig-zag lines, often with branches. *Each end or bend of a zig-zag line or branch represents a C atom attached to the number of H atoms that gives it a total of four bonds*:

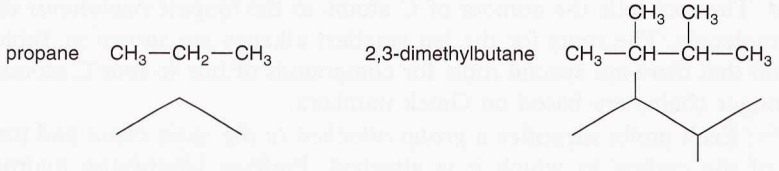


Figure 15.5 shows these types of formulas, together with ball-and-stick and space-filling models, of the compound named in Table 15.2.

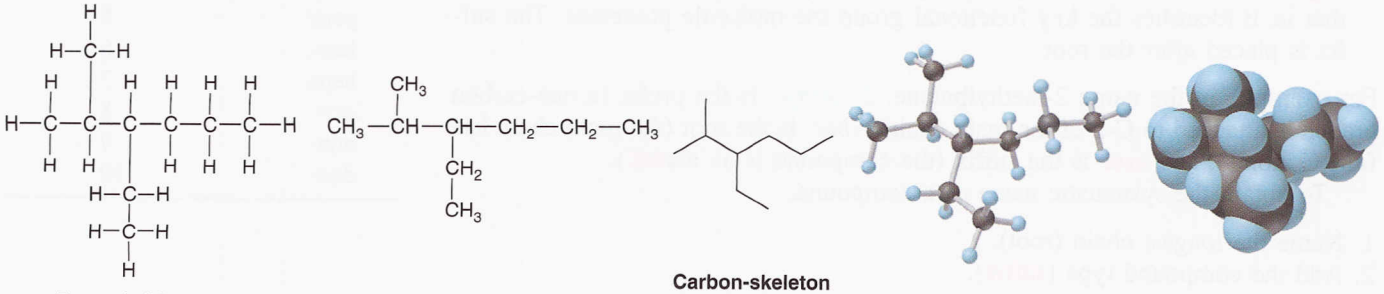
Figure 15.5 Ways of depicting an alkane.



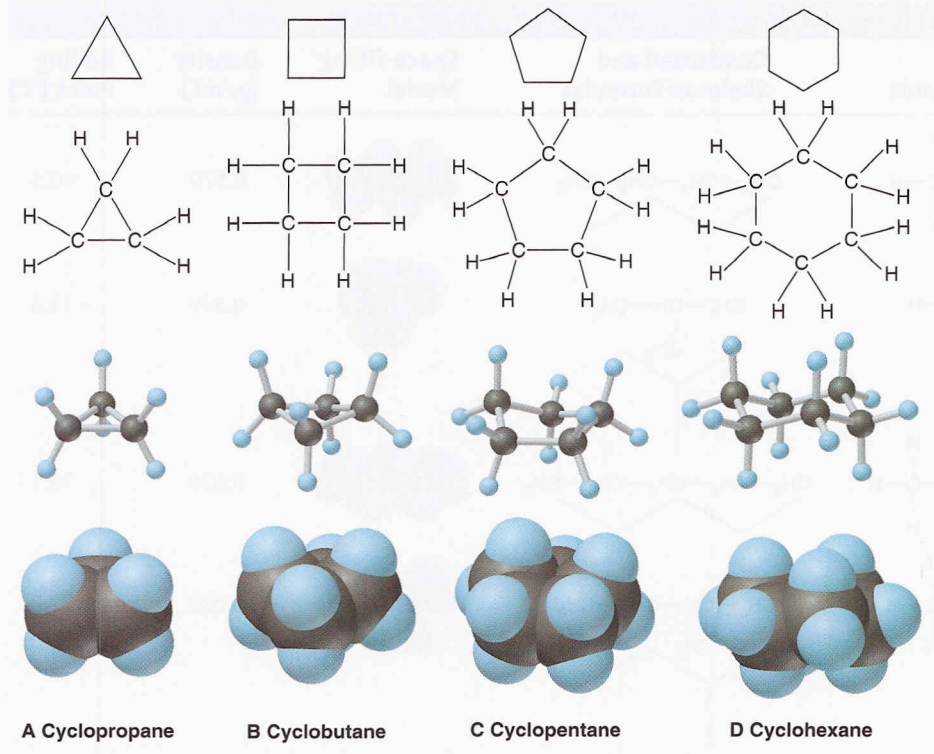


Figure 15.6 Depicting cycloalkanes. Cycloalkanes are usually drawn as regular polygons. Each side is a C—C bond, and each corner represents a C atom with its required number of H atoms. The expanded formulas show each bond in the molecule. The ball-and-stick and space-filling models show that, except for cyclopropane, the rings are not planar. These conformations minimize electron repulsions between adjacent H atoms. Cyclohexane **(D)** is shown in its more stable chair conformation.

Cyclic Hydrocarbons A **cyclic hydrocarbon** contains one or more rings in its structure. When a straight-chain alkane (C_nH_{2n+2}) forms a ring, two H atoms are lost as the C—C bond forms to join the two ends of the chain. Thus, *cycloalkanes* have the general formula C_nH_{2n}. Cyclic hydrocarbons are often drawn with carbon-skeleton formulas, as shown at the top of Figure 15.6. Except for three-carbon rings, *cycloalkanes are nonplanar.* This structural feature arises from the tetrahedral shape around each C atom and the need to minimize electron repulsions between adjacent H atoms. As a result, orbital overlap of adjacent C atoms is maximized. The most stable form of cyclohexane, called the *chair conformation,* is shown in Figure 15.6D.

Constitutional Isomerism and the Physical Properties of Alkanes

Recall from Section 3.2 that two or more compounds with the same molecular formula but different properties are called **isomers.** Those with *different arrangements of bonded atoms* are **constitutional** (or **structural**) **isomers;** alkanes with the same number of C atoms but different skeletons are examples. The smallest alkane to exhibit constitutional isomerism has four C atoms: two different compounds have the formula C_4H_{10}, as shown in Table 15.3, on the next page. The unbranched one is butane (common name, *n*-butane; *n*- stands for "normal," or having a straight chain), and the other is 2-methylpropane (common name, *iso*butane). Similarly, three compounds have the formula C_5H_{12} (shown in Table 15.3). The unbranched isomer is pentane (common name, *n*-pentane); the one with a

Table 15.3 The Constitutional Isomers of C_4H_{10} and C_5H_{12}

Systematic Name (Common Name)	Expanded Formula	Condensed and Skeleton Formulas	Space-filling Model	Density (g/mL)	Boiling Point (°C)
Butane (*n*-butane)				0.579	−0.5
2-Methylpropane (isobutane)				0.549	−11.6
Pentane (*n*-pentane)				0.626	36.1
2-Methylbutane (isopentane)				0.620	27.8
2,2-Dimethylpropane (neopentane)				0.614	9.5

methyl group at C-2 of a four-C chain is 2-methylbutane (common name, *iso*pentane). The third isomer has two methyl branches on C-2 of a three-C chain, so its name is 2,2-dimethylpropane (common name, *neo*pentane).

Because alkanes are nearly nonpolar, we expect their physical properties to be determined by dispersion forces, and the boiling points in Table 15.3 certainly bear this out. The four-C alkanes boil lower than the five-C compounds. Moreover, within each group of isomers, the more spherical member (isobutane or neopentane) boils lower than the more elongated one (*n*-butane or *n*-pentane). As you saw in Chapter 12, this trend occurs because a spherical shape leads to less intermolecular contact, and thus lower total dispersion forces, than does an elongated shape.

A particularly clear example of the effect of dispersion forces on physical properties occurs among the unbranched alkanes (*n*-alkanes). Among these compounds, boiling points increase steadily with chain length: the longer the chain, the greater the intermolecular contact, the stronger the dispersion forces, and the higher the boiling point (Figure 15.7). Pentane (five C atoms) is the smallest *n*-alkane that exists as a liquid at room temperature. The solubility of alkanes, and of all hydrocarbons, is easy to predict from the like-dissolves-like rule (Section 13.1). Alkanes are miscible in each other and in other nonpolar solvents, such as benzene, but are nearly insoluble in water. The solubility of pentane in water, for example, is only 0.36 g/L at room temperature.

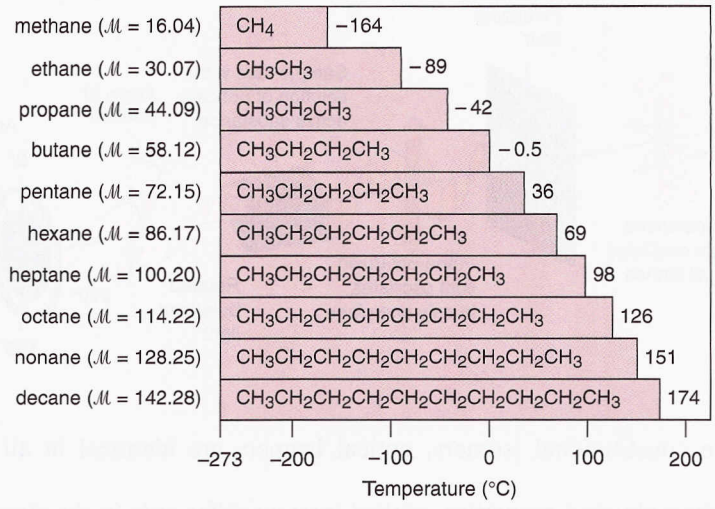

Figure 15.7 Boiling points of the first 10 unbranched alkanes. Boiling point increases smoothly with chain length because dispersion forces increase. Each entry includes the name, molar mass ($\mathcal{M}$, in g/mol), formula, and boiling point at 1 atm pressure.

Chiral Molecules and Optical Isomerism

Another type of isomerism exhibited by some alkanes and many other organic (as well as some inorganic) compounds is called *stereoisomerism.* **Stereoisomers** are molecules with the same arrangement of atoms *but different orientations of groups in space. Optical isomerism* is one type of stereoisomerism: *when two objects are mirror images of each other and cannot be superimposed, they are* ***optical isomers,*** also called *enantiomers.* To use a familiar example, your right hand is an optical isomer of your left. Look at your right hand in a mirror, and you will see that the *image* is identical to your left hand (Figure 15.8). No matter how you twist your arms around, however, your hands cannot lie on top of each other with all parts superimposed. They are not superimposable because each is *asymmetric:* there is no plane of symmetry that divides your hand into two identical parts.

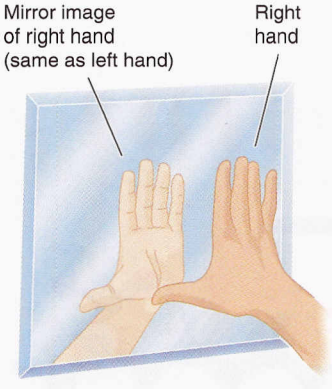

Figure 15.8 An analogy for optical isomers. The reflection of your right hand looks like your left hand. Each hand is asymmetric, so you cannot superimpose them with your palms facing in the same direction.

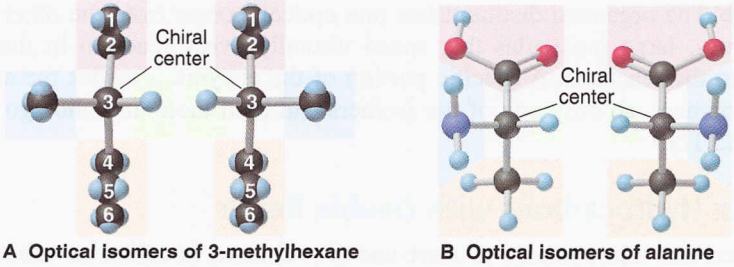
An asymmetric molecule is called **chiral** (Greek *cheir,* "hand"). Typically, an organic molecule *is chiral if it contains a carbon atom that is bonded to four* ***different*** *groups.* This C atom is called a *chiral center* or an asymmetric carbon. In 3-methylhexane, for example, C-3 is a chiral center because it is bonded to four different groups: H—, CH_3—, CH_3—CH_2—, and CH_3—CH_2—CH_2— (Figure 15.9A). Like your two hands, the two forms are mirror images and cannot be superimposed on each other: when two of the groups are superimposed, the other two are opposite each other. Thus, the two forms are optical isomers. The central C atom in the amino acid alanine is also a chiral center (Figure 15.9B).



A Optical isomers of 3-methylhexane B Optical isomers of alanine

Figure 15.9 Two chiral molecules. A, 3-Methylhexane is chiral because C-3 is bonded to four different groups. These two models are optical isomers (enantiomers). **B,** The central C in the amino acid alanine is also bonded to four different groups.

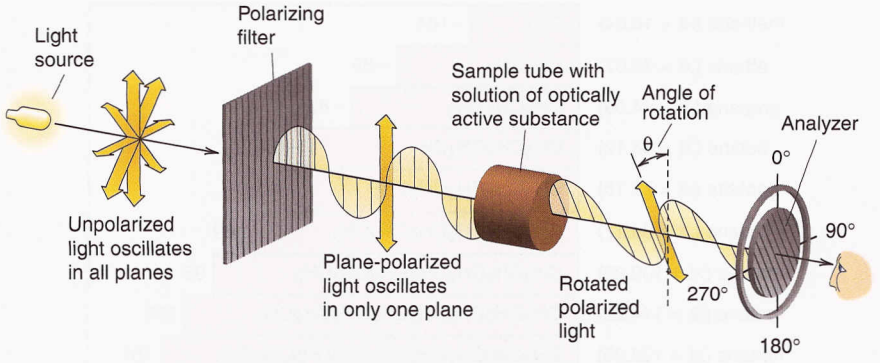


Figure 15.10 The rotation of plane-polarized light by an optically active substance. The source emits light oscillating in all planes. When the light passes through the first polarizing filter, light oscillating in only one plane emerges. The plane-polarized light enters the sample compartment, which contains a known concentration of an optical isomer, and the plane rotates as the light passes through the solution. For the experimenter to see the light, it must pass through a second polarizing filter (called the *analyzer*), which is attached to a movable ring that is calibrated in degrees and measures the angle of rotation.

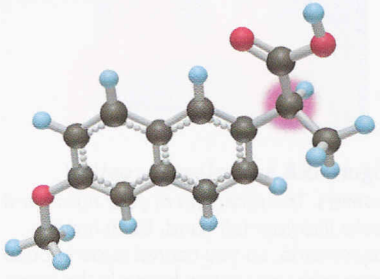
Unlike constitutional isomers, optical isomers are identical in all but two respects:

1. In their physical properties, *optical isomers differ only in the direction that each isomer rotates the plane of polarized light.* A **polarimeter** is used to measure the angle that the plane is rotated (Figure 15.10). A beam of light consists of waves that oscillate in all planes. A polarizing filter blocks all waves except those in one plane, so the light emerging through the filter is *plane-polarized.* An optical isomer is **optically active** because it rotates the plane of this polarized light. (Liquid crystal displays incorporate polarizing filters and optically active compounds; see Figure 12.45, p. 469.) The *dextrorotatory* isomer (designated *d* or +) rotates the plane of light clockwise; the *levorotatory* isomer (designated *l* or −) is the mirror image of the *d* isomer and rotates the plane counterclockwise. An equimolar mixture of the two isomers (called a *racemic mixture*) does not rotate the plane at all because the dextrorotation cancels the levorotation. The *specific rotation* is a characteristic, measurable property of the isomer at a certain temperature, concentration, and wavelength of light.

2. In their chemical properties, *optical isomers differ only in a chiral (asymmetric) chemical environment,* one that distinguishes "right-handed" from "left-handed" molecules. As an analogy, your right hand fits well in your right glove but not in your left glove. Typically, one isomer of an optically active reactant is added to a mixture of optical isomers of another compound. The products of the reaction have different properties and can be separated. For example, when the anion *d*-lactate is added to a mixture of the cationic forms *d*-alanine and *l*-alanine, the *d* isomer of alanine crystallizes as the *d*-lactate/*d*-alanine salt, but the *d*-lactate/*l*-alanine salt is more soluble and remains in solution.

Optical isomerism plays a vital role in living cells. Nearly all carbohydrates and amino acids are optically active, but only one of the isomers is biologically usable. For example, *d*-glucose is metabolized for energy, but *l*-glucose is excreted unused. Similarly, *l*-alanine is incorporated naturally into proteins, but *d*-alanine is not. The organism distinguishes one optical isomer from the other through its enzymes, large molecules that speed virtually every reaction in the cell by binding to the reactants. A specific portion of the enzyme provides the asymmetric environment, so only one of the isomers can bind there and undergo reaction (Figure 15.11).



Chiral Medicines Many drugs are chiral molecules of which one optical isomer is biologically active and the other has either a different type of activity or none at all. Naproxen, the pain reliever and anti-inflammatory agent, is an example; one isomer (see the model) is active as an anti-arthritic agent, and the other is a potent liver toxin that must be removed from the mixture during synthesis. The notorious drug thalidomide is another example. One optical isomer is active against depression, whereas the other causes fetal mutations and deaths. Tragically, the drug was sold in the 1950s as the racemic mixture and caused limb malformations in many children whose mothers had it prescribed to relieve "morning sickness" during pregnancy.

Alkenes: Hydrocarbons with Double Bonds

A hydrocarbon that contains at least one C=C bond is called an **alkene.** With two H atoms removed to make the double bond, alkenes have the general formula $\mathbf{C_nH_{2n}}$. The double-bonded C atoms are sp^2 hybridized. Because their carbon atoms are bonded to fewer than the maximum of four atoms each, alkenes are considered **unsaturated hydrocarbons.**

Alkene names differ from those of alkanes in two respects:

1. The main chain (root) *must* contain both C atoms of the double bond, even if it is not the longest chain. The chain is numbered from the end *closer* to the C=C bond, and the position of the bond is indicated by the number of the *first* C atom in it.
2. The suffix for alkenes is *-ene*.

For example, there are three four-C alkenes (C_4H_8), two unbranched and one branched (see Sample Problem 15.1b). The branched isomer is 2-methylpropene; the unbranched isomer with the C=C bond between C-1 and C-2 is 1-butene; the unbranched isomer with the C=C bond between C-2 and C-3 is 2-butene. As you'll see next, there are two isomers of 2-butene, but they are of a different sort (discussed briefly in Sections 10.3 and 11.2).

The C=C Bond and Geometric (*cis-trans*) Isomerism There are two major structural differences between alkenes and alkanes. First, alkanes have a *tetrahedral* geometry (bond angles of ~109.5°) around each C atom, whereas the double-bonded C atoms in alkenes are *trigonal planar* (~120°). Second, the C—C bond *allows* rotation of bonded groups, so the atoms in an alkane continually change their relative positions. In contrast, the π bond of the C=C bond *restricts* rotation, which fixes the relative positions of the atoms bonded to it.

This rotational restriction leads to another type of stereoisomerism. **Geometric isomers** (also called ***cis-trans* isomers**) have different orientations of groups around a double bond (or similar structural feature). Table 15.4 shows the two geometric isomers of 2-butene (also see Comment, Sample Problem 15.1). One isomer, *cis*-2-butene, has the CH_3 groups on the *same* side of the C=C bond, whereas the other isomer, *trans*-2-butene, has them on *opposite* sides of the C=C bond. In general, a *cis* isomer has the *larger portions of the main chain on the same side* of the double bond, and a *trans* isomer has them on opposite sides. (Cis-trans isomerism also occurs in many transition metal compounds, which have a different structural feature that restricts rotation, as we discuss in Chapter 23.) For a molecule to have geometric isomers, *each C atom in the C=C bond must be bonded to two different groups*. Like other isomers, geometric isomers have different properties. Note in Table 15.4 that the two 2-butenes differ in molecular shape *and* physical properties. The *cis* isomer has a bend in the chain that the *trans* isomer lacks. In Chapters 10 and 12, you saw how such a difference affects molecular polarity and physical properties, which arise from differing strengths of intermolecular attractions. The upcoming Chemical Connections essay shows how this simple difference in geometry has profound effects in biological systems as well.

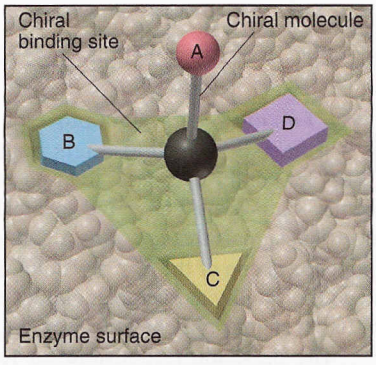


Figure 15.11 The binding site of an enzyme. Organisms can utilize only one of a pair of optical isomers because their enzymes have binding sites with shapes that are chiral (asymmetric). The shape of the mirror image of this molecule does not allow it to bind at this site.

Table 15.4 The Geometric Isomers of 2-Butene

Systematic Name	Condensed and Skeleton Formulas	Space-filling Model	Density (g/mL)	Boiling Point (°C)
cis-2-Butene	CH_3 CH_3 C=C H H		0.621	3.7
trans-2-Butene	CH_3 H C=C H CH_3		0.604	0.9

Geometric Isomers and the Chemistry of Vision

Of all our senses, sight provides the most information about the external world. Light bouncing off objects enters the lens of the eye and is focused on the retina. From there, molecular signals are converted to mechanical signals and then to electrical signals that are transmitted to the brain. This remarkable sequence is one of the few physiological processes that we understand thoroughly at the molecular level. The first step relies on the different shapes of geometric isomers.

The molecule responsible for receiving the light energy is *retinal*. It is derived from retinol (vitamin A), which we obtain mostly from β-carotene in yellow and green vegetables. Retinal is a 20-C compound consisting of a 15-C chain and five 1-C branches. As you can see from the ball-and-stick model in Figure B15.1, the chain includes five C=C bonds, a six-C ring at one end, and a C=O bond at the other. There are two biologically occurring isomers of retinal. The all-*trans* isomer, shown on the right, has a *trans* orientation around all five double bonds. The 11-*cis* isomer, shown on the left, has a *cis* orientation around the C=C bond between C-11 and C-12. Note the significant difference in shape between the two isomers.

Certain cells of the retina are densely packed with *rhodopsin*, which consists of the relatively small 11-*cis*-retinal covalently bonded to a large protein. The initial chemical event in vision occurs when rhodopsin absorbs a photon of visible light. The energy of visible photons (between 165 and 293 kJ/mol) lies in the range needed to break a C=C π bond (~250 kJ/mol). Retinal is bonded to the protein in such a way that the 11-*cis* π bond is the most susceptible to breakage. The photon is absorbed in a few trillionths of a second, the *cis* π bond breaks, the groups attached to the intact σ bond rotate, and a π bond re-forms to produce all-*trans*-retinal in another few millionths of a second. In effect, light energy is converted into the mechanical energy of the moving molecular chain.

This rapid and relatively large change in the shape of retinal causes the protein portion of rhodopsin to change shape as well—a process that breaks the bond between the protein portion and retinal. The change in protein shape triggers a flow of ions into the retina cells, initiating electrical impulses to the optic nerve, which conducts them to the brain. Meanwhile, the free all-*trans*-retinal diffuses away and is changed back to the *cis* form, which then binds to the protein portion again.

Retinal must be ideally suited to its function because it has been selected through evolution as a photon absorber in organisms as different as purple bacteria, mollusks, insects, and vertebrates. The features that make it the perfect choice are its strong absorption in the visible region, the efficiency with which light converts the *cis* to the *trans* form, and the large structural change it undergoes when this takes place.

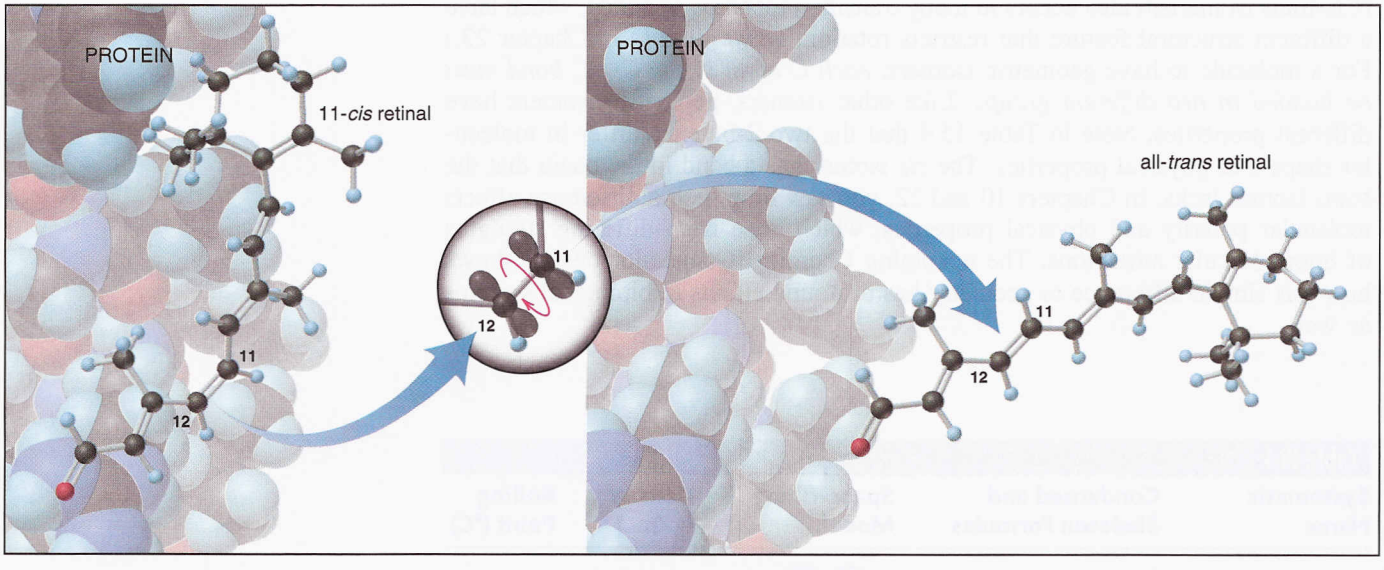

Figure B15.1 The initial chemical event in vision. In rhodopsin, the geometric isomer 11-*cis*-retinal is bonded to (*shown here as lying on*) a large protein. A photon absorbed by the retinal breaks the 11-*cis* π bond. The two parts of the retinal chain rotate around the σ bond (*shown in circle*), and the π bond forms again but with a *trans* orientation. This change in the shape of retinal changes the shape of the protein, causing it to release the all-*trans*-retinal.

Alkynes: Hydrocarbons with Triple Bonds

Hydrocarbons that contain at least one C≡C bond are called **alkynes.** Their general formula is $\mathbf{C_nH_{2n-2}}$ because they have two H atoms fewer than alkenes with the same number of carbons. Because a carbon in a C≡C bond can bond to only one other atom, the geometry around each C atom is linear (180°): each C is *sp* hybridized. Alkynes are named in the same way as alkenes, except that the suffix is *-yne*. Because of their localized π electrons, C=C and C≡C bonds are electron rich and act as functional groups. Thus, alkenes and alkynes are much more reactive than alkanes, as we'll discuss in Section 15.4.

SAMPLE PROBLEM 15.2 Naming Alkanes, Alkenes, and Alkynes

Problem Give the systematic name for each of the following, indicate the chiral center in part (d), and draw two geometric isomers for part (e):

(a) $CH_3-C(CH_3)(CH_3)-CH_2-CH_3$ **(b)** $CH_3-CH_2-CH(CH_3)-CH(CH_2CH_3)-CH_3$ **(c)**  **(d)** $CH_3-CH_2-CH(CH_3)-CH=CH_2$ **(e)** $CH_3-CH_2-CH=C(CH_3)-CH(CH_3)-CH_3$

Plan For (a) to (c), we refer to Table 15.2, p. 624. We first name the longest chain (*root-* + *-ane*). Then we find the *lowest* branch numbers by counting C atoms from the end *closer* to a branch. Finally, we name each branch (*root-* + *-yl*) and put the names alphabetically before the chain name. For (d) and (e), the longest chain that *includes* the multiple bond is numbered from the end closer to it. For (d), the chiral center is the C atom bonded to four different groups. In (e), the *cis* isomer has larger groups on the same side of the double bond, and the *trans* isomer has them on opposite sides.

Solution

(a) 
2,2-dimethylbutane

When a type of branch appears more than once, we group the chain numbers and indicate the number of branches with a numerical prefix, such as 2,2-*di*methyl.

(b) 
3,4-dimethylhexane

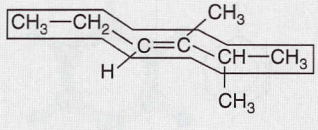
In this case, we can number the chain from either end because the branches are the same and are attached to the two central C atoms.

(c) 
1-ethyl-2-methylcyclopentane

We number the ring C atoms so that a branch is attached to C-1.

(d) 
3-methyl-1-pentene

(e) 
cis-2,3-dimethyl-3-hexene



trans-2,3-dimethyl-3-hexene

Check A good check (and excellent practice) is to reverse the process by drawing structures for the names to see if you come up with the structures given in the problem.

Comment In part (b), C-3 and C-4 are also chiral centers, as are C-1 and C-2 in part (c). However, in (b) the molecule is not chiral: it has a plane of symmetry between C-3 and C-4, so half of the molecule rotates light opposite to the other half. Avoid these common mistakes: In (b), 2-ethyl-3-methylpentane is wrong: the longest chain is *hexane*. In (c), 1-methyl-2-ethylcyclopentane is wrong: the branch names appear *alphabetically*.

FOLLOW-UP PROBLEM 15.2 Draw condensed formulas for the following compounds: **(a)** 3-ethyl-3-methyloctane; **(b)** 1-ethyl-3-propylcyclohexane (also draw a carbon-skeleton formula for this compound); **(c)** 3,3-diethyl-1-hexyne; **(d)** *trans*-3-methyl-3-heptene.

Aromatic Hydrocarbons: Cyclic Molecules with Delocalized π Electrons

Unlike the cycloalkanes, **aromatic hydrocarbons** are planar molecules, usually with one or more rings of six C atoms, and are often drawn with alternating single and double bonds. As you learned for benzene (Section 10.1), however, all the ring bonds are identical, with values of length and strength *between* those of a C—C and a C=C bond. To indicate this, benzene is also shown as a resonance hybrid, with a circle (or dashed circle) representing the delocalized character of the π electrons (Figure 15.12A). An orbital picture shows the two lobes of the delocalized π cloud above and below the hexagonal plane of the σ-bonded C atoms (Figure 15.12B).

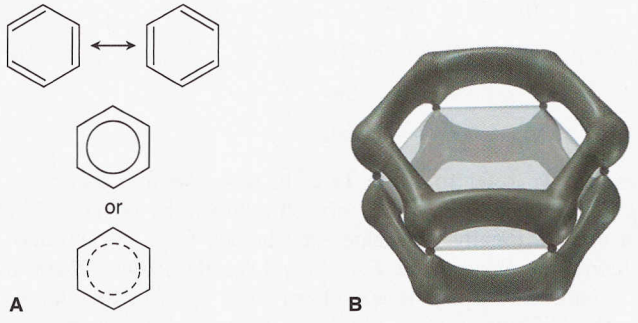


Figure 15.12 Representations of benzene. **A,** Benzene is often drawn with two resonance forms, showing alternating single and double bonds in different positions. The molecule is more correctly depicted as the resonance hybrid, with the delocalized electrons shown as an unbroken or dashed circle. **B,** The delocalized π cloud and the σ-bond plane of the benzene ring.

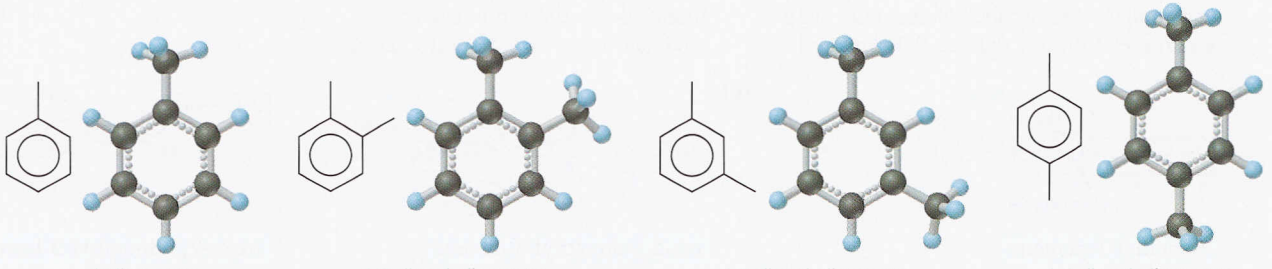
The systematic naming of simple aromatic compounds is quite straightforward. Usually, benzene is the parent compound, and attached groups, or *substituents,* are named as prefixes. However, many common names are still in use. For example, benzene with one methyl group attached is systematically named *methylbenzene* but is better known by its common name *toluene*. With only one substituent present in toluene, we do not number the ring C atoms; when two or more groups are attached, however, we number in such a way that one of the groups is attached to ring C-1. Thus, toluene and the three structural isomers with two methyl groups attached are



methylbenzene
(toluene)
bp = 110.6°C

1,2-dimethylbenzene
(*o*-xylene)
bp = 144.4°C

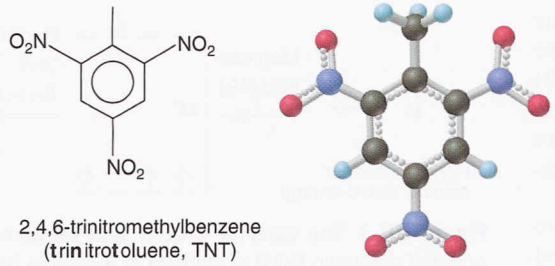
1,3-dimethylbenzene
(*m*-xylene)
bp = 139.1°C

1,4-dimethylbenzene
(*p*-xylene)
bp = 138.3°C

In common names, the positions of two groups are indicated by *o*- (ortho) for groups on adjacent ring C atoms, *m*- (meta) for groups separated by one ring C atom, and *p*- (para) for groups on opposite ring C atoms. The dimethylbenzenes (commonly known as *xylenes*) are important solvents and feedstocks for polyester fibers and dyes. (See the margin note on the opposite page.)

The number of isomers increases with more than two attached groups. For example, there are six isomers for a compound with one methyl and three nitro

($—NO_2$) groups attached to a benzene ring; the explosive TNT, shown below, is only one:



2,4,6-trinitromethylbenzene
(trinitrotoluene, TNT)

One of the most important methods for determining the structures of organic molecules is discussed in the upcoming Tools of the Laboratory essay.

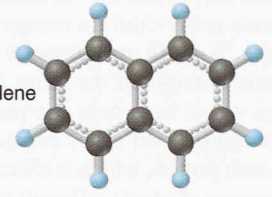
Variations on a Theme: Catenated Inorganic Hydrides

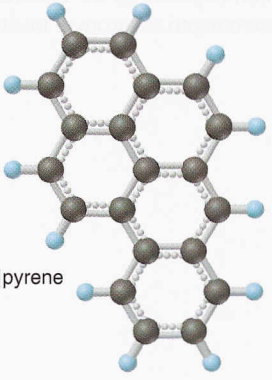
In short discussions called *Variations on a Theme* found throughout this chapter, we examine similarities between organic and inorganic compounds. From this perspective, you'll see that the behavior of carbon is remarkable, but not unique, in the chemistry of the elements.

Although no element approaches carbon in the variety and complexity of its hydrides, catenation occurs frequently in the periodic table, and many ring, chain, and cage structures are known. Some of the most fascinating belong to the boron hydrides, or boranes (Section 14.5). Although their shapes rival even those of the hydrocarbons, the weakness of their unusual bridge bonds renders most of them thermally and chemically unstable.

An obvious structural similarity exists between alkanes and the silicon hydrides, or silanes (Section 14.6). Silanes even have an analogous general formula (Si_nH_{2n+2}). Branched silanes are also known, but no cyclic or unsaturated (containing an Si=Si bond) compounds had been prepared until very recently. Unlike alkanes, silanes are unstable thermally and ignite spontaneously in air.

Sulfur's ability to catenate is second only to carbon's, and many chains and rings occur among its allotropes (Section 14.8). A large series of sulfur hydrides, or polysulfanes, is known. However, these molecules are unbranched chains with H atoms at the ends only ($H—S_n—H$). Like the silanes, the polysulfanes are oxidized easily and decompose readily to sulfur's only stable hydride, H_2S, and its most stable allotrope, cyclo-S_8.





Aromatic Carcinogens *Polycyclic aromatic compounds* have "fused" ring systems, in which two or more rings share one or more sides. The simplest is naphthalene, a feedstock for dyes. Many of these compounds (and benzene itself) have been shown to have carcinogenic (cancer-causing) activity. One of the most potent, benzo[*a*]pyrene, is found in soot, cigarette smoke, car exhaust, and even the smoke from barbecue grills!

SECTION SUMMARY

Hydrocarbons contain only C and H atoms, so their physical properties depend on the strength of their dispersion forces. The names of the organic compounds have a root for the longest chain, a prefix for any attached group, and a suffix for the type of compound. Alkanes (C_nH_{2n+2}) have only single bonds. Cycloalkanes (C_nH_{2n}) have ring structures that are typically nonplanar. Alkenes (C_nH_{2n}) have at least one C=C bond. Alkynes (C_nH_{2n-2}) have at least one C≡C bond. Aromatic hydrocarbons have at least one planar ring with delocalized π electrons.

Isomers are compounds with the same molecular formula but different properties. Structural isomers have different atom arrangements. Stereoisomers (optical and geometric) have the same arrangement of atoms, but their atoms are oriented differently in space. Optical isomers cannot be superimposed on each other because they are asymmetric, with four different groups bonded to the C that is the chiral center. They have identical physical and chemical properties except in their rotation of plane-polarized light and their reaction with chiral reactants. Geometric (*cis-trans*) isomers have groups oriented differently around a C=C bond, which restricts rotation. Light converts a *cis* isomer of retinal to the all-*trans* form, which initiates the visual response. ^{1}H-NMR spectroscopy indicates the relative numbers of H atoms in the various environments within an organic molecule.

Nuclear Magnetic Resonance (NMR) Spectroscopy

Chemists rely on a battery of instrumental methods to determine the complex structures of organic molecules. We discussed the methods of mass spectrometry in Chapter 2 and infrared (IR) spectroscopy in Chapter 9. One of the most useful tools for analyzing organic and biochemical structures is **nuclear magnetic resonance (NMR) spectroscopy,** which measures environments of certain nuclei in a molecule to elucidate its structure.

In Chapter 8, we saw that an electron can spin in either of two directions, each of which creates a tiny magnetic field. Several types of nuclei behave in a similar way. The most important of these are ^{1}H, ^{13}C, ^{19}F, and ^{31}P. In this discussion we focus primarily on the proton, ^{1}H, the nucleus of the most common isotope of hydrogen, and therefore refer to ^{1}H-NMR spectroscopy. Generally, the magnetic fields of all the protons in a sample of compound are oriented randomly. When placed in a strong external magnetic field ($\boldsymbol{H}_0$), however, the proton fields become aligned with it (parallel) or against it (antiparallel). The parallel orientation is slightly lower in energy, with the energy difference (ΔE) between the two energy states (spin states) lying in the radio-frequency (rf) region of the spectrum.

The protons in the sample oscillate rapidly between the two spin states, and in a process known as *resonance,* the rf value is varied until it matches the frequency of this oscillation. At this point, the protons are "in resonance" with the rf radiation and they absorb and re-emit the energy, which is detected by the rf receiver of the ^{1}H-NMR spectrometer (Figure B15.2). If all the protons in a sample required the same ΔE for resonance, a ^{1}H-NMR spectrum would have only one peak and be useless. However, the ΔE between the two states depends on the *actual* magnetic field felt by each proton, which is affected by the tiny magnetic fields of the *electrons* of atoms adjacent to that proton. Thus, the ΔE of each proton depends on the electrons in the adjacent atoms—C atoms, electronegative atoms, multiple bonds, and aromatic rings—

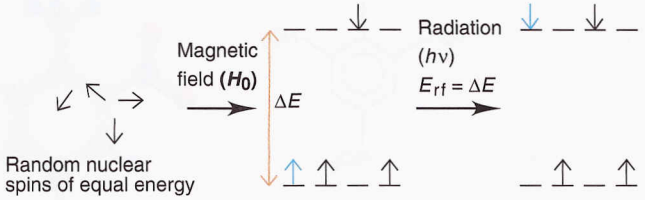


Figure B15.2 The basis of proton spin resonance. The randomly oriented magnetic fields of protons in a sample become aligned in a strong external field ($\boldsymbol{H}_0$), with slightly more protons in the lower spin state. In a process called *resonance,* the spin flips when the proton absorbs a photon with energy equal to ΔE (radio-frequency region).

in other words, on the specific molecular environment. Therefore, the ^{1}H-NMR spectrum is *unique* to that compound.

The ^{1}H-NMR spectrum of a compound is a series of peaks that represents the resonance of each proton as a function of the changing magnetic field. The *chemical shift* of the protons in a given environment is where a peak appears; it represents the ratio of the frequency at which resonance occurs for that proton to the magnitude of the external magnetic field. The chemical shifts are shown relative to that of an added standard, tetramethylsilane [$(CH_3)_4Si$, TMS], which has 12 protons bonded to four C atoms that are bonded to one Si atom. Because the shape of TMS is tetrahedral around Si, all 12 protons are in identical environments and so produce one peak. Figure B15.3 shows the ^{1}H-NMR spectrum of acetone. The six protons of acetone also have identical environments—bonded to two C atoms that are each bonded to the C atom in a C=O bond—so they, too, produce one peak, but at a different position from that for TMS. (The axes need not concern us.) The spectrum of dimethoxymethane in Figure B15.4 shows *two* peaks in addition to the TMS peak. The taller one is due

15.3 SOME IMPORTANT CLASSES OF ORGANIC REACTIONS

In Chapter 4, we classified chemical reactions based on the chemical process involved (precipitation, acid-base, or redox) and then briefly included a classification based on the number of reactants and products (combination, decomposition, or displacement). We take a similar approach here with organic reactions.

From here on, we use the notation of an uppercase R with a single bond, R—, to signify a general organic group attached to one of the atoms shown; you can usually picture R— as an **alkyl group,** a saturated hydrocarbon chain with one bond available to link to another atom. Thus, R—CH_2—Br has an alkyl group attached to a CH_2 group bearing a Br atom; R—CH=CH_2 is an alkene with an alkyl group attached to one of the carbons in the double bond; and so forth. (Often, when more than one R group is present, we write R, R′, R″, and so forth, to indicate that these groups may be different.)

Types of Organic Reactions

Most organic reactions are examples of three broad types that can be identified by comparing the *number of bonds to C* in reactants and products:

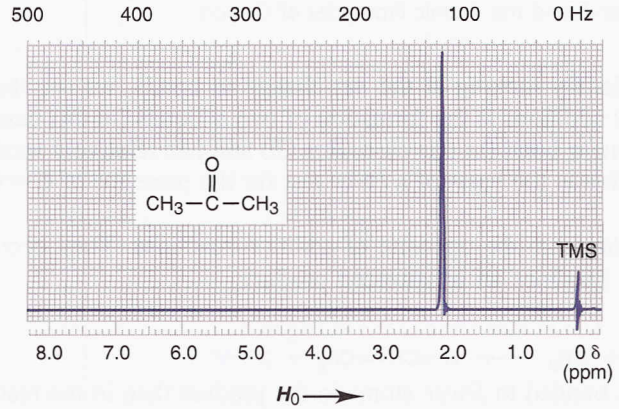

Figure B15.3 The ^{1}H-NMR spectrum of acetone. The six CH_3 protons are in identical environments, so they produce one peak; it has a different chemical shift from that for the 12 protons of the TMS standard.

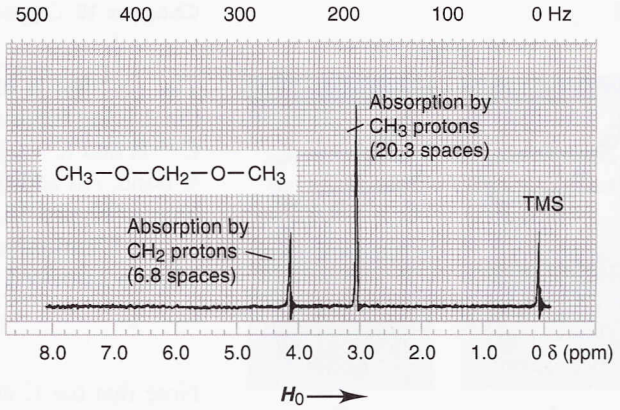

Figure B15.4 The ^{1}H-NMR spectrum of dimethoxymethane. The two peaks show chemical shifts of protons in two different environments. The area under each peak is proportional to the number of protons.

to the six CH_3 protons, and the shorter is due to the two CH_2 protons. The area under each peak (given here in units of chart-paper spaces) is proportional to *the number of protons in a given environment*. Note that the area ratio is 20.3:6.8 ≈ 3:1, the same as the ratio of six CH_3 protons to two CH_2 protons. Thus, by analyzing the chemical shifts and peak areas, the chemist learns the type and number of hydrogens in the compound.

Newer NMR methods measure the resonance of protons and other nuclei and have many applications in biochemistry and medicine. In fact, Kurt Wüthrich shared the 2002 Nobel Prize in chemistry for developing NMR methods to study biopolymer structures in solution. ^{13}C-NMR is used to monitor changes in protein and nucleic acid shape and function, and ^{31}P-NMR can determine the health of various organs. For example, the extent of damage from a heart attack can be learned by using ^{31}P-NMR to measure the concentrations of specific phosphate-containing molecules involved in energy utilization by cardiac muscle tissue.

Computer-aided magnetic resonance imaging (MRI) has allowed visualization of damage to organs and greatly assists physicians in medical diagnosis. For example, an MRI scan of the head (Figure B15.5) can show various levels of metabolic activity in different regions of the brain. The 2003 Nobel Prize in physiology or medicine was awarded to Paul C. Lauterbur and Peter Mansfield for their discoveries applying magnetic resonance to imaging organs and other body parts.

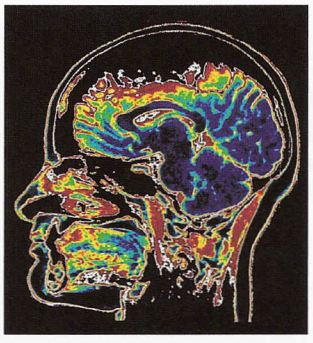

Figure B15.5 Magnetic resonance imaging (MRI) of a human head. Colors indicate a range from high (*red*) to low (*blue*) metabolic activity.

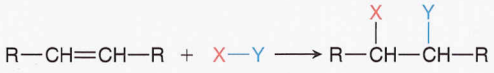
1. An **addition reaction** occurs when an unsaturated reactant becomes a saturated product:

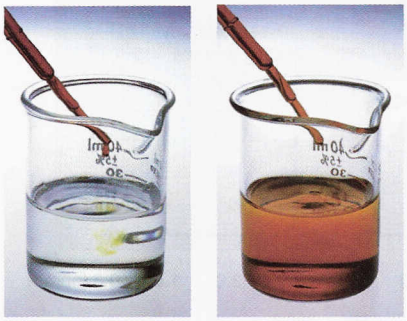


Note the C atoms are bonded to *more* atoms in the product than in the reactant.

The C=C and C≡C bonds and the C=O bond commonly undergo addition reactions. In each case, the π bond breaks, leaving the σ bond intact. In the product, the two C atoms (or C and O) form two additional σ bonds. Let's examine the standard heat of reaction (ΔH^0_{rxn}) for a typical addition reaction to see why these reactions occur. Consider the reaction between ethene (common name, ethylene) and HCl:

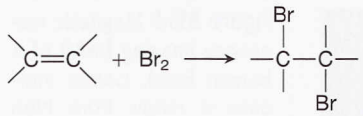
Reactants (bonds broken)		Product (bonds formed)	
1 C=C	= 614 kJ	1 C—C	= −347 kJ
4 C—H	= 1652 kJ	5 C—H	= −2065 kJ
1 H—Cl	= 427 kJ	1 C—Cl	= −339 kJ
Total	= 2693 kJ	Total	= −2751 kJ

$$\Delta H^0_{rxn} = \Sigma\Delta H^0_{\text{bonds broken}} + \Sigma\Delta H^0_{\text{bonds formed}} = 2693\text{ kJ} + (-2751\text{ kJ}) = -58\text{ kJ}$$



A B

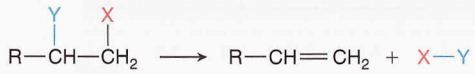
Figure 15.13 A color test for C═C bonds. **A,** Br_2 (in pipet) reacts with a compound that has a C═C bond (in beaker), and its orange-brown color disappears:



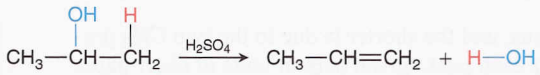
B, The compound in this beaker has no C═C bond, so the Br_2 does not react, and the orange-brown color remains.

The reaction is exothermic. By looking at the *net* change in bonds, we see that the driving force for many additions is the formation of two σ bonds (in this case, C—H and C—Cl) from one σ bond (in this case, H—Cl) and one relatively weak π bond. An addition reaction is the basis of a color test for the presence of C═C bonds (Figure 15.13).

2. **Elimination reactions** are the opposite of addition reactions. They occur when a saturated reactant becomes an unsaturated product:

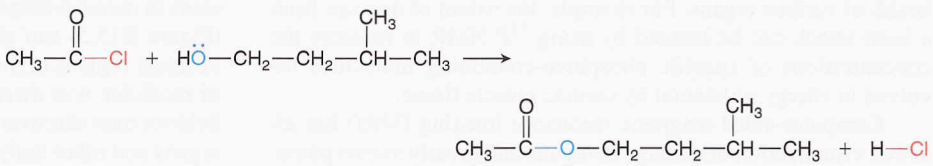


Note that the C atoms are bonded to *fewer* atoms in the product than in the reactant. A pair of halogen atoms, an H atom and a halogen atom, or an H atom and an —OH group are typically eliminated, but C atoms are not. Thus, the driving force for many elimination reactions is the formation of a small, stable molecule, such as HCl(*g*) or H_2O, which increases the entropy of the system (Section 13.3):



3. A **substitution reaction** occurs when an atom (or group) from an added reagent substitutes for one in the organic reactant:

Note that the C atom is bonded to the *same number* of atoms in the product as in the reactant. The C atom may be saturated or unsaturated, and X and Y can be many different atoms, but generally *not* C. The main flavor ingredient in banana oil, for instance, forms through a substitution reaction; note that the O substitutes for the Cl:



SAMPLE PROBLEM 15.3 Recognizing the Type of Organic Reaction

Problem State whether each reaction is an addition, elimination, or substitution:

(a) $CH_3—CH_2—CH_2—Br \longrightarrow CH_3—CH{=}CH_2 + HBr$

(b) 
(c)

Plan We determine the type of reaction by looking for any change in the number of atoms bonded to C:

- More atoms bonded to C is an *addition.*
- Fewer atoms bonded to C is an *elimination.*
- Same number of atoms bonded to C is a *substitution.*

Solution

(a) Elimination: two bonds in the reactant, C—H and C—Br, are absent in the product, so fewer atoms are bonded to C.

(b) Addition: two more C—H bonds have formed in the product, so more atoms are bonded to C.

(c) Substitution: the reactant C—Br bond becomes a C—O bond in the product, so the same number of atoms are bonded to C.

FOLLOW-UP PROBLEM 15.3 Write a balanced equation for each of the following:
(a) An addition reaction between 2-butene and Cl_2
(b) A substitution reaction between $CH_3—CH_2—CH_2—Br$ and OH^-
(c) The elimination of H_2O from $(CH_3)_3C—OH$

The Redox Process in Organic Reactions

An important process in many organic reactions is *oxidation-reduction*. But chemists do not usually monitor the change in oxidation numbers of the various C atoms in a reaction. Rather, they note the movement of electron density around a C atom by counting the number of bonds to more electronegative atoms (usually O) or to less electronegative atoms (usually H). A more electronegative atom takes some electron density from the C, whereas a less electronegative atom gives some electron density to the C. Moreover, even though a redox reaction always involves both an oxidation and a reduction, organic chemists typically *focus on the organic reactant only*. Therefore,

- When a C atom in the organic reactant forms more bonds to O or fewer bonds to H, the reactant is oxidized and the reaction is called an *oxidation*.
- When a C atom in the organic reactant forms fewer bonds to O or more bonds to H, the reactant is reduced and the reaction is called a *reduction*.

The most dramatic redox reactions are combustion reactions. All organic compounds contain C and H atoms and burn in excess O_2 to form CO_2 and H_2O. For ethane, the reaction is

$$2CH_3—CH_3 + 7O_2 \longrightarrow 4CO_2 + 6H_2O$$

Obviously, when ethane is converted to CO_2 and H_2O, each of its C atoms has more bonds to O and fewer bonds to H. Thus, ethane is oxidized, and this reaction is referred to as an *oxidation,* even though O_2 is reduced as well.

Most oxidations do not involve such a total breaking apart of the molecule, however. When 2-propanol reacts with potassium dichromate in acidic solution (a common oxidizing agent in organic reactions), the organic compound that forms is 2-propanone:

$$\underset{\text{2-propanol}}{CH_3—\underset{\displaystyle OH}{\underset{|}{CH}}—CH_3} \xrightarrow[H_2SO_4]{K_2Cr_2O_7} \underset{\text{2-propanone}}{CH_3—\underset{\displaystyle O}{\overset{\|}{C}}—CH_3}$$

Note that C-2 has one fewer bond to H and one more bond to O in 2-propanone than it does in 2-propanol. Thus, 2-propanol is oxidized, so this is an *oxidation*. Don't forget, however, that the dichromate ion is reduced at the same time:

$$Cr_2O_7^{2-} + 14H^+ + 6e^- \longrightarrow 2Cr^{3+} + 7H_2O$$

The addition of H_2 to an alkene is referred to as a *reduction:*

$$CH_2=CH_2 + H_2 \xrightarrow{Pd} CH_3—CH_3$$

Note that each C has more bonds to H in ethane than it has in ethene, so the ethene is reduced. (The H_2 is oxidized in the process, and the palladium shown over the arrow acts as a catalyst to speed up the reaction.)

SECTION SUMMARY

In an addition reaction, a π bond breaks and the two C atoms bond to more atoms. In an elimination, a π bond forms and the two C atoms bond to fewer atoms. In a substitution, one atom replaces another atom, but the total number of atoms bonded to C does not change. In an organic redox process, the organic reactant is oxidized if a C atom in the compound forms more bonds to O atoms (or fewer bonds to H atoms), and it is reduced if a C atom forms more bonds to H (or fewer bonds to O).

15.4 PROPERTIES AND REACTIVITIES OF COMMON FUNCTIONAL GROUPS

The central organizing principle of organic reaction chemistry is the *functional group*. To predict how an organic compound might react, we narrow our focus there because *the distribution of electron density in a functional group affects the reactivity.* The electron density can be high, as in the C=C and C≡C bonds, or it can be low at one end of a bond and high at the other, as in the C—Cl and C—O bonds. Such bond sites enhance a dipole in the other reactant. As a result, the reactants attract each other and begin a sequence of bond-forming and bond-breaking steps that lead to product. Thus, *the intermolecular forces that affect physical properties and solubility also affect reactivity.* Table 15.5 lists some of the important functional groups in organic compounds.

When we classify functional groups by bond order (single, double, and so forth), they tend to follow certain patterns of reactivity:

- Functional groups with only single bonds undergo substitution or elimination.
- Functional groups with double or triple bonds undergo addition.
- Functional groups with both single and double bonds undergo substitution.

Functional Groups with Only Single Bonds

The most common functional groups with only single bonds are alcohols, haloalkanes, and amines.

Alcohols The **alcohol** functional group consists of carbon bonded to an —OH group, $-\overset{|}{\underset{|}{C}}-\ddot{O}-H$, and the general formula of an alcohol is R—OH. Alcohols are named by dropping the final *-e* from the parent hydrocarbon name and adding the suffix *-ol*. Thus, the two-carbon alcohol is ethanol (ethan- + -ol). The common name is the hydrocarbon *root-* + *-yl,* followed by "alcohol"; thus, the common name of ethanol is ethyl alcohol. (This substance, obtained from fermented grain, has been consumed by people as an intoxicant in beverages since ancient times; today, it is recognized as the most abused drug in the world.) Alcohols are important laboratory reagents, and the functional group occurs in many biomolecules, including carbohydrates, sterols, and some amino acids. Figure 15.14 shows the names, structures, and uses of some important compounds that contain the alcohol group.

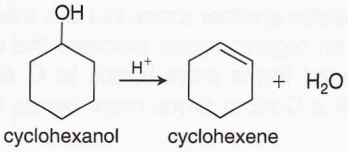
You can think of an alcohol as a water molecule with an R group in place of one of the H atoms. In fact, alcohols react with very active metals, such as the alkali metals [Group 1A(1)], in a manner similar to water:

$$2Na + 2HOH \longrightarrow 2NaOH + H_2$$

$$2Na + 2CH_3{-}CH_2{-}OH \longrightarrow 2CH_3{-}CH_2{-}ONa + H_2$$

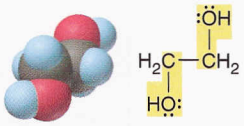
Water forms a solution of the strongly basic hydroxide ion (HO^-), and an alcohol forms a solution of the strongly basic *alkoxide ion* (RO^-): ethanol forms the ethoxide ion ($CH_3{-}CH_2{-}O^-$). The physical properties of the smaller alcohols are also similar to those of water. They have high melting and boiling points as a result of hydrogen bonding, and they dissolve polar molecules and some salts. (Substitution of R groups for both H atoms of water gives *ethers,* R—O—R.)

Alcohols undergo elimination and substitution reactions. Dehydration, the elimination of H and OH, requires acid and forms alkenes:

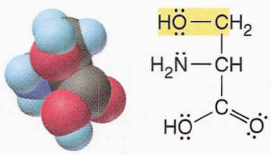


cyclohexanol cyclohexene

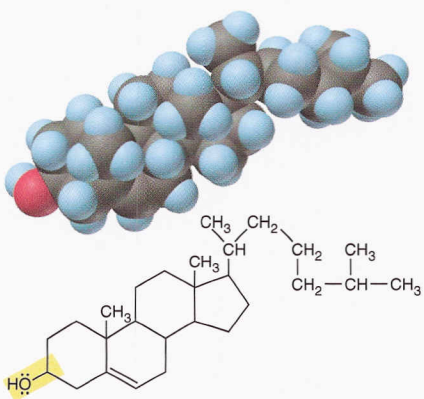
Methanol (methyl alcohol)
By-product in coal gasification; de-icing agent; gasoline substitute; precursor of organic compounds



1,2-Ethanediol (ethylene glycol)
Main component of auto antifreeze



Serine
Amino acid found in most proteins



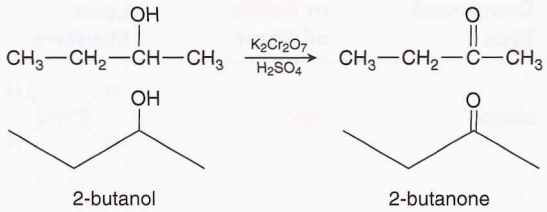
Cholesterol
Major sterol in animals; essential for cell membranes; precursor of steroid hormones

Figure 15.14 Some molecules with the alcohol functional group.

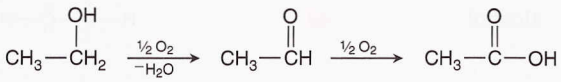
Table 15.5 Important Functional Groups in Organic Compounds

Functional Group	Compound Type	Prefix or Suffix of Name	Example		
			Lewis Structure	Ball-and-stick Model	Systematic Name (Common Name)
	alkene	-ene			ethene (ethylene)
	alkyne	-yne			ethyne (acetylene)
	alcohol	-ol			methanol (methyl alcohol)
 (X=halogen)	haloalkane	halo-			chloromethane (methyl chloride)
	amine	-amine			ethanamine (ethylamine)
	aldehyde	-al			ethanal (acetaldehyde)
	ketone	-one			2-propanone (acetone)
	carboxylic acid	-oic acid			ethanoic acid (acetic acid)
	ester	-oate			methyl ethanoate (methyl acetate)
	amide	-amide			ethanamide (acetamide)
	nitrile	-nitrile			ethanenitrile (acetonitrile, methyl cyanide)

Elimination of two H atoms requires inorganic oxidizing agents, such as $K_2Cr_2O_7$ in aqueous H_2SO_4. As we saw in Section 15.3, the reaction is an oxidation and produces the C=O group (shown with condensed and carbon-skeleton formulas):



For alcohols with an OH group at the end of the chain (R—CH_2—OH), another oxidation occurs. Wine turns sour, for example, when the ethanol in contact with air is oxidized to acetic acid:



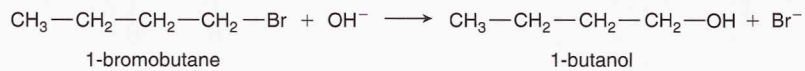
Substitution yields products with other single-bonded functional groups. With hydrohalic acids, many alcohols give haloalkanes:

$$R_2CH{-}OH + HBr \longrightarrow R_2CH{-}Br + HOH$$

As you'll see below, *the C atom undergoing the change in a substitution is bonded to a more electronegative element,* which makes it partially positive and, thus, a target for a negatively charged or electron-rich group of an incoming reactant.

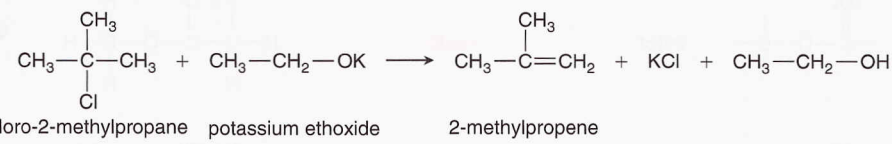
Haloalkanes A *halogen* atom (X) bonded to C gives the **haloalkane** functional group, , and compounds with the general formula R—X. Haloalkanes (common name, **alkyl halides**) are named by adding the halogen as a prefix to the hydrocarbon name and numbering the C atom to which the halogen is attached, as in bromomethane, 2-chloropropane, or 1,3-diiodohexane.

Just as many alcohols undergo substitution to alkyl halides when treated with halide ions in acid, many halides undergo substitution to alcohols in base. For example, OH^- attacks the positive C end of the C—X bond and displaces X^-:



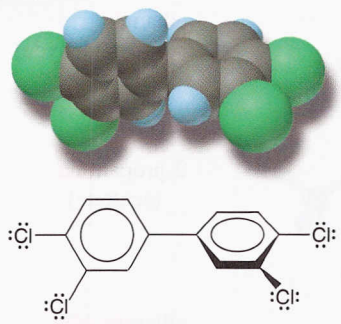
Substitution by groups such as —CN, —SH, —OR, and —NH_2 allows chemists to convert alkyl halides to a host of other compounds.

Just as addition of HX *to* an alkene produces haloalkanes, elimination of HX *from* a haloalkane by reaction with a strong base, such as potassium ethoxide, produces an alkene:



Haloalkanes have many important uses, but many are carcinogenic in mammals and have severe neurological effects in humans. Their stability has made them notorious environmental contaminants.

Amines The **amine** functional group is . Chemists classify amines as derivatives of ammonia, with R groups in place of one or more H atoms. *Primary* (1°) amines are RNH_2, *secondary* (2°) amines are R_2NH, and *tertiary* (3°) amines are R_3N. Like ammonia, amines have trigonal pyramidal shapes and a lone pair



Pollutants in the Food Chain Until recently, halogenated aromatic hydrocarbons, such as the *polychlorinated biphenyls* (*PCBs;* one of 209 different compounds is shown above), were used as insulating fluids in electrical transformers and then discharged in wastewater. Because of their low solubility and high stability, they accumulate for decades in river and lake sediment and are eaten by microbes and invertebrates. Fish eat the invertebrates, and birds and mammals, including humans, eat the fish. PCBs become increasingly concentrated in body fat at each stage. As a result of their health risks, PCBs in natural waters present an enormous cleanup problem.

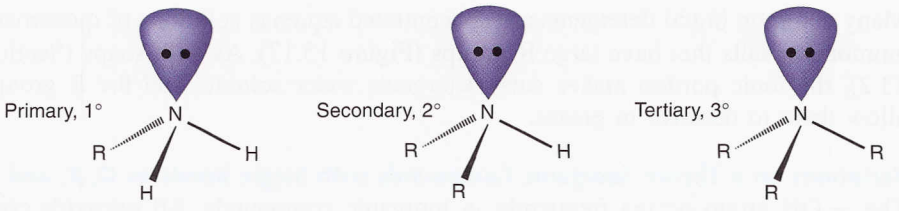


Figure 15.15 General structures of amines. Amines have a trigonal pyramidal shape and are classified by the number of R groups bonded to N. The lone pair on the nitrogen atom is the key to amine reactivity.

of electrons on a partially negative N atom (Figure 15.15). Systematic names drop the final *-e* of the alkane and add the suffix *-amine,* as in ethanamine. However, there is still wide usage of common names, in which the suffix *-amine* follows the name of the alkyl group; thus, methylamine has one methyl group attached to N, diethylamine has two ethyl groups attached, and so forth. Figure 15.16 shows that the amine functional group occurs in many biomolecules.

Primary and secondary amines can form H bonds, so they have higher melting and boiling points than hydrocarbons and alkyl halides of similar molar mass. For example, dimethylamine ($\mathcal{M}$ = 45.09 g/mol) boils 45°C higher than ethyl fluoride ($\mathcal{M}$ = 48.06 g/mol). Trimethylamine has a greater molar mass than dimethylamine, but it melts more than 20°C *lower* because trimethylamine molecules are not H bonded.

Amines of low molar mass are fishy smelling, water soluble, and weakly basic. The reaction with water proceeds only slightly to the right to reach equilibrium:

$$CH_3{-}\ddot{N}H_2 + H_2O \rightleftharpoons CH_3{-}\overset{+}{N}H_3 + OH^-$$

Amines undergo substitution reactions in which the lone pair on N attacks the partially positive C in alkyl halides to displace X^- and form a larger amine:

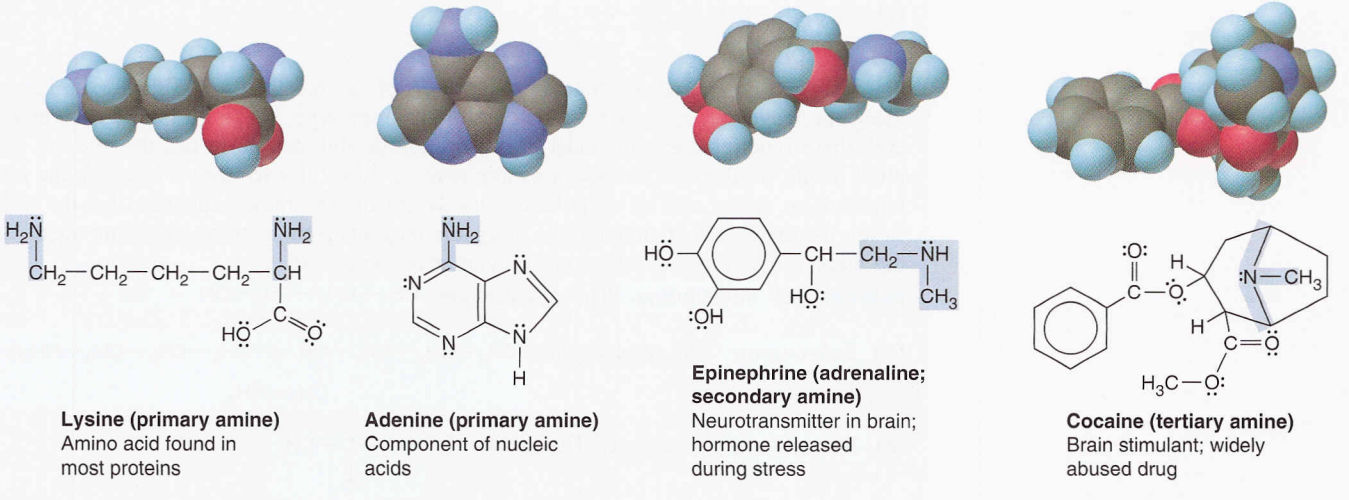
$$2CH_3{-}CH_2{-}\ddot{N}H_2 + CH_3{-}CH_2{-}Cl \longrightarrow CH_3{-}CH_2{-}\underset{\displaystyle CH_3{-}CH_2}{\overset{\displaystyle |}{\ddot{N}H}} + CH_3{-}CH_2{-}\overset{+}{N}H_3Cl^-$$

ethylamine — chloroethane — diethylamine — ethylammonium chloride

(One molecule of ethylamine participates in the substitution, while the other binds the released H^+ and prevents it from remaining on the diethylamine product.)

Four R groups bonded to an N atom give an ionic compound called a *quaternary (4°) ammonium salt:*

$$4NH_3 + 4RCl \longrightarrow 3NH_4Cl + R_4N^+Cl^- \quad \text{(a quaternary ammonium chloride)}$$



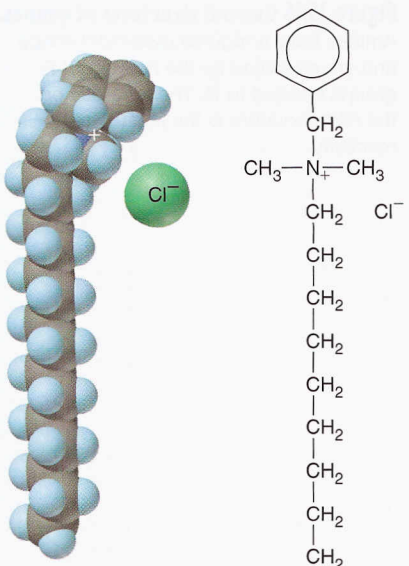
Lysine (primary amine)
Amino acid found in most proteins

Adenine (primary amine)
Component of nucleic acids

Epinephrine (adrenaline; secondary amine)
Neurotransmitter in brain; hormone released during stress

Cocaine (tertiary amine)
Brain stimulant; widely abused drug

Figure 15.16 Some biomolecules with the amine functional group.



Benzylcetyldimethyl-ammonium chloride

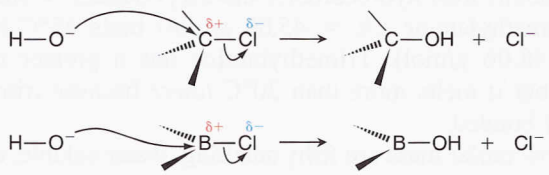
Figure 15.17 Structure of a cationic detergent. Quaternary ammonium salts are used as detergents. The charged portion dissolves in water, and the hydrocarbon portion dissolves in grease.

Many common liquid detergents are concentrated aqueous solutions of quaternary ammonium salts that have large R groups (Figure 15.17). As with soaps (Section 13.2), the ionic portion makes such detergents water soluble, and the R groups allow them to dissolve in grease.

Variations on a Theme: Inorganic Compounds with Single Bonds to O, X, and N

The —OH group occurs frequently in inorganic compounds. All oxoacids contain at least one —OH, usually bonded to a relatively electronegative nonmetal atom, which in most cases is bonded to other O atoms. Oxoacids are acidic in water because these additional O atoms pull electron density from the central nonmetal, which pulls electron density from the O—H bond, releasing an H^+ ion and stabilizing the oxoanion through resonance. Alcohols are *not* acidic in water because they lack the additional O atoms and the electronegative nonmetal.

Halides of nearly every nonmetal are known, and many undergo substitution reactions in base. As in the case of an alkyl halide, the process involves an attack on the partially positive central atom by OH^-:



Thus, alkyl halides undergo the same general reaction as other nonmetal halides, such as BCl_3, SiF_4, and PCl_5.

The bonds between nitrogen and larger nonmetals, such as Si, P, and S, have significant double-bond character, which affects structure and reactivity. For example, trisilylamine, the Si analog of trimethylamine (see Figure 14.16, p. 578), is planar, rather than trigonal pyramidal, partially as a result of p,d-π bonding. The lone pair on N is delocalized in this π bond, so trisilylamine is not basic.

SAMPLE PROBLEM 15.4 Predicting the Reactions of Alcohols, Alkyl Halides, and Amines

Problem Determine the reaction type and predict the product(s) for each of the following reactions:

(a) $CH_3—CH_2—CH_2—I + NaOH \longrightarrow$

(b) $CH_3—CH_2—Br + 2CH_3—CH_2—CH_2—NH_2 \longrightarrow$

(c) $CH_3—\underset{\displaystyle OH}{\underset{|}{CH}}—CH_3 \xrightarrow[H_2SO_4]{Cr_2O_7^{2-}}$

Plan We first determine the functional group(s) of the reactant(s) and then examine any inorganic reagent(s) to decide on the possible reaction type, keeping in mind that, in general, these functional groups undergo substitution or elimination. In **(a)**, the reactant is an alkyl halide, so the OH^- of the inorganic reagent substitutes for the —I. In **(b)**, the reactants are an amine and an alkyl halide, so the N: of the amine substitutes for the —Br. In **(c)**, the reactant is an alcohol, the inorganic reagents form a strong oxidizing agent, and the alcohol undergoes elimination to a carbonyl compound.

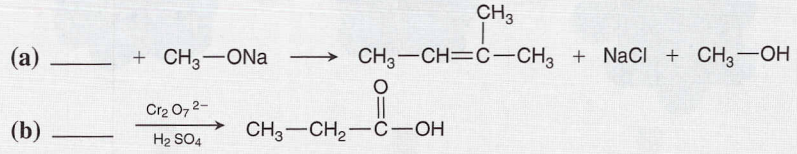
Solution **(a)** Substitution: The products are $CH_3—CH_2—CH_2—OH + NaI$

(b) Substitution: The products are $CH_3—CH_2—CH_2—\underset{\displaystyle CH_2—CH_3}{\underset{|}{NH}} + CH_3—CH_2—CH_2—\overset{+}{N}H_3Br^-$

(c) Elimination: (oxidation): The product is $CH_3—\underset{\displaystyle O}{\underset{\|}{C}}—CH_3$

Check The only changes should be at the functional group.

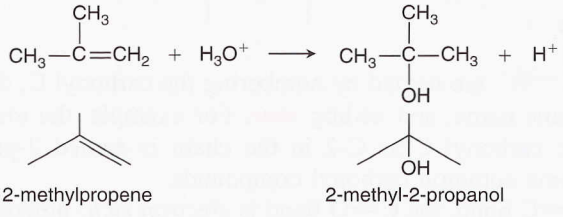
FOLLOW-UP PROBLEM 15.4 Fill in the blank in each reaction. (*Hint:* Examine any inorganic compounds and the organic product to determine the organic reactant.)

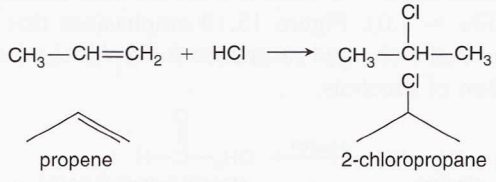


Functional Groups with Double Bonds

The most important functional groups with double bonds are the C=C of alkenes and the C=O of aldehydes and ketones. Both appear in many organic and biological molecules. *Their most common reaction type is addition.*

Comparing the Reactivity of Alkenes and Aromatic Compounds The C=C bond is the essential portion of the alkene functional group,  . Although they can be further unsaturated to alkynes, *alkenes typically undergo addition.* The electron-rich double bond is readily attracted to the partially positive H atoms of hydronium ions and hydrohalic acids, yielding alcohols and alkyl halides, respectively:

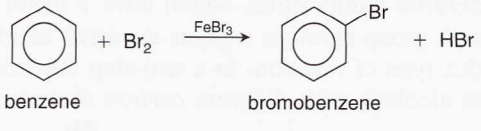




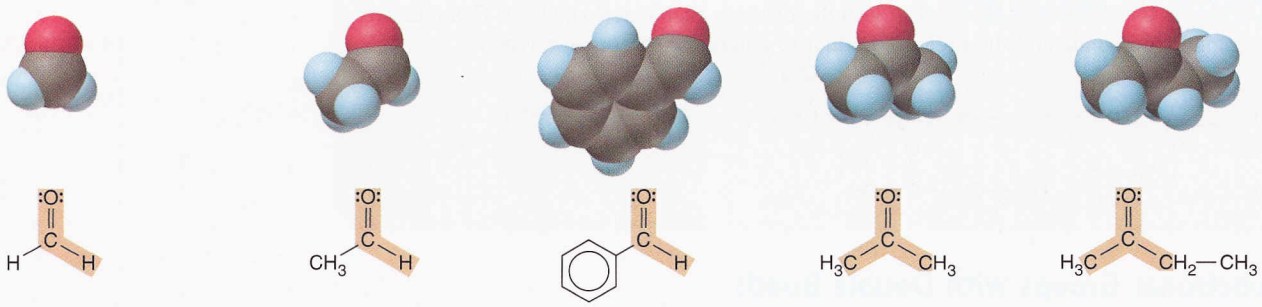
The *localized* unsaturation of alkenes is very different from the *delocalized* unsaturation of benzene. Since benzene does *not* have double bonds, despite the way we depict its resonance forms, it does *not* behave like an alkene. Benzene, for example, does not decolorize bromine because there are no isolated π-electron pairs to bond with Br_2.

In general, aromatic rings are much *less* reactive than alkenes because delocalized π electrons stabilize such a ring, making it *lower* in energy than one with localized π electrons. Data indicate that benzene is about 150 kJ/mol more stable than a six-C ring with three C=C bonds would be; in other words, benzene requires about 150 kJ/mol more energy to react.

An *addition* reaction with benzene, therefore, requires additional energy to break up the delocalized π system. Benzene does undergo many *substitution* reactions, however, in which the delocalization is retained when an H atom attached to a ring C is replaced by another group:



Aldehydes and Ketones The C=O bond, or **carbonyl group,** is one of the most chemically versatile. In the **aldehyde** functional group, the carbonyl C is bonded to H (and often to another C), so it occurs *at the end of a chain,*  .



Methanal (formaldehyde)
Used to make resins in plywood, dishware, countertops; biological preservative

Ethanal (acetaldehyde)
Narcotic product of ethanol metabolism; used to make perfumes, flavors, plastics, other chemicals

Benzaldehyde
Artificial almond flavoring

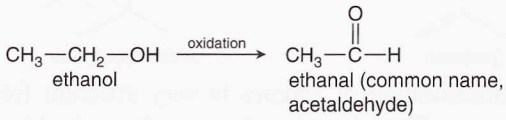
2-Propanone (acetone)
Solvent for fat, rubber, plastic, varnish, lacquer; chemical feedstock

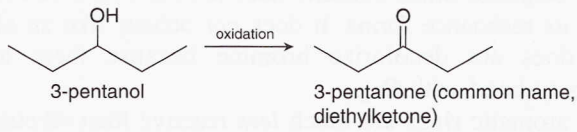
2-Butanone (methyl ethyl ketone)
Important solvent

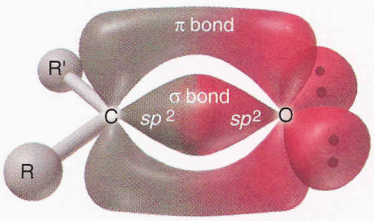
Figure 15.18 Some common aldehydes and ketones.

Aldehyde names drop the final *-e* from the alkane name and add *-al*, so that the three-C aldehyde is propanal. In the **ketone** functional group, the carbonyl C is bonded to two other C atoms,  , so it occurs *within the chain*. Ketones,  , are named by numbering the carbonyl C, dropping the final *-e* from the alkane name, and adding *-one*. For example, the unbranched, five-C ketone with the carbonyl C as C-2 in the chain is named 2-pentanone. Figure 15.18 shows some common carbonyl compounds.

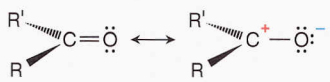
Like the C=C bond, the C=O bond is *electron rich;* unlike the C=C bond, it is *highly polar* ($\Delta EN = 1.0$). Figure 15.19 emphasizes this polarity with an electron density model and a charged resonance form. Aldehydes and ketones are formed by the oxidation of alcohols:







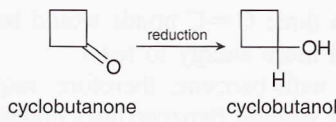
A



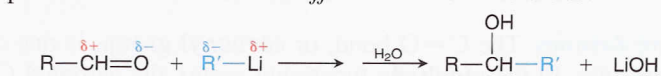
B

Figure 15.19 The carbonyl group. A, The σ and π bonds that make up the C=O bond of the carbonyl group. **B,** The charged resonance form shows that the C=O bond is polar ($\Delta EN = 1.0$).

Conversely, as a result of their unsaturation, carbonyl compounds can undergo *addition* and be reduced to alcohols:

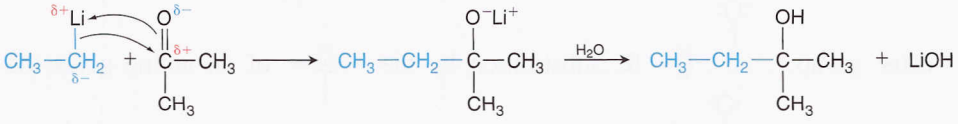


As a result of the bond polarity, addition often occurs with an electron-rich group bonding to the carbonyl C and an electron-poor group bonding to the carbonyl O. **Organometallic compounds,** which have a metal atom (usually Li or Mg) attached to an R group through a polar covalent bond (Sections 14.3 and 14.4), take part in this type of reaction. In a two-step sequence, they convert carbonyl compounds to alcohols with *different carbon skeletons:*



In the following reaction steps, for example, the electron-rich C bonded to Li in ethyllithium, CH_3CH_2—Li, attacks the electron-poor carbonyl C of 2-propanone,

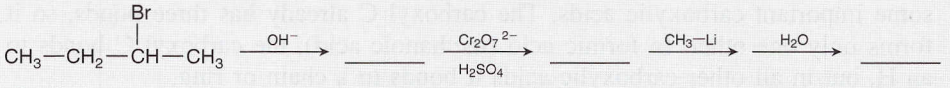
adding its ethyl group; at the same time, the Li adds to the carbonyl O. Treating the mixture with water forms the C—OH group:



Note that the product skeleton combines the two reactant skeletons. The field of *organic synthesis* often employs organometallic compounds to create molecules with different skeletons and, thus, synthesize new compounds.

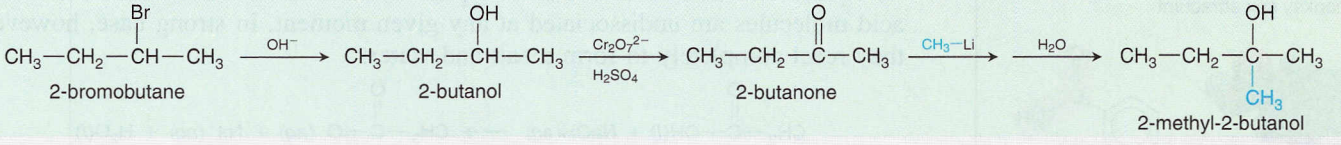
SAMPLE PROBLEM 15.5 Predicting the Steps in a Reaction Sequence

Problem Fill in the blanks in the following reaction sequence:



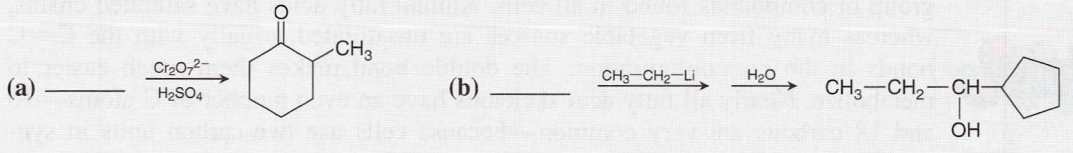
Plan For each step, we examine the functional group of the reactant and the reagent above the yield arrow to decide on the most likely product.

Solution The sequence starts with an alkyl halide reacting with OH^-. Substitution gives an alcohol. Oxidation of this alcohol with acidic dichromate gives a ketone. Finally, a two-step reaction of a ketone with CH_3—Li and then water forms an alcohol with a carbon skeleton that has the CH_3— group attached to the carbonyl C:

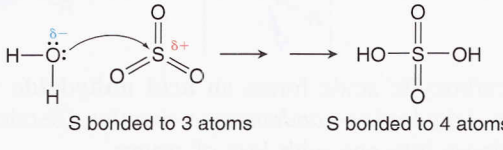


Check In this case, make sure that the first two reactions alter the functional group only and that the final steps change the C skeleton.

FOLLOW-UP PROBLEM 15.5 Choose reactants to obtain the following products:



Variations on a Theme: Inorganic Compounds with Double Bonds Homonuclear (same kind of atom) double bonds are rare for atoms other than C. However, we've seen many double bonds between O and other nonmetals, for example, in the oxides of S, N, and the halogens. Like carbonyl compounds, these substances undergo addition reactions. For example, the partially negative O of water attacks the partially positive S of SO_3 to form sulfuric acid:



Functional Groups with Both Single and Double Bonds

A family of three functional groups contains C double bonded to O (a carbonyl group) *and* single bonded to O or N. The parent of the family is the **carboxylic acid** group, —C(=O)—Ö:H, also called the *carboxyl group* and written —COOH.

The most important reaction type of this family is substitution from one member to another. Substitution for the —OH by the —OR of an alcohol gives the **ester** group, —C(=O)—O—R; substitution by the —N(H)— of an amine gives the **amide** group, —C(=O)—N(H)—.

Carboxylic Acids Carboxylic acids, R—C(=O)—OH, are named by dropping the *-e* from the alkane name and adding *-oic acid;* however, many common names are used. For example, the four-C acid is butanoic acid (the carboxyl C is counted when choosing the root); its common name is butyric acid. Figure 15.20 shows some important carboxylic acids. The carboxyl C already has three bonds, so it forms only one other. In formic acid (methanoic acid), the carboxyl C bonds to an H, but in all other carboxylic acids it bonds to a chain or ring.

Carboxylic acids are weak acids in water:

$$CH_3—C(=O)—OH(l) + H_2O(l) \rightleftharpoons CH_3—C(=O)—O^-(aq) + H_3O^+(aq)$$

ethanoic acid (acetic acid)

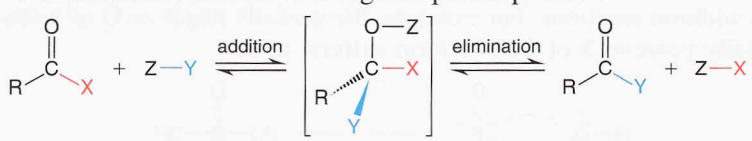
At equilibrium in acid solutions of typical concentration, more than 99% of the acid molecules are undissociated at any given moment. In strong base, however, they react completely to form a salt and water:

$$CH_3—C(=O)—OH(l) + NaOH(aq) \longrightarrow CH_3—C(=O)—O^-(aq) + Na^+(aq) + H_2O(l)$$

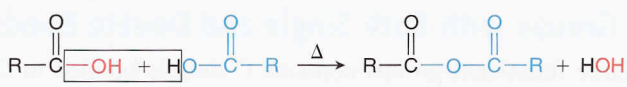
The anion is the *carboxylate ion,* named by dropping *-oic acid* and adding *-oate;* the sodium salt of butanoic acid, for instance, is sodium butanoate.

Carboxylic acids with long hydrocarbon chains are **fatty acids,** an essential group of compounds found in all cells. Animal fatty acids have saturated chains, whereas many from vegetable sources are unsaturated, usually with the C=C bonds in the *cis* configuration. The double bond makes them much easier to metabolize. Nearly all fatty acid skeletons have an even number of C atoms—16 and 18 carbons are very common—because cells use two-carbon units in synthesizing them. Fatty acid salts are soaps, with the cation usually from Group 1A(1) or 2A(2) (Section 13.2).

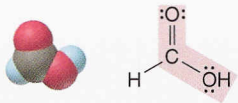
Substitution of carboxylic acids occurs through a two-step sequence: *addition plus elimination equals substitution.* Addition to the trigonal planar shape of the carbonyl group gives an unstable tetrahedral intermediate, which immediately undergoes elimination to revert to a trigonal planar product:



Strong heating of carboxylic acids forms an **acid anhydride** through a type of substitution called a *dehydration-condensation reaction* (Section 14.7), in which two molecules condense into one with loss of water:



Esters *An alcohol and a carboxylic acid form an ester.* The first part of an ester name designates the alcohol portion and the second the acid portion (named in the same way as the carboxylate ion). For example, the ester formed between



Methanoic acid (formic acid)

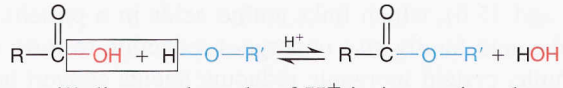
Figure 15.21 Some lipid molecules with the ester functional group.

ethanol and ethanoic acid is ethyl ethanoate (common name, ethyl acetate), a solvent for nail polish and model glue.

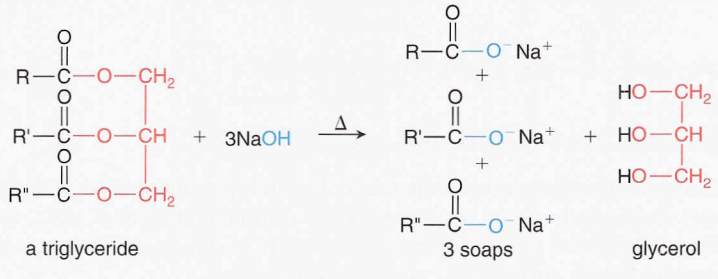
The ester group occurs commonly in **lipids,** a large group of fatty biological substances. Most dietary fats are *triglycerides,* esters composed of three fatty acids linked to the alcohol 1,2,3-trihydroxypropane (common name, glycerol) that function as energy stores. Some important lipids are shown in Figure 15.21; lecithin is one of several phospholipids that make up the lipid bilayer in all cell membranes (Section 13.2).

Esters, like acid anhydrides, form through a dehydration-condensation reaction; in this case, it is called an *esterification*:



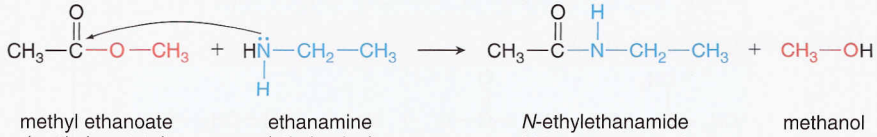
In Chapter 16, we will discuss the role of H^+ in increasing the rate of this multistep reaction.

Note that the esterification reaction is reversible. The opposite of dehydration-condensation is called **hydrolysis,** in which the O atom of water is attracted to the partially positive C atom of the ester, cleaving (lysing) the molecule into two parts. One part receives water's —OH, and the other part receives water's other H. In the process of soap manufacture, or *saponification* (Latin *sapon,* "soap"), begun in ancient times, ester bonds in animal or vegetable fats are hydrolyzed with strong base:



a triglyceride | 3 soaps | glycerol

Amides The product of a substitution between an amine (or NH_3) and an ester is an amide. The partially negative N of the amine is attracted to the partially positive C of the ester, an alcohol (ROH) is lost, and an amide forms:



methyl ethanoate (methyl acetate) | ethanamine (ethylamine) | *N*-ethylethanamide (*N*-ethylacetamide) | methanol

Amides are named by denoting the amine portion with *N*- and replacing *-oic acid* from the parent carboxylic acid with *-amide*. In the amide from the previous

A Pungent, Pleasant Banquet Many organic compounds have strong odors, but none can rival the diverse odors of carboxylic acids and esters. From the pungent, vinegary odors of the one-C and two-C acids to the cheesy stench of slightly larger ones, carboxylic acids possess some awful odors. When butanoic acid reacts with ethanol, however, its rancid-butter smell becomes the peachy pineapple scent of ethyl butanoate, and when pentanoic acid reacts with pentanol, its Limburger cheese odor becomes the fresh apple aroma of pentyl pentanoate. Naturally occurring and synthetic esters are used to add fruity, floral, and herbal odors to foods, cosmetics, household deodorizers, and medicines.

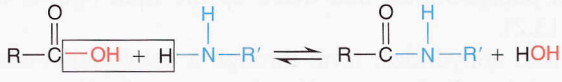
Figure 15.22 Some molecules with the amide functional group.

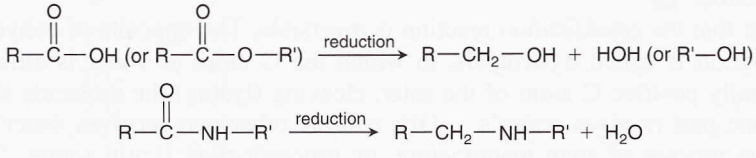
reaction, the ethyl group comes from the amine, and the acid portion comes from ethanoic acid (acetic acid). Some amides are shown in Figure 15.22.

Amides are hydrolyzed in hot water (or base) to a carboxylic acid and an amine. Thus, even though amides are not normally formed in the following way, they can be viewed as the result of a reversible dehydration-condensation:



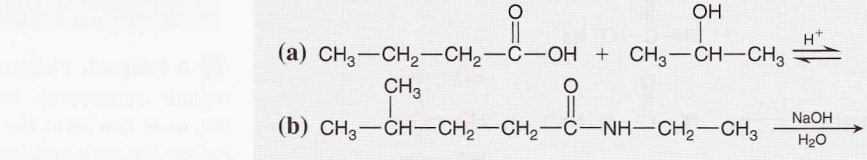
The most important example of the amide group is the *peptide bond* (discussed in Sections 13.2 and 15.6), which links amino acids in a protein.

The carboxylic acid family also undergoes reduction to form other functional groups. For example, certain inorganic reducing agents convert acids or esters to alcohols and convert amides to amines:



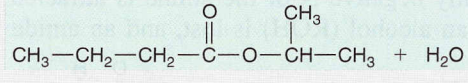
SAMPLE PROBLEM 15.6 Predicting Reactions of the Carboxylic Acid Family

Problem Predict the product(s) of the following reactions:

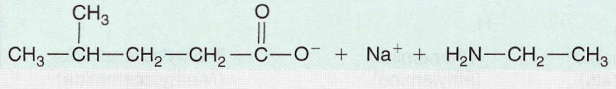


Plan We discussed substitution reactions (including addition-elimination and dehydration-condensation) and hydrolysis. In **(a),** a carboxylic acid and an alcohol react, so the reaction must be a substitution to form an ester and water. In **(b),** an amide reacts with OH^-, so it is hydrolyzed to an amine and a sodium carboxylate.

Solution **(a)** Formation of an ester:

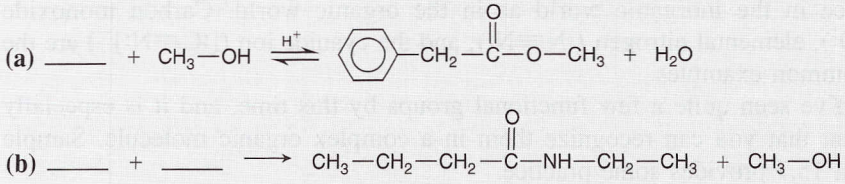


(b) Basic hydrolysis of an amide:



Check Note that in part (b), the carboxylate ion forms, rather than the acid, because the aqueous NaOH that is present reacts with the carboxylic acid.

FOLLOW-UP PROBLEM 15.6 Fill in the blanks in the following reactions:



Variations on a Theme: Oxoacids, Esters, and Amides of Other Nonmetals

A nonmetal that is both double and single bonded to O occurs in most inorganic oxoacids, such as phosphoric, sulfuric, and chlorous acids. Those with additional O atoms are stronger acids than carboxylic acids.

Diphosphoric and disulfuric acids are acid anhydrides formed by dehydration-condensation reactions, just as a carboxylic acid anhydride is formed (Figure 15.23). Inorganic oxoacids form esters and amides that are part of many biological molecules. We already saw that certain lipids are phosphate esters (see Figure 15.21). The first compound formed when glucose is digested is a phosphate ester (Figure 15.24A); a similar phosphate ester is a major structural feature of nucleic acids, as we'll see shortly. Amides of organic sulfur-containing oxoacids, called *sulfonamides*, are potent antibiotics; the simplest of these is depicted in Figure 15.24B. More than 10,000 different sulfonamides have been synthesized.

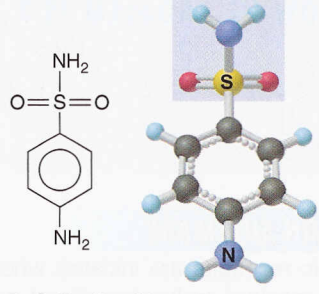
A Glucose-6-phosphate

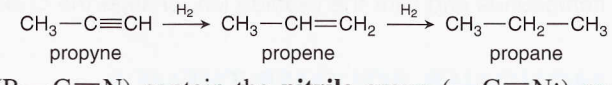


B Sulfanilamide

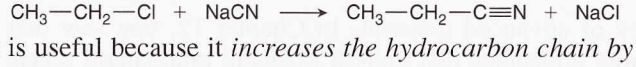
Figure 15.24 An ester and an amide with another nonmetal. A, Glucose-6-phosphate contains a phosphate ester group. **B,** Sulfanilamide contains a sulfonamide group.

Functional Groups with Triple Bonds

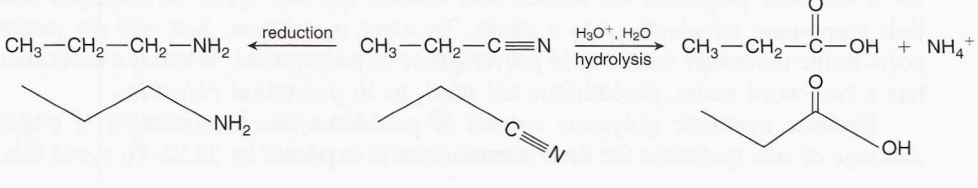
There are only two important functional groups with triple bonds. *Alkynes,* with their electron-rich —C≡C— groups, undergo addition (by H_2O, H_2, HX, X_2, and so forth) to form double-bonded or saturated compounds:



Nitriles (R—C≡N) contain the **nitrile** group (—C≡N:) and are made by substituting a CN^- (cyanide) ion for X^- in a reaction with an alkyl halide:



This reaction is useful because it *increases the hydrocarbon chain by one C atom.* Nitriles are versatile because once they are formed, they can be reduced to amines or hydrolyzed to carboxylic acids:



Variations on a Theme: Inorganic Compounds with Triple Bonds Triple bonds are as scarce in the inorganic world as in the organic world. Carbon monoxide (:C≡O:), elemental nitrogen (:N≡N:), and the cyanide ion ([:C≡N:]$^-$) are the only common examples.

You've seen quite a few functional groups by this time, and it is especially important that you can recognize them in a complex organic molecule. Sample Problem 15.7 provides some practice.

SAMPLE PROBLEM 15.7 Recognizing Functional Groups

Problem Circle and name the functional groups in the following molecules:

(a) 
(b)

FOLLOW-UP PROBLEM 15.7 Circle and name the functional groups:

(a) 
(b) 
SECTION SUMMARY

Organic reactions are initiated when regions of high and low electron density of different reactant molecules attract each other. Groups containing only single bonds—alcohols, amines, and alkyl halides—take part in substitution and elimination reactions. Groups with double or triple bonds—alkenes, aldehydes, ketones, alkynes, and nitriles—generally take part in addition reactions. Aromatic compounds typically undergo substitution, rather than addition, because delocalization of the π electrons stabilizes the ring. Groups with both double and single bonds—carboxylic acids, esters, and amides—generally take part in substitution reactions. Many reactions change one functional group to another, but some, especially reactions with organometallic compounds and with the cyanide ion, change the C skeleton.

15.5 THE MONOMER-POLYMER THEME I: SYNTHETIC MACROMOLECULES

In our survey of advanced materials in Chapter 12, you saw that polymers are extremely large molecules that consist of many monomeric repeat units. In that chapter, we focused on the mass, shape, and physical properties of polymers. Now we'll see how polymers are named and discuss the two types of reactions that link monomers covalently into a chain. To name a polymer, just add the prefix *poly-* to the monomer name, as in *polyethylene* or *polystyrene*. When the monomer has a two-word name, parentheses are used, as in *poly(vinyl chloride)*.

Because synthetic polymers consist of petroleum-based monomers, a major shortage of raw materials for their manufacture is expected by 2150. To avoid this,

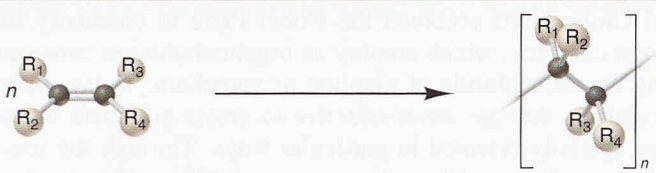
green chemists are devising polymers based on corn, sugarcane, and even cashew-nut shells. Before being embraced as a "green" technology, however, the total impact of growing, transporting, and manufacturing must be assessed.

The two major types of reaction processes that form synthetic polymers lend their names to the resulting classes of polymer—addition and condensation.

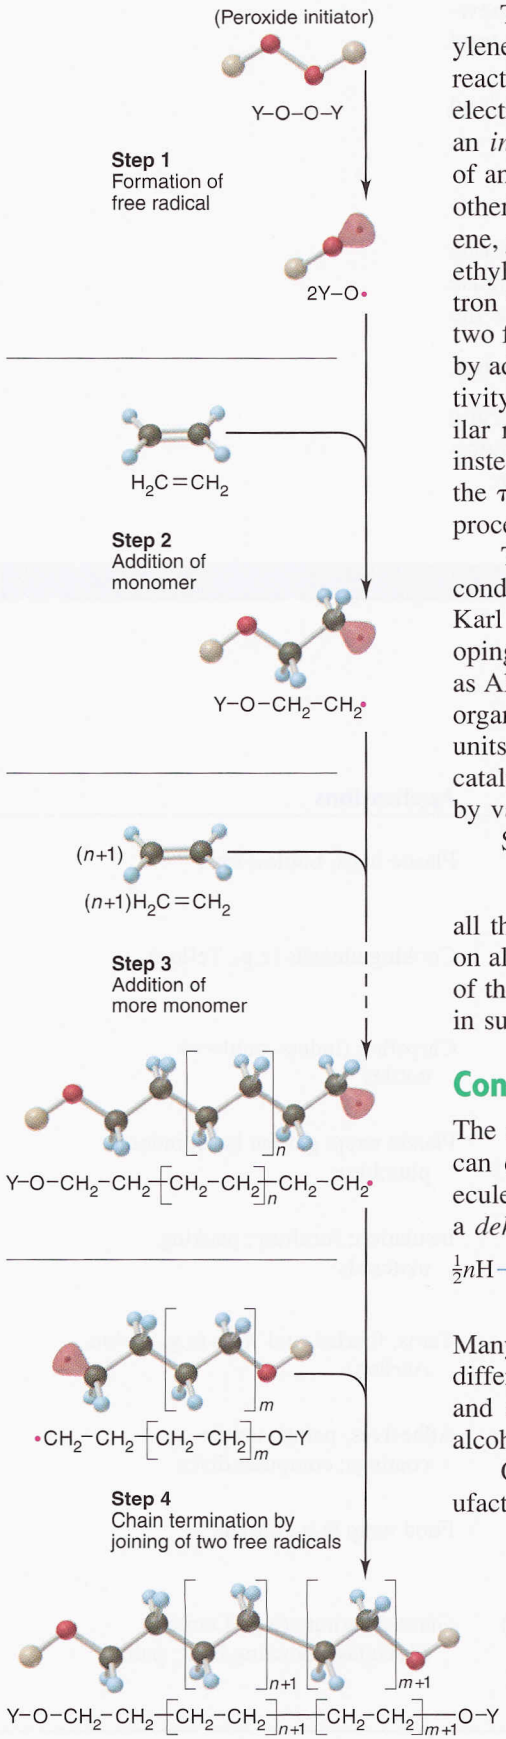
Addition Polymers

Addition polymers form when monomers undergo an addition reaction with one another. These are also called *chain-reaction (or chain-growth) polymers* because as each monomer adds to the chain, it forms a new reactive site to continue the process. The monomers of most addition polymers have the  grouping. As you can see from Table 15.6, the essential differences between an acrylic sweater, a plastic grocery bag, and a bowling ball are due to the different chemical groups that are attached to the double-bonded C atoms of the monomer.

Table 15.6 Some Major Addition Polymers



Monomer	Polymer	Applications
	polyethylene	Plastic bags; bottles; toys
	polytetrafluoroethylene	Cooking utensils (e.g., Teflon)
	polypropylene	Carpeting (indoor-outdoor); bottles
	poly(vinyl chloride)	Plastic wrap; garden hose; indoor plumbing
	polystyrene	Insulation; furniture; packing materials
	polyacrylonitrile	Yarns, fabrics, and wigs (e.g., Orlon, Acrilan)
	poly(vinyl acetate)	Adhesives; paints; textile coatings; computer disks
	poly(vinylidene chloride)	Food wrap (e.g., Saran)
	poly(methyl methacrylate)	Glass substitute (e.g., Lucite, Plexiglas); bowling balls; paint



The *free-radical polymerization* of ethene (ethylene, $CH_2{=}CH_2$) to polyethylene is a simple example of the addition process. In Figure 15.25, the monomer reacts to form a *free radical,* a species with an unpaired electron, that seeks an electron from another monomer to form a covalent bond. The process begins when an *initiator,* usually a peroxide, generates a free radical that attacks the π bond of an ethylene unit, forming a σ bond with one of the *p* electrons and leaving the other unpaired. This new free radical then attacks the π bond of another ethylene, joining it to the chain end, and the backbone of the polymer grows. As each ethylene adds, it leaves an unpaired electron on the growing end to find an electron "mate" and make the chain one repeat unit longer. This process stops when two free radicals form a covalent bond or when a very stable free radical is formed by addition of an *inhibitor* molecule. Recent progress in controlling the high reactivity of free-radical species promises an even wider range of polymers. In a similar method, polymerization is initiated by the formation of a cation (or anion) instead of a free radical. The cationic (or anionic) reactive end of the chain attacks the π bond of another monomer to form a new cationic (or anionic) end, and the process continues.

The most important polymerization reactions take place under relatively mild conditions through the use of catalysts that incorporate transition metals. In 1963, Karl Ziegler and Giulio Natta received the Nobel Prize in chemistry for developing *Ziegler-Natta catalysts,* which employ an organoaluminum compound, such as $Al(C_2H_5)_3$, and the tetrachloride of titanium or vanadium. Today, chemists use organometallic catalysts that are *stereoselective* to create polymers whose repeat units have groups spatially oriented in particular ways. Through the use of these catalysts, polyethylene chains with molar masses of 10^4 to 10^5 g/mol are made by varying conditions and reagents.

Similar methods are used to make polypropylenes, $\text{–}[\text{CH}_2\text{–CH(CH}_3\text{)}]_n\text{–}$, that have all the CH_3 groups of the repeat units oriented either on one side of the chain or on alternating sides. The different orientations lead to different packing efficiencies of the chains and, thus, different degrees of crystallinity, which lead to differences in such physical properties as density, rigidity, and elasticity (Section 12.7).

Condensation Polymers

The monomers of **condensation polymers** must have *two functional groups;* we can designate such a monomer as A—**R**—B (where **R** is the rest of the molecule). Most commonly, the monomers link when an A group on one undergoes a *dehydration-condensation reaction* with a B group on another:

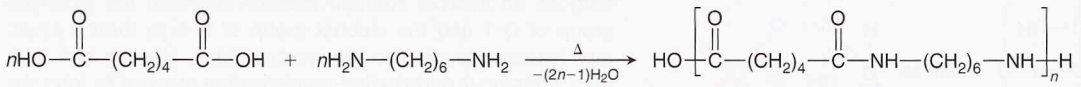
$$\tfrac{1}{2}n\text{H—A—R—B—OH} + \tfrac{1}{2}n\text{H—A—R—B—OH} \xrightarrow{-(n-1)\text{HOH}} \text{H}\text{–}[\text{–A—R—B–}]_n\text{OH}$$

Many condensation polymers are *copolymers,* those consisting of two or more different repeat units (Section 12.7). For example, condensation of carboxylic acid and amine monomers forms *polyamides (nylons),* whereas carboxylic acid and alcohol monomers form *polyesters.*

One of the most common polyamides is *nylon-66* (see the Gallery, p. 72), manufactured by mixing equimolar amounts of a six-C diamine (1,6-diaminohexane)

Figure 15.25 Steps in the free-radical polymerization of ethylene. In this polymerization method, free radicals initiate, propagate, and terminate the formation of an addition polymer. An initiator (Y—O—O—Y) is split to form two molecules of a free radical (Y—O·). The free radical attacks the π bond of a monomer and creates another free radical (Y—O—CH_2—CH_2·). The process continues, and the chain grows (propagates) until an inhibitor is added (not shown) or two free radicals combine.

and a six-C diacid (1,6-hexanedioic acid). The basic amine reacts with the acid to form a "nylon salt." Heating drives off water and forms the amide bonds:



In the laboratory, this nylon is made without heating by using a more reactive acid component (Figure 15.26). Covalent bonds within the chains give nylons great strength, and H bonds between chains give them great flexibility. About half of all nylons are made to reinforce automobile tires, the remainder being used for rugs, clothing, fishing line, and so forth.

Dacron, a popular polyester fiber, is woven from polymer strands formed when equimolar amounts of 1,4-benzenedicarboxylic acid and 1,2-ethanediol react. Blending these polyester fibers with various amounts of cotton gives fabrics that are durable, easily dyed, and crease resistant. Extremely thin Mylar films, used for recording tape and food packaging, are also made from this polymer.

Variations on a Theme: Inorganic Polymers You already know that some synthetic polymers have inorganic backbones. In Chapter 14, we discussed the silicones, polymers with the repeat unit $-(R_2)Si-O-$. Depending on the chain crosslinks and the R groups, silicones range from oily liquids to elastic sheets to rigid solids and have applications that include artificial limbs and spacesuits. We also mentioned the polyphosphazenes in Chapter 14, which exist as flexible chains even at low temperatures, and have the repeat unit $-(R_2)P=N-$.

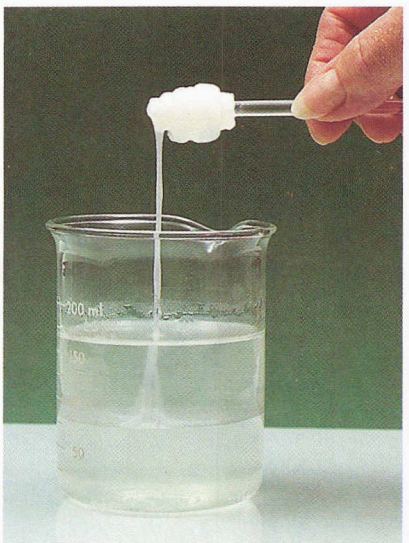


Figure 15.26 The formation of nylon-66. Nylons are formed industrially by the reaction of diamine and diacid monomers. In this laboratory demonstration, the six-C diacid chloride, which is more reactive than the diacid, is used as one monomer; the polyamide forms between the two liquid phases.

SECTION SUMMARY

Polymers are extremely large molecules that are made of repeat units called monomers. Addition polymers are formed from unsaturated monomers that commonly link through free-radical reactions. Most condensation polymers are formed by linking two types of monomer through dehydration-condensation reactions. Reaction conditions, catalysts, and monomers can be varied to produce polymers with different properties.

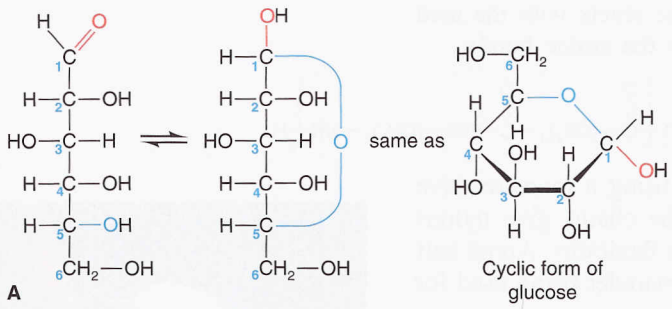
15.6 THE MONOMER-POLYMER THEME II: BIOLOGICAL MACROMOLECULES

The monomer-polymer theme was being played out in nature eons before humans employed it to such great advantage. Biological macromolecules are nothing more than condensation polymers created by nature's reaction chemistry and improved through evolution. These remarkable molecules are the greatest proof of the versatility of carbon and its handful of atomic partners.

Natural polymers are the "stuff of life"—polysaccharides, proteins, and nucleic acids. Some have structures that make wood strong, hair curly, fingernails hard, and wool flexible. Others speed up the myriad reactions that occur in every cell or defend the body against infection. Still others possess the genetic information needed to forge other biomolecules. Remarkable as these giant molecules are, the functional groups of their monomers and the reactions that link them are identical to those of other, smaller organic molecules. Moreover, as you saw in Section 13.2, the same intermolecular forces that dissolve smaller molecules stabilize these giant molecules in the aqueous medium of the cell.

Sugars and Polysaccharides

In essence, the same chemical change occurs when you burn a piece of wood or eat a piece of bread. Wood and bread are mixtures of carbohydrates, substances that provide energy through oxidation.



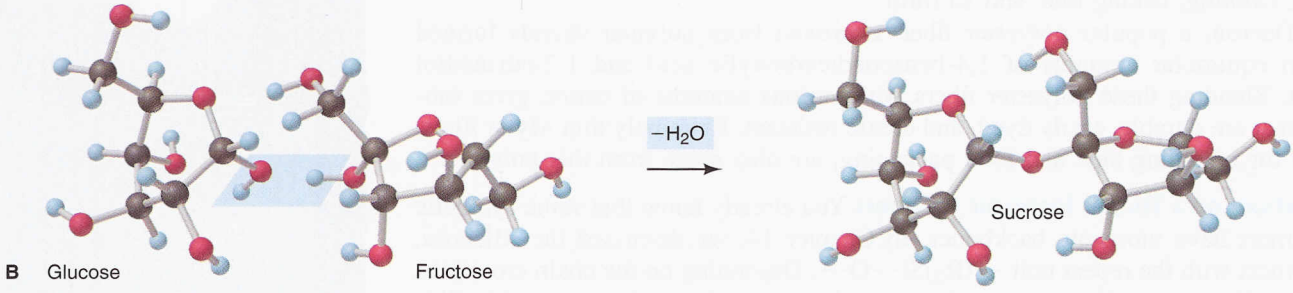


Figure 15.27 The structure of glucose in aqueous solution and the formation of a disaccharide. A, A molecule of glucose undergoes an internal addition reaction between the aldehyde group of C-1 and the alcohol group of C-5 to form a cyclic monosaccharide. **B,** Two monosaccharides, glucose and fructose, undergo a dehydration-condensation reaction to form the disaccharide sucrose (table sugar) and a water molecule.

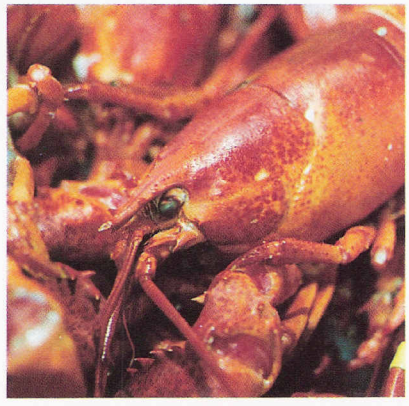
Monomer Structure and Linkage Glucose and other simple sugars, from the three-C *trioses* to the seven-C *heptoses,* are called **monosaccharides** and consist of carbon chains with attached hydroxyl and carbonyl groups. In addition to their roles as individual molecules engaged in energy metabolism, they serve as the monomer units of **polysaccharides.** Most natural polysaccharides are formed from five- and six-C units. In aqueous solution, *an alcohol group and the aldehyde (or ketone) group of a given monosaccharide react with each other to form a cyclic molecule with either a five- or six-membered ring* (Figure 15.27A).

When two monosaccharides undergo a dehydration-condensation reaction, a **disaccharide** forms. For example, sucrose (table sugar) is a disaccharide of glucose (linked at C-1) and fructose (linked at C-2) (Figure 15.27B); lactose (milk sugar) is a disaccharide of glucose (C-1) and galactose (C-4); and maltose, used in brewing and as a sweetener, is a disaccharide of two glucose units (C-1 to C-4).

Types of Polysaccharides A polysaccharide consists of *many* monosaccharide units linked together. The three major natural polysaccharides—cellulose, starch, and glycogen—consist entirely of glucose units, but they differ in the ring positions of the links, in the orientation of certain bonds, and in the extent of crosslinking. Some other polysaccharides contain nitrogen in their attached groups.

Cellulose is the most abundant organic chemical on Earth. More than 50% of the carbon in plants occurs in the cellulose of stems and leaves; wood is largely cellulose, and cotton is more than 90% cellulose (see Section 13.2). Cellulose consists of long chains of glucose. The great strength of wood is due largely to the H bonds between cellulose chains. The monomers are linked in a particular way from C-1 in one unit to C-4 in the next. Humans lack the enzymes to break this link, so we cannot digest cellulose (unfortunately!); however, microorganisms in the digestive tracts of some animals, such as cows, sheep, and termites, can.

Starch is a mixture of polysaccharides of glucose and serves as an *energy store* in plants. When a plant needs energy, some starch is broken down by hydrolysis of the bonds between units, and the released glucose is oxidized through a multistep metabolic pathway. Starch occurs in plant cells as insoluble granules of amylose, a helical molecule of several thousand glucose units, and amylopectin, a highly branched, bushlike molecule of up to a million glucose units. Most of the glucose units are linked by C-1 to C-4 bonds, as in cellulose, but a different



Polysaccharide Skeletons of Lobsters and Roaches The variety of polysaccharide properties that arises from simple changes in the monomers is amazing. For example, substituting an $-NH_2$ group for the —OH group at C-2 in glucose produces *glucosamine*. The amide that is formed from glucosamine and acetic acid (*N*-acetylglucosamine) is the monomer of *chitin* (pronounced "KY-tin"), a polysaccharide that is the main component of the tough, brittle, external skeletons of insects and crustaceans.

orientation around the chiral C-1 allows our digestive enzymes to break starch down into monomers. A C-6 to C-1 crosslink joins chains every 24 to 30 units.

Glycogen functions as the energy storage molecule in animals. It occurs in liver and muscle cells as large, insoluble granules consisting of glycogen molecules made from 1000 to more than 500,000 glucose units. In glycogen, the units are also linked by C-1 to C-4 bonds, but the molecule is more highly crosslinked than starch, with C-6 to C-1 crosslinks every 8 to 12 units.

Amino Acids and Proteins

As you saw in Section 15.5, synthetic polyamides (such as nylon-66) are formed from two monomers, one with a carboxyl group at each end and the other with an amine group at each end. **Proteins,** the polyamides of nature, are unbranched polymers formed from monomers called **amino acids.** As we discussed in Section 13.2, *each amino acid has a carboxyl group and an amine group.*

Monomer Structure and Linkage An amino acid has both its carboxyl group and its amine group attached to the α-*carbon,* the second C atom in the chain. Proteins are made up of about 20 different types of amino acids, each with its own particular R group, ranging from an H atom to a polycyclic N-containing aromatic structure (Figure 15.28).

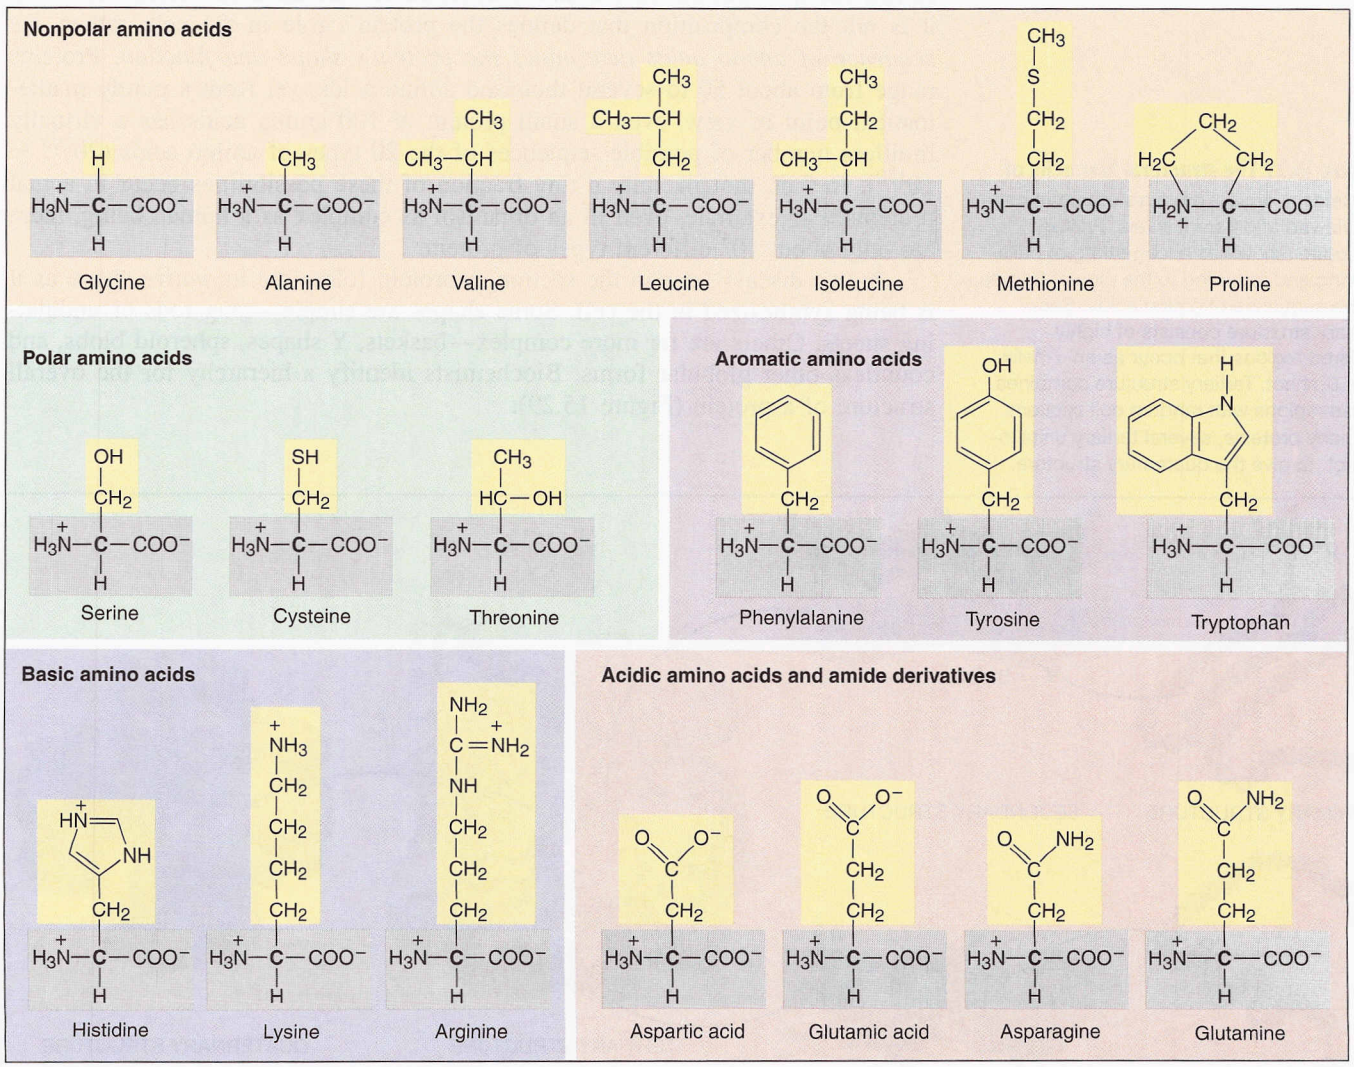


Figure 15.28 The common amino acids. About 20 different amino acids occur in proteins. The R groups are screened yellow, and the α-carbons (*boldface*), with carboxyl and amino groups, are screened grey. Here the amino acids are shown with the charges they have under physiological conditions. They are grouped by polarity, acid-base character, and presence of an aromatic ring. The R groups play a major role in the shape and function of the protein.

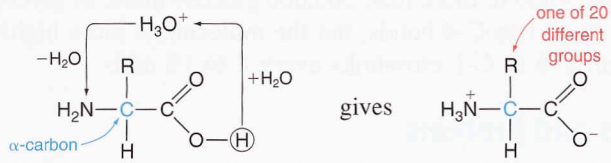
In the aqueous cell fluid, the amino-acid NH_2 and COOH groups are charged because the carboxyl group transfers an H^+ ion to H_2O to form H_3O^+, which transfers the H^+ to the amine group. The overall process is, in effect, an intramolecular acid-base reaction:



An H atom is the third group bonded to the α-carbon, and the fourth is the R group (also called the *side chain*).

Each amino acid is linked to the next one through a *peptide* (amide) bond formed by a dehydration-condensation reaction in which the carboxyl group of one monomer reacts with the amine group of the next. Therefore, as was pointed out in Section 13.2, the polypeptide chain, the backbone of the protein, consists of an *α-carbon bonded to an amide group bonded to the next α-carbon bonded to the next amide group,* and so forth (see Figure 13.6, p. 496). The various R groups dangle from the α-carbons on alternate sides of the chain.

The Hierarchy of Protein Structure *Each type of protein has its own amino acid composition,* a specific number and proportion of various amino acids. However, it is not the composition that defines the protein's role in the cell; rather, *the sequence of amino acids determines the protein's shape and function.* Proteins range from about 50 to several thousand amino acids, yet from a purely mathematical point of view, even a small protein of 100 amino acids has a virtually limitless number of possible sequences of the 20 types of amino acids ($20^{100} \approx 10^{130}$). In fact, though, only a tiny fraction of these possibilities occur in actual proteins. For example, even in an organism as complex as a human being, there are only about 10^5 different types of protein.

As we discuss later in the section, a protein folds into its *native* shape as it is being synthesized in the cell. Some shapes are simple—long rods or undulating sheets. Others are far more complex—baskets, Y shapes, spheroid blobs, and countless other globular forms. Biochemists identify a hierarchy for the overall structure of a protein (Figure 15.29):

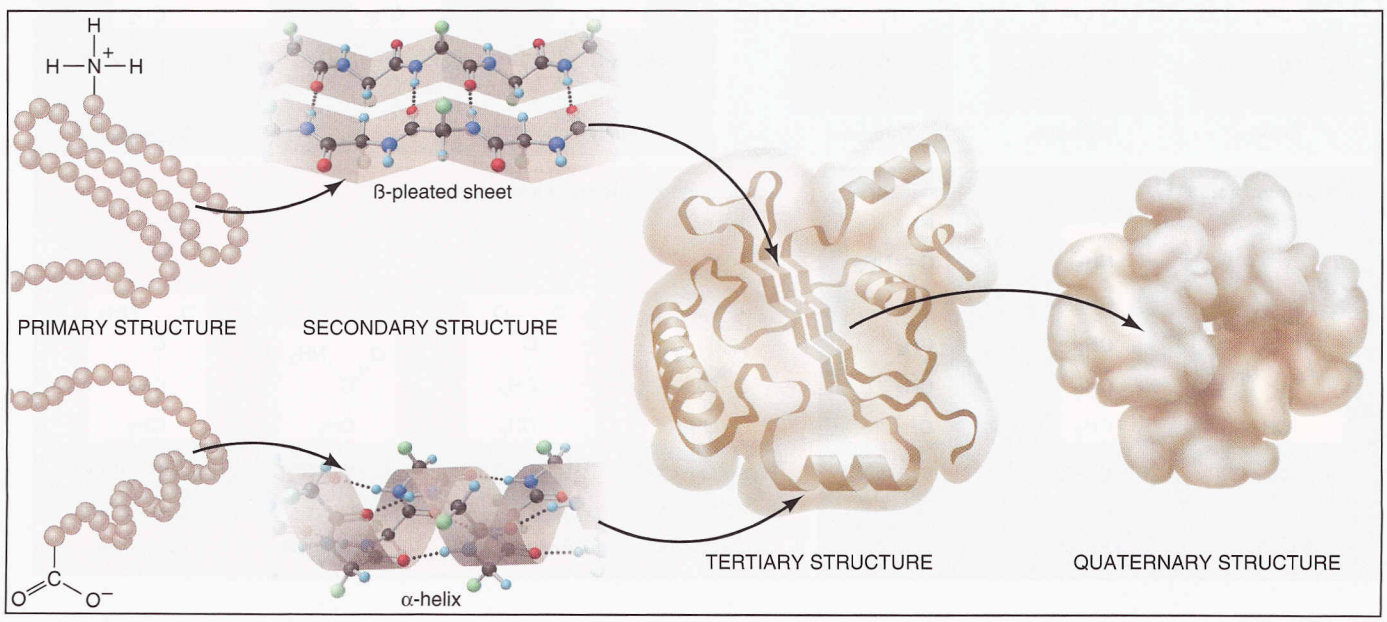


Figure 15.29 The structural hierarchy of proteins. A typical protein's structure can be viewed at different levels. Primary structure (shown as a long string of balls leaving and returning to the picture frame) is the sequence of amino acids. Secondary structure consists of highly ordered regions that occur as an α-helix or a β-sheet. Tertiary structure combines these regions with random coil sections. In many proteins, several tertiary units interact to give the quaternary structure.

1. *Primary (1°) structure*, the most basic level, refers to the sequence of covalently bonded amino acids in the polypeptide chain.
2. *Secondary (2°) structure* refers to sections of the chain that, as a result of H bonding between nearby peptide groupings, adopt shapes called α-helices and β-pleated sheets.
3. *Tertiary (3°) structure* refers to the three-dimensional folding of the whole polypeptide chain. In some proteins, certain folding patterns form characteristic regions that play a role in the protein's function—binding a hormone, attaching to a membrane, forming a polar channel, and so forth.
4. *Quaternary (4°) structure*, the most complex level, occurs in proteins made up of several polypeptide chains (subunits) and refers to the way the chains assemble into the overall protein.

Note that *only the 1° structure involves covalent bonds; the 2°, 3°, and 4° structures rely on intermolecular forces*, as we discussed in Section 13.2.

The Relation Between Structure and Function Two broad classes of proteins differ in the complexity of their amino acid compositions and sequences and, therefore, in their structure and function:

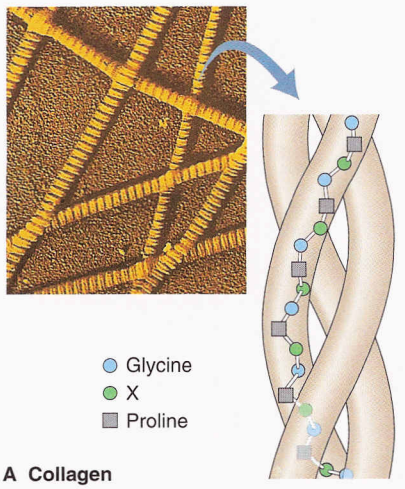
1. *Fibrous proteins* have relatively simple amino acid compositions and correspondingly simple structures. They are key components of hair, wool, skin, and connective tissue—materials that require strength and flexibility. Like synthetic polymers, these proteins have a small number of different amino acids in a repeating sequence. Consider collagen, the most common animal protein, which makes up as much as 40% of human body weight. More than 30% of its amino acids are glycine (G) and another 20% are proline (P). It exists as three chains, each an extended helix, that wind tightly around each other as the peptide C═O groups in one chain form H bonds to the peptide N—H groups in another. The result is a long, triple-helical cable with the sequence —G—X—P—G—X—P— and so on (where X is another amino acid), as shown in Figure 15.30A. As the main component of tendons, skin, and blood vessels, collagen has a high tensile strength; in fact, a 1-mm thick strand can support a 10-kg weight!

In silk fibroin, secreted by the silk moth caterpillar, more than 85% of the amino acids are glycine, alanine, and serine (Figure 15.30B). Fibroin chain segments bend back and forth, running alongside each other, and form interchain H bonds to create a *pleated sheet*. Stacks of sheets interact through dispersion forces, which make fibroin strong and flexible but not very extendable—perfect for a silkworm's cocoon.

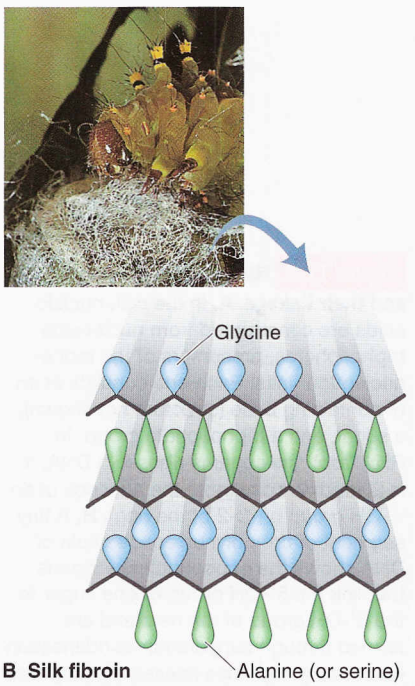
2. *Globular proteins* have much more complex compositions, often containing varying proportions of all 20 different amino acids. As the name implies, globular proteins are typically more rounded and compact, with a wide variety of shapes and a correspondingly wide range of functions: defenders against bacterial invasion, messengers that trigger cell actions, catalysts of chemical change, membrane gatekeepers that maintain aqueous concentrations, and many others. The locations of particular amino-acid R groups are crucial to the protein's function. For example, in catalytic proteins, a few R groups form a crevice that closely matches the shapes of reactant molecules. These groups typically hold the reactants through intermolecular forces and speed their reaction to products by bringing them together and twisting and stretching their bonds. Experiment has shown repeatedly that a slight change in one of these critical R groups decreases function dramatically. This fact supports the essential idea that *the protein's amino acid sequence determines its structure, which in turn determines its function*:

SEQUENCE ⟹ STRUCTURE ⟹ FUNCTION

Next, we'll see how the amino acid sequence of every protein in every organism is prescribed by the genetic information that is held within the organism's nucleic acids.



A Collagen



B Silk fibroin

Figure 15.30 The shapes of fibrous proteins. Fibrous proteins have largely structural roles in an organism, and their amino acid sequence is relatively simple. **A,** The triple helix of a collagen molecule has a glycine as every third amino acid along the chain. **B,** The pleated sheet structure of silk fibroin has a repeating sequence of glycine alternating with either alanine or serine. The sheets interact through dispersion forces.

Nucleotides and Nucleic Acids

An organism's nucleic acids construct its proteins. And, given that the proteins determine how the organism looks and behaves, no job could be more essential.

Monomer Structure and Linkage **Nucleic acids** are unbranched polymers that consist of linked monomer units called **mononucleotides,** which consist of an N-containing base, a sugar, and a phosphate group. The two types of nucleic acid, ***ribo**nucleic **a**cid* (RNA) and ***d**eoxyribo**n**ucleic **a**cid* (DNA), differ in the sugar portions of their mononucleotides. RNA contains *ribose,* a five-C sugar, and DNA contains *deoxyribose,* in which —H substitutes for —OH on the 2′ position of ribose. (Carbon atoms in the sugar portion are given numbers with a prime to distinguish them from carbon atoms in the base.)

The cellular precursors that form a nucleic acid are *nucleoside triphosphates* (Figure 15.31A). Dehydration-condensation reactions between them release inorganic diphosphate ($H_2P_2O_7^{2-}$) and create *phosphodiester* bonds to form a polynucleotide chain. Therefore, the repeating pattern of the nucleic acid backbone is *—sugar—phosphate—sugar—phosphate—,* and so on (Figure 15.31B). Attached to each sugar is one of four N-containing bases, either a pyrimidine (six-membered ring) or a purine (six- and five-membered rings sharing a side). The pyrimidines are thymine (T) and cytosine (C); the purines are guanine (G) and adenine (A); in RNA, uracil (U) substitutes for thymine. The bases dangle off the sugar-phosphate chain, much as R groups dangle off the polypeptide chain of a protein.

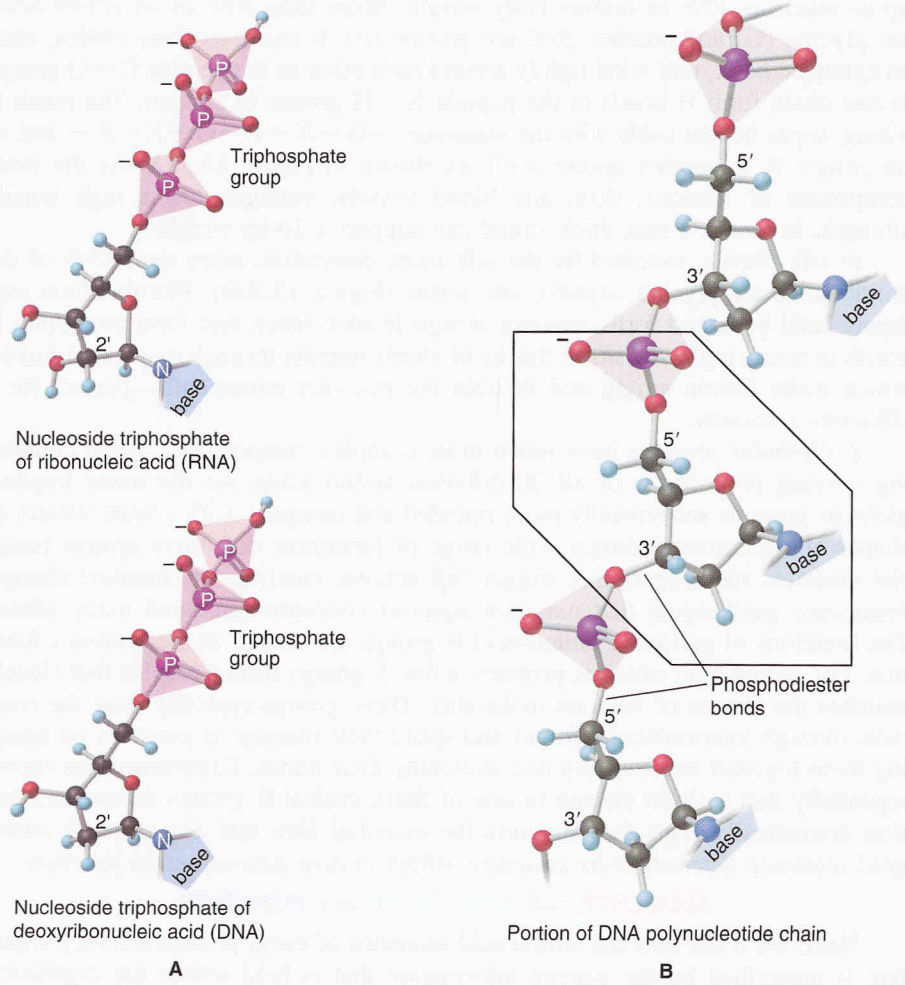


Figure 15.31 Nucleic acid precursors and their linkage. A, In the cell, nucleic acids are constructed from nucleoside triphosphates, precursors of the mononucleotide units. Each one consists of an N-containing base (structure not shown), a sugar, and a triphosphate group. In RNA (*top*), the sugar is ribose; in DNA, it is 2′-deoxyribose (note the absence of an —OH group on C-2 of the ring). **B,** A tiny segment of the polynucleotide chain of DNA shows the phosphodiester bonds that link the 5′-OH group of one sugar to the 3′-OH group of the next and are formed through dehydration-condensation reactions (which also release diphosphate ion). The bases dangle off the chain.

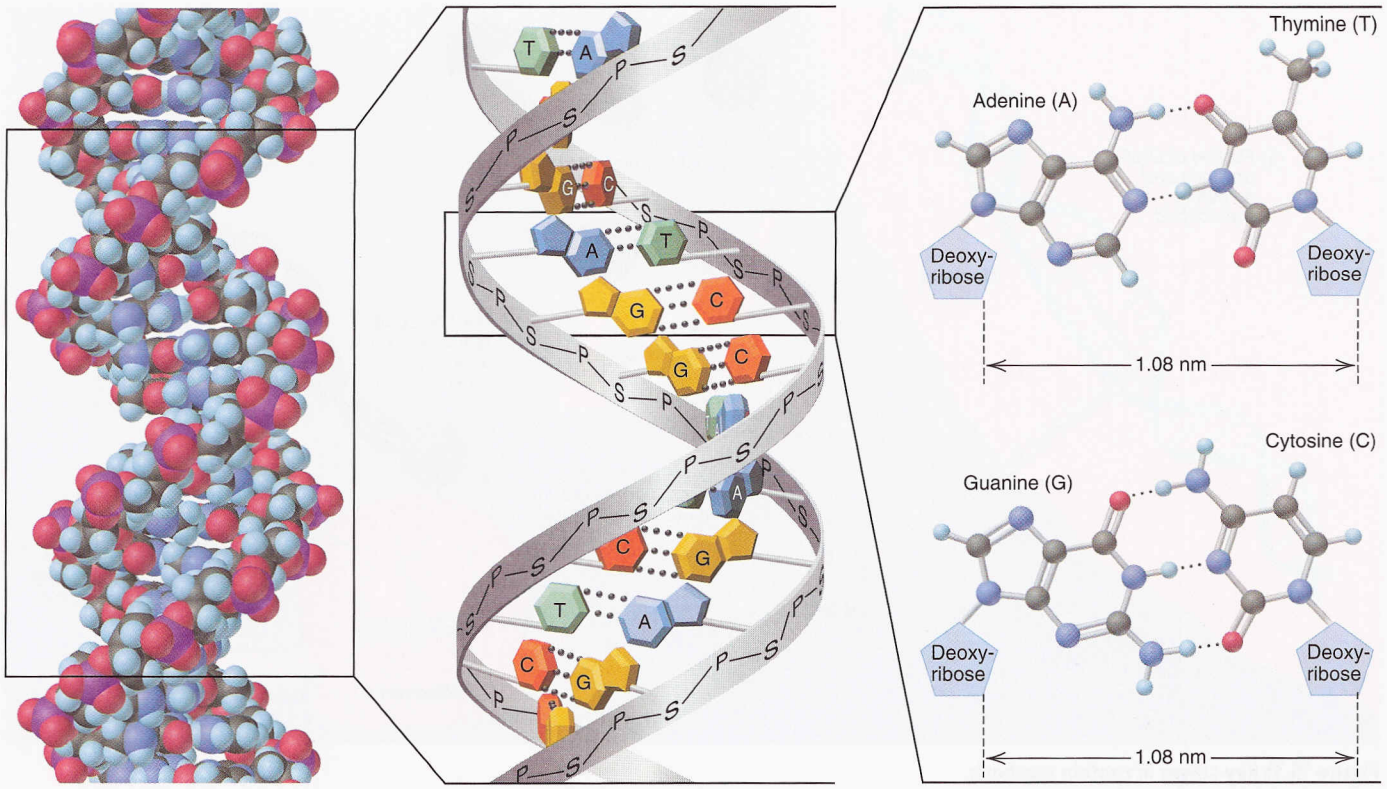

Figure 15.32 The double helix of DNA. A segment of DNA is shown as a space-filling model (*left*). The boxed area is expanded (*center*) to show how the polar sugar(S)-phosphate(P) backbone faces the watery outside, and the nonpolar bases form H bonds to each other in the DNA core. The boxed area is expanded (*right*) to show how a pyrimidine and a purine always form H-bonded base pairs to maintain the double helix width. The members of the pairs are always the same: A pairs with T, and G pairs with C.

The Central Importance of Base Pairing In the nucleus of the cell, DNA exists as two chains wrapped around each other in a **double helix** (Figure 15.32). Each base in one chain "pairs" with a base in the other through H bonding. A double-helical DNA molecule may contain many millions of H-bonded bases in specified pairs. Two features of these **base pairs** are crucial to the structure and function of DNA:

- A pyrimidine and a purine are always paired, which gives the double helix a constant diameter.
- Each base is always paired with the same partner: A with T and G with C. Thus, *the base sequence on one chain is the complement of the sequence on the other.* For example, the sequence A—C—T on one chain is *always* paired with T—G—A on the other: A with T, C with G, and T with A.

Each DNA molecule is folded into a tangled mass that forms one of the cell's *chromosomes*. The DNA molecule is amazingly long and thin: if the largest human chromosome were stretched out, it would be 4 cm long; in the cell nucleus, however, it is wound into a structure only 5 nm long—8 million times shorter! Segments of the DNA chains are the *genes* that contain the chemical information for synthesizing the organism's proteins.

An Outline of Protein Synthesis *The information content of a gene resides in its base sequence.* In the **genetic code,** each base acts as a "letter," each three-base sequence as a "word," and *each word codes for a specific amino acid.* For example, the sequence C—A—C codes for the amino acid histidine, A—A—G codes for lysine, and so on. Through a complex series of interactions, greatly simplified

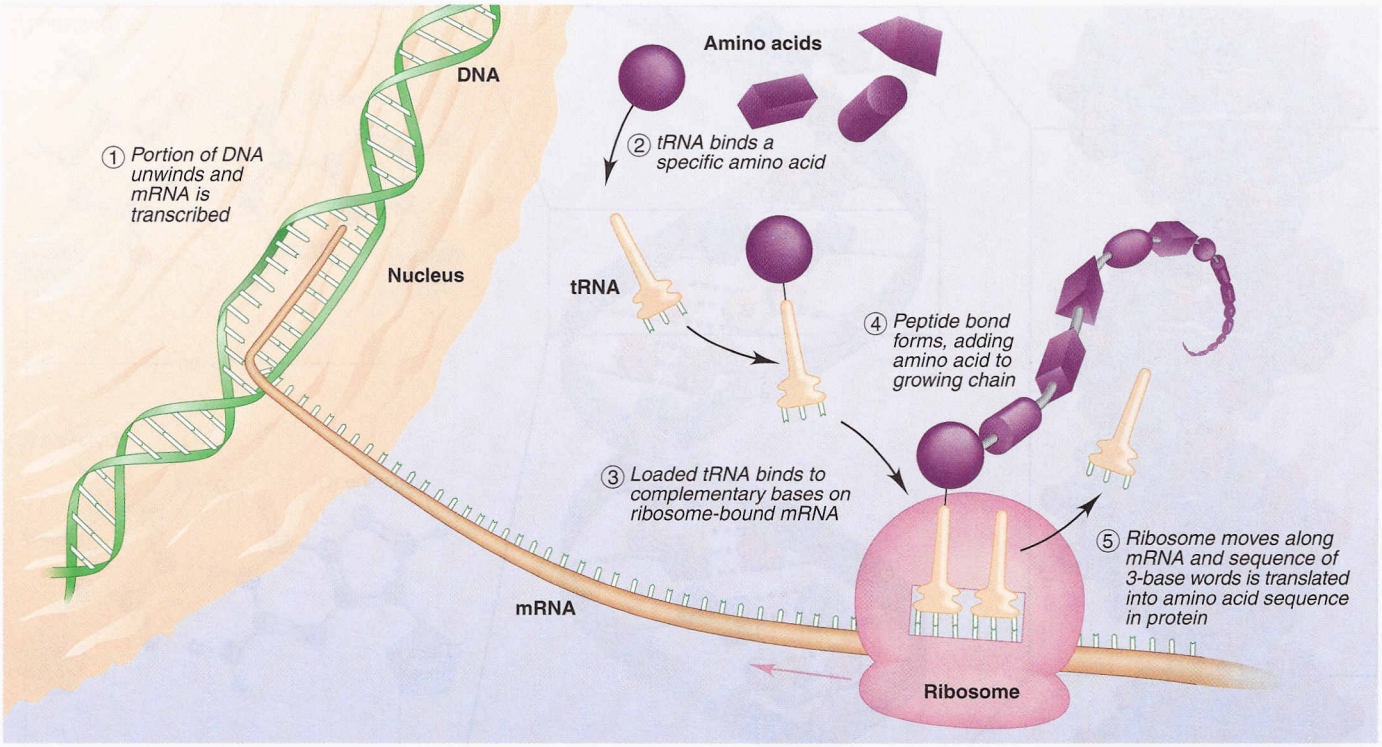

Figure 15.33 Key stages in protein synthesis.

in the overview in Figure 15.33, one amino acid at a time is positioned and linked to the next in the process of protein synthesis. To fully appreciate this aspect of the chemical basis of biology, keep in mind that *this amazingly complex process occurs largely through H bonding between base pairs.*

Here is an outline of *protein synthesis*. DNA occurs in the cell nucleus, but the genetic message is decoded outside it, so the information must be sent to the synthesis site. RNA serves in this messenger role, as well as in several others. A portion of the DNA is temporarily unwound and one chain segment acts as a *template* for the formation of a complementary chain of *messenger RNA* (mRNA) made by individual mononucleoside triphosphates linking together; thus, *the DNA code words are transcribed into RNA code words* through base pairing. The mRNA leaves the nucleus and binds, again through base pairing, to an RNA-rich particle in the cell called a *ribosome*. The words (three-base sequences) in the mRNA are then decoded by molecules of *transfer RNA* (tRNA). These smaller nucleic acid "shuttles" have two key portions on opposite ends of their structures:

- A three-base sequence that is the complement of a word on the mRNA
- A binding site for the amino acid coded by that word

The ribosome moves along the bound mRNA, one word at a time, while tRNAs bind to the mRNA and position their amino acids near one another in preparation for peptide bond formation and synthesis of the protein.

In essence, then, protein synthesis involves the DNA message of three-base words being transcribed into the RNA message of three-base words, which is then translated into a sequence of amino acids that are linked to make a protein:

DNA BASE SEQUENCE $\Longrightarrow$ RNA BASE SEQUENCE $\Longrightarrow$ PROTEIN AMINO ACID SEQUENCE

An Outline of DNA Replication Another complex series of interactions allows *DNA replication,* the ability of DNA to copy itself. When a cell divides, its chromosomes are replicated, or reproduced, ensuring that the new cells have the same number and types of chromosomes. In this process, a small portion of the dou-

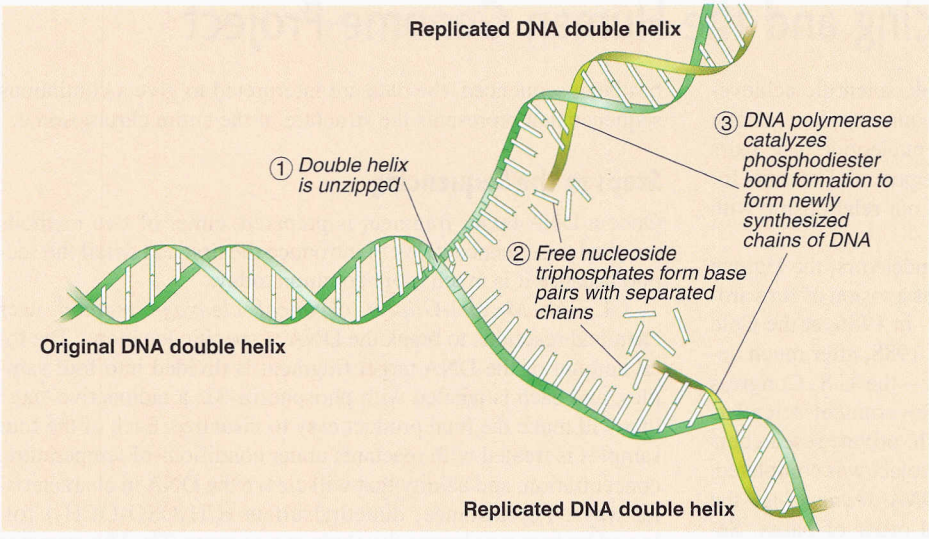

Figure 15.34 Key stages in DNA replication.

ble helix is "unzipped," and each DNA chain acts as a template for the base pairing of its mononucleotide monomers with free mononucleoside triphosphates (Figure 15.34). These new units, H-bonded to their complements, are linked through phosphodiester bonds into a chain by an enzyme called *DNA polymerase*. Gradually, each of the unzipped chains forms the complementary half of a double helix, leading to *two* double helices. Because each base always pairs with its complement, the original double helix is copied and the genetic makeup of the cell preserved. (Base pairing is central to methods for learning the sequence of nucleotides in our genes, as the upcoming Chemical Connections essay shows.)

The biopolymers provide striking evidence for the folly of vitalism—that some sort of vital force exists only in substances from living systems. No unknowable force is required to explain the marvels of the living world. The same atomic properties that give rise to covalent bonds, molecular shape, and intermolecular forces provide the means for all life forms to flourish.

SECTION SUMMARY

The three types of natural polymers—polysaccharides, proteins, and nucleic acids—are formed by dehydration-condensation reactions. Polysaccharides are formed from cyclic monosaccharides, such as glucose. Cellulose, starch, and glycogen have structural or energy-storage roles. Proteins are polyamides formed from as many as 20 different types of amino acids. Fibrous proteins have extended shapes and play structural roles. Globular proteins have compact shapes and play metabolic, immunologic, and hormonal roles. The amino acid sequence of a protein determines its shape and function. Nucleic acids (DNA and RNA) are polynucleotides consisting of four different mononucleotides. The base sequence of the DNA chain determines the sequence of amino acids in an organism's proteins. Hydrogen bonding between specific base pairs is the key to protein synthesis and DNA replication.

Chapter Perspective

The amazing diversity of organic compounds highlights the importance of atomic properties. While gaining an appreciation for the special properties of carbon, you've seen similar types of bonding, molecular shapes, intermolecular forces, and reactivities in organic and inorganic compounds. Upcoming chapters focus on the dynamic aspects of all reactions—their speed, extent, and direction—as we explore the kinetics, equilibrium, and thermodynamics of chemical and physical change. We'll have many opportunities to exemplify these topics with organic compounds and biochemical systems.

DNA Sequencing and the Human Genome Project

As a result of one of the most remarkable scientific achievements in modern times, we now know our complete genetic makeup, the sequence of the 3 billion nucleotide base pairs in the DNA of the entire human genome! The potential benefits for medical science and for an understanding of our relationship with other creatures are profound.

As is true of so many large scientific endeavors, the Human Genome Project (www.genome.gov) began as a vision of forward-thinking scientists meeting at a conference—in 1986, at the Cold Spring Harbor Symposium in New York. In 1988, after much debate over feasibility—and even advisability—the U.S. Congress funded the $3-billion, 15-year program. Government scientists worked independently of, but in parallel with, private researchers at Celera Genomics, and in early 2003, the project was completed.

Central to this accomplishment is *DNA sequencing,* the process used to determine the identity and order of bases. Sequencing is an indispensable tool in molecular biology and biochemical genetics research. The process usually begins with a series of enzymatic and cloning steps to prepare the sample, but we will focus on the chemical steps that yield the final result.

An Overview of DNA Sequencing

The genome consists of DNA molecules; segments of their chains are the genes, the functional units of heredity. The DNA exists in each cell's nucleus as tightly coiled threads arranged, in the human, into 23 pairs of chromosomes (Figure B15.6). A given chromosome may have 100 million nucleotide bases, but the sequencing process can handle, at one time, DNA fragments only about 2000 bases long. Therefore, the chromosome is first broken into pieces by enzymes that cleave at specific sites. Then, through a variety of "amplification" methods, many copies of the individual DNA "target" fragments are made. After each target fragment has been sequenced, the data are interpreted to give a continuous sequence that represents the structure of the entire chromosome.

Steps in the Sequencing

Once a DNA target fragment is prepared, either of two methods are used to sequence it. We'll introduce the first and detail the second because it is much more common today.

1. *The Maxam-Gilbert chemical cleavage method* uses chemical reactions to break the DNA at specific locations. The total amount of the DNA target fragment is divided into four samples, and each is labeled with phosphorus-32, a radioactive "tag" that will make the final product easy to visualize. Each of the four samples is treated with reactants under conditions of temperature, concentration, and acidity that will cleave the DNA in characteristic ways. For instance, dimethylsulfate ($CH_3OSO_2OCH_3$) followed by heating cleaves the chain at a guanine (G). The cleavage products in each tube are then separated by size (length) through gel electrophoresis (discussed below). Photographic film placed on the gel is exposed by the radioactive tags in the cleavage products. The result is a series of dark bands, from which the sequence of the original DNA target fragment is determined.

2. *The Sanger chain-termination method* uses chemically altered bases to stop the growth of a complementary DNA chain at specific locations. As you've seen, the chain consists of linked 2′-deoxyribonucleoside monophosphate units (dNMP, where N represents A, T, G, or C). The link is a phosphodiester bond from the 3′-OH of one unit to the 5′-OH of the next. The free monomers used to construct the chain are 2′-deoxyribonucleoside triphosphates (dNTP). The Sanger method uses a modified monomer, called a *di*deoxyribonucleoside triphosphate (ddNTP), in which the 3′-OH group is also missing from the ribose unit (Figure B15.7). As soon as the ddNTP is incorporated into the growing chain,

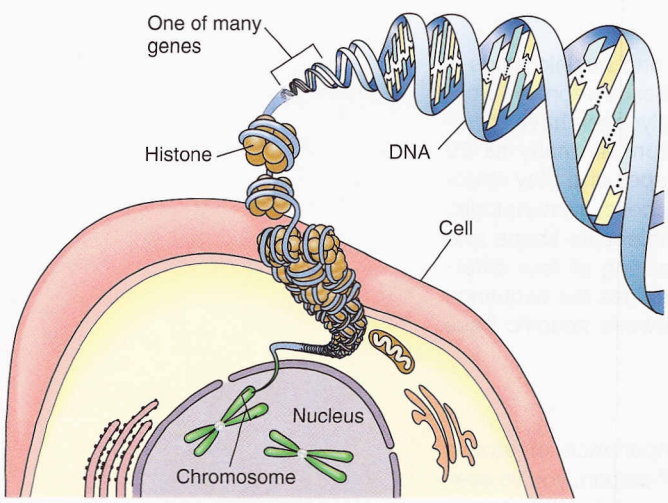

Figure B15.6 DNA, the genetic material. In the cell nucleus, each chromosome consists of a DNA molecule wrapped around globular proteins called histones. Segments of the DNA chains are genes.

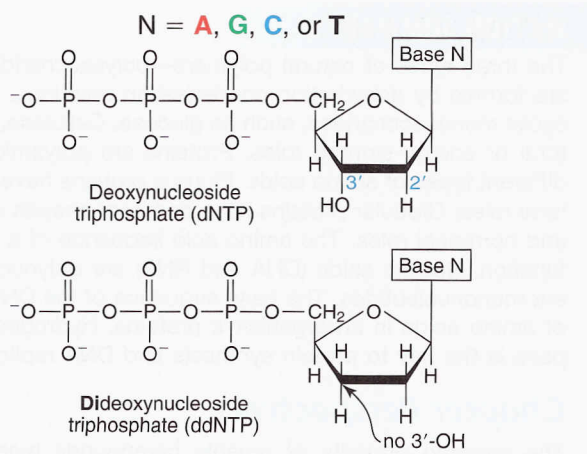

Figure B15.7 Nucleoside triphosphate monomers. The normal *deoxy* monomer (dNTP; *top*) has no 2′-OH group but *does* have a 3′-OH group to continue growth of the polynucleotide chain. The modified *dideoxy* monomer in the Sanger method (ddNTP; *bottom*) also lacks the 3′-OH group.

polymerization stops, because there is no —OH on the 3′ position to form a phosphodiester bond.

Here is a simplified description of the procedure. After several preparation steps, the sample to be sequenced consists of a single-stranded DNA target fragment, which is attached to one strand of a double-stranded segment of DNA (Figure B15.8A). This sample is divided into four tubes, and to each tube is added a mixture of DNA polymerase, large amounts of all four dNTP's, and a small amount of one of the four ddNTP's. Thus, tube 1 contains polymerase, dATP, dGTP, dCTP, and dTTP, and, say, ddATP; tube 2 contains the same, except ddGTP instead of ddATP; and so forth. After the polymerization reaction is complete, each tube contains the original target fragment paired to complementary chains of varying length (Figure B15.8B). The chain lengths vary because in tube 1, each complementary chain ends in ddA (designated A in the figure); in tube 2, each ends in ddG (G); in tube 3, each ends in ddC (C); and in tube 4, each ends in ddT (**T**).

Each double-stranded product is divided into single strands, and then the complementary chains are separated by means of *high-resolution polyacrylamide-gel electrophoresis*. This technique, which is also used in the Maxam-Gilbert method, separates charged species by size through differences in their rate of migration through pores in the gel in the presence of an electric field: smaller species move faster than larger species. Because they have charged phosphate groups, polynucleotide fragments are commonly separated by electrophoresis. Polyacrylamide gels can be made with pores of varying size, and high-resolution gels can separate fragments that differ by a single nucleotide.

Each sample is applied to its own "lane" on a gel and, after electrophoresis, the gel is scanned to locate the chains, which appear in bands. Because all four ddNTP's were used, all possible chain fragments are formed, so the sequence of the original DNA fragment can be determined (Figure B15.8C).

An automated approach begins with each ddNTP tagged with a different fluorescent dye that emits light of a distinct color. In this method, the entire mixture of complementary chains is introduced onto the gel and separated. The gel then passes a laser, which activates the dyes. The fluorescent intensity versus distance along the chain is detected and plotted by a computer (Figure B15.8D).

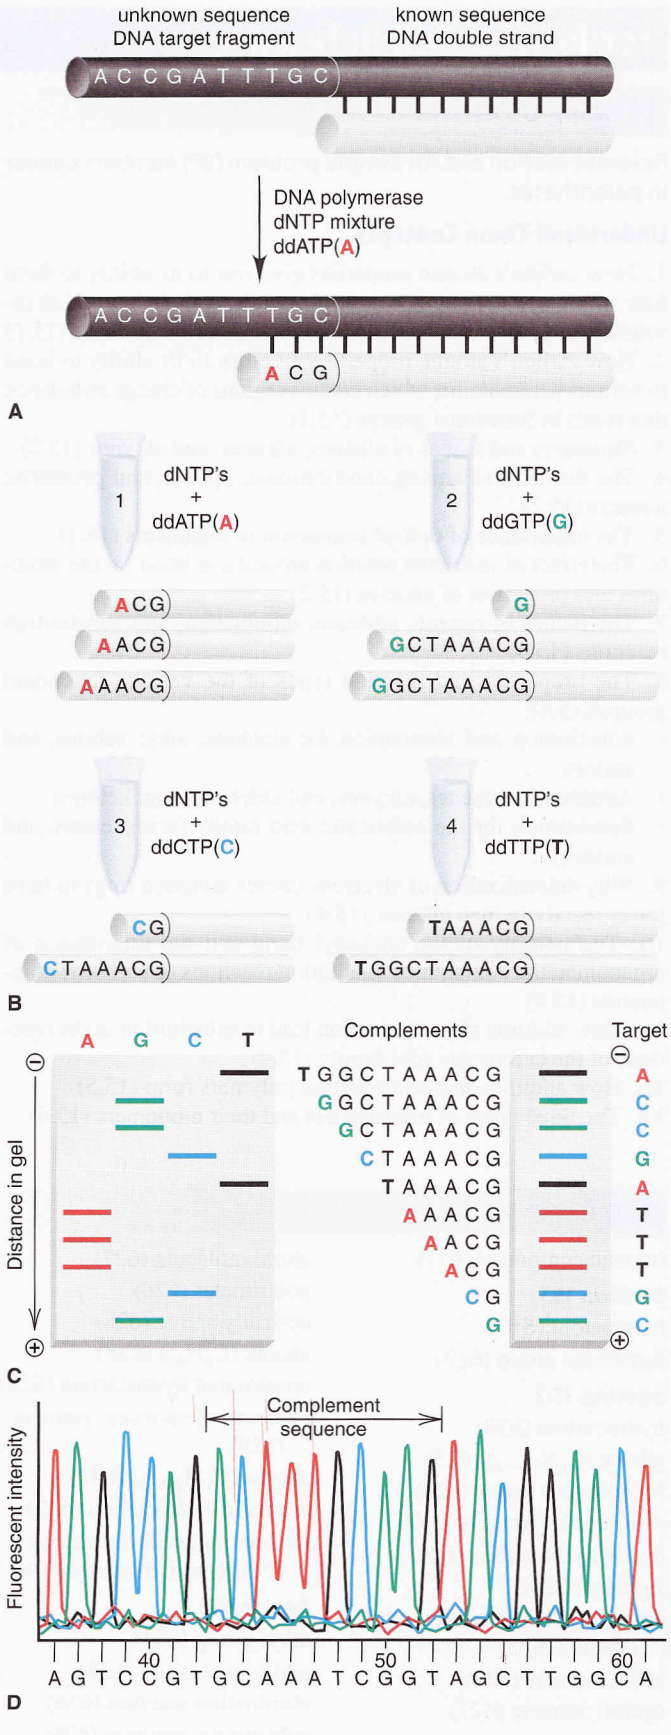

Figure B15.8 Steps in the Sanger method of DNA sequencing. A, The sample is the DNA target fragment, which is bonded to one strand (*black*) of a double-stranded segment. After polymerization, shown here in the presence of fluorescent-tagged ddATP, a complementary chain forms that ends with the base A. **B,** The sample is divided into four tubes, and each is treated with the dNTP mixture and a different ddNTP. Thus, every possible complementary chain forms. **C,** Electrophoresis of each mixture on its own lane of a polyacrylamide gel (*left*) separates the complements by length. The complement and target sequences are shown next to the bands. In the automated approach, all four ddNTP's are present in one tube, and electrophoresis gives bands on a gel (*right*). The gel is then scanned by a laser, which activates the fluorescent tags to emit their specific colors. **D,** A computer plot of light intensity against position in the chain shows the target sequence within the sequences of neighboring fragments.

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. How carbon's atomic properties give rise to its ability to form four strong covalent bonds, multiple bonds, and chains, which results in the great structural diversity of organic compounds (15.1)
2. How carbon's atomic properties give rise to its ability to bond to various heteroatoms, which creates regions of charge imbalance that result in functional groups (15.1)
3. Structures and names of alkanes, alkenes, and alkynes (15.2)
4. The distinctions among constitutional, optical, and geometric isomers (15.2)
5. The importance of optical isomerism in organisms (15.2)
6. The effect of restricted rotation around a π bond on the structures and properties of alkenes (15.2)
7. The nature of organic addition, elimination, and substitution reactions (15.3)
8. The properties and reaction types of the various functional groups (15.4):
   - Substitution and elimination for alcohols, alkyl halides, and amines
   - Addition for alkenes, alkynes, and aldehydes and ketones
   - Substitution for the carboxylic acid family (acids, esters, and amides)
9. Why delocalization of electrons causes aromatic rings to have lower reactivity than alkenes (15.4)
10. The polarity of the carbonyl bond and the importance of organometallic compounds in addition reactions of carbonyl compounds (15.4)
11. How addition plus elimination lead to substitution in the reactions of the carboxylic acid family (15.4)
12. How addition and condensation polymers form (15.5)
13. The three types of biopolymers and their monomers (15.6)
14. How amino acid sequence determines protein shape, which determines function (15.6)
15. How complementary base pairing controls the processes of protein synthesis and DNA replication (15.6)
16. How DNA base sequence determines RNA base sequence, which determines amino acid sequence (15.6)

Master These Skills

1. Drawing hydrocarbon structures given the number of C atoms, multiple bonds, and rings (SP 15.1)
2. Naming hydrocarbons and drawing expanded, condensed, and carbon skeleton formulas (15.2 and SP 15.2)
3. Drawing geometric isomers and identifying chiral centers of molecules (SP 15.2)
4. Recognizing the type of reaction from the structures of reactants and products (SP 15.3)
5. Recognizing a reaction as an oxidation or reduction from the structures of reactants and products (15.3)
6. Determining the reactants and products of the reactions of alcohols, alkyl halides, and amines (SP 15.4 and Follow-up)
7. Determining the products in a stepwise reaction sequence (SP 15.5)
8. Determining the reactants of the reactions of aldehydes and ketones (Follow-up Problem 15.5)
9. Determining the reactants and products of the reactions of the carboxylic acid family (SP 15.6 and Follow-up)
10. Recognizing and naming the functional groups in an organic molecule (SP 15.7)
11. Drawing an abbreviated synthetic polymer structure based on monomer structures (15.5)
12. Drawing small peptides from amino acid structures (15.6)
13. Using the base-paired sequence of one DNA strand to predict the sequence of the other (15.6)

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

The Special Nature of Carbon and the Characteristics of Organic Molecules

Concept Review Questions

15.1 Give the names and formulas of two carbon compounds that are organic and two that are inorganic.

15.2 Through the first quarter of the 19th century, the concept of vitalism—that a key difference existed between substances isolated from animate sources and those from inanimate sources—was widely accepted. What was the central notion of vitalism? Give an example of a finding that led to its eventual downfall.

15.3 Explain each statement in terms of atomic properties:
(a) Carbon engages in covalent rather than ionic bonding.
(b) Carbon has four bonds in all its organic compounds.
(c) Carbon forms neither stable cations, like many metals, nor stable anions, like many nonmetals.
(d) Carbon bonds to itself more extensively than does any other element.
(e) Carbon forms stable multiple bonds.

15.4 Carbon bonds to many elements other than itself.
(a) Name six elements that commonly bond to carbon in organic compounds.
(b) Which of these elements are heteroatoms?
(c) Which of these elements are more electronegative than carbon? Less electronegative?
(d) How does bonding of carbon to heteroatoms increase the number of organic compounds?

15.5 Silicon lies just below carbon in Group 4A(14) and also forms four covalent bonds. Why aren't there as many silicon compounds as carbon compounds?

15.6 What is the range of oxidation states for carbon? Name a compound in which carbon has its highest oxidation state and one in which it has its lowest.

15.7 Which of these bonds to carbon would you expect to be relatively reactive: C—H, C—C, C—I, C=O, C—Li? Explain.

The Structures and Classes of Hydrocarbons

(Sample Problems 15.1 and 15.2)

Concept Review Questions

15.8 (a) What structural feature is associated with each type of hydrocarbon: an alkane; a cycloalkane; an alkene; an alkyne?
(b) Give the general formula for each.
(c) Which hydrocarbons are considered saturated?

15.9 Define each type of isomer: (a) constitutional; (b) geometric; (c) optical. Which types of isomers are stereoisomers?

15.10 Among alkenes, alkynes, and aromatic hydrocarbons, only alkenes exhibit *cis-trans* isomerism. Why don't the others?

15.11 Which objects are asymmetric (have no plane of symmetry): (a) a circular clock face; (b) a football; (c) a dime; (d) a brick; (e) a hammer; (f) a spring?

15.12 Explain how a polarimeter works and what it measures.

15.13 How does an aromatic hydrocarbon differ from a cycloalkane in terms of its bonding? How does this difference affect structure?

Skill-Building Exercises *(grouped in similar pairs)*

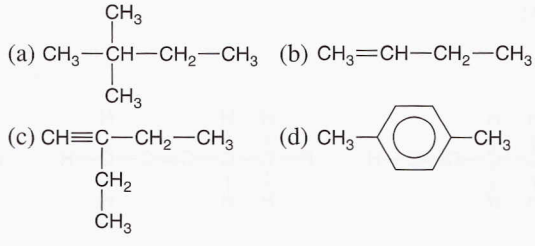
15.14 Draw all possible skeletons for a 7-C compound with
(a) A 6-C chain and 1 double bond
(b) A 5-C chain and 1 double bond
(c) A 5-C ring and no double bonds

15.15 Draw all possible skeletons for a 6-C compound with
(a) A 5-C chain and 2 double bonds
(b) A 5-C chain and 1 triple bond
(c) A 4-C ring and no double bonds

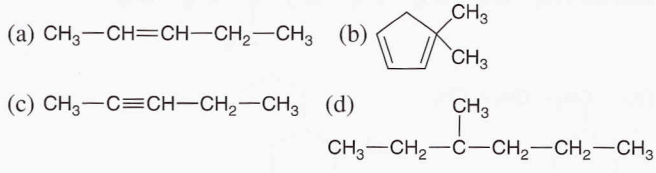
15.16 Add the correct number of hydrogens to each of the skeletons in Problem 15.14.

15.17 Add the correct number of hydrogens to each of the skeletons in Problem 15.15.

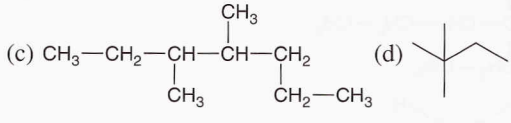
15.18 Draw correct structures, by making a single change, for any that are incorrect:



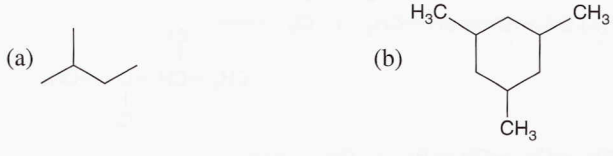
15.19 Draw correct structures, by making a single change, for any that are incorrect:



15.20 Draw the structure or give the name of each compound:
(a) 2,3-dimethyloctane (b) 1-ethyl-3-methylcyclohexane



15.21 Draw the structure or give the name of each compound:



(c) 1,2-diethylcyclopentane (d) 2,4,5-trimethylnonane

15.22 Each of the following names is wrong. Draw structures based on them, and correct the names:
(a) 4-methylhexane (b) 2-ethylpentane
(c) 2-methylcyclohexane (d) 3,3-methyl-4-ethyloctane

15.23 Each of the following names is wrong. Draw structures based on them, and correct the names:
(a) 3,3-dimethylbutane (b) 1,1,1-trimethylheptane
(c) 1,4-diethylcyclopentane (d) 1-propylcyclohexane

15.24 Each of the following compounds can exhibit optical activity. Circle the chiral center(s) in each:

(a) 
(b) 
15.25 Each of the following compounds can exhibit optical activity. Circle the chiral center(s) in each:

(a) 
(b) 
15.26 Draw structures from the following names, and determine which compounds are optically active:
(a) 3-bromohexane (b) 3-chloro-3-methylpentane
(c) 1,2-dibromo-2-methylbutane

15.27 Draw structures from the following names, and determine which compounds are optically active:
(a) 1,3-dichloropentane (b) 3-chloro-2,2,5-trimethylhexane
(c) 1-bromo-1-chlorobutane

15.28 Which of the following structures exhibit geometric isomerism? Draw and name the two isomers in each case:
(a) $CH_3—CH_2—CH=CH—CH_3$ (b) (c) $CH_3—C(CH_3)=CH—CH(CH_3)—CH_2—CH_3$

15.29 Which of the following structures exhibit geometric isomerism? Draw and name the two isomers in each case:
(a) $CH_3—C(CH_3)(CH_3)—CH=CH—CH_3$ (b) (c) $Cl—CH_2—CH=C(CH_3)—CH_2—CH_2—CH_2—CH_3$

15.30 Which compounds exhibit geometric isomerism? Draw and name the two isomers in each case:
(a) propene (b) 3-hexene
(c) 1,1-dichloroethene (d) 1,2-dichloroethene

15.31 Which compounds exhibit geometric isomerism? Draw and name the two isomers in each case:
(a) 1-pentene (b) 2-pentene
(c) 1-chloropropene (d) 2-chloropropene

15.32 Draw and name all the constitutional isomers of dichlorobenzene.

15.33 Draw and name all the constitutional isomers of trimethylbenzene.

Problems in Context

15.34 Butylated hydroxytoluene (BHT) is a common preservative added to cereals and other dry foods. Its systematic name is 1-hydroxy-2,6-di-*tert*-butyl-4-methylbenzene (where "*tert*-butyl" is 1,1-dimethylethyl). Draw the structure of BHT.

15.35 There are two compounds with the name 2-methyl-3-hexene, but only one with the name 2-methyl-2-hexene. Explain with structures.

15.36 Any tetrahedral atom with four different groups attached can be a chiral center. Which of these compounds is optically active?
(a) $CHClBrF$ (b) $NBrCl_2H^+$ (c) $PFClBrI^+$ (d) $SeFClBrH$

15.37 The number of peaks in the ^1H-NMR spectrum of a compound depends on the number of different kinds (environments) of H atoms. How many peaks appear in the spectrum of each isomer of C_4H_{10} and of C_5H_{12} (see Table 15.3, p. 626)?

Some Important Classes of Organic Reactions

(Sample Problem 15.3)

Concept Review Questions

15.38 In terms of numbers of reactant and product substances, which organic reaction type corresponds to (a) a combination reaction, (b) a decomposition reaction, (c) a displacement reaction?

15.39 The same type of bond is broken in an addition reaction and formed in an elimination reaction. Name the type.

15.40 Can a redox reaction also be an addition, elimination, or substitution reaction? Explain with examples.

Skill-Building Exercises *(grouped in similar pairs)*

15.41 Determine the type of each of the following reactions:

(a) $CH_3—CH_2—CH(Br)—CH_3 \xrightarrow[\Delta]{NaOH} CH_3—CH=CH—CH_3 + NaBr + H_2O$

(b) $CH_3—CH=CH—CH_2—CH_3 + H_2 \xrightarrow{Pt} CH_3—CH_2—CH_2—CH_2—CH_3$

15.42 Determine the type of each of the following reactions:

(a) $CH_3—C(=O)H + HCN \longrightarrow CH_3—CH(OH)—CN$

(b) $CH_3—C(=O)—O—CH_3 + CH_3—NH_2 \xrightarrow{H^+} CH_3—C(=O)—NH—CH_3 + CH_3—OH$

15.43 Write equations for the following:
(a) An addition reaction between H_2O and 3-hexene (H^+ is a catalyst)
(b) An elimination reaction between 2-bromopropane and hot potassium ethoxide, $CH_3—CH_2—OK$ (KBr and ethanol are also products)
(c) A light-induced substitution reaction between Cl_2 and ethane to form 1,1-dichloroethane

15.44 Write equations for the following:
(a) A substitution reaction between 2-bromopropane and KI
(b) An addition reaction between cyclohexene and Cl_2
(c) An addition reaction between 2-propanone and H_2 (Ni metal is a catalyst)

15.45 Based on the number of bonds and the nature of the bonded atoms, state whether each of the following changes is an oxidation or a reduction:

(a) $=CH_2$ becomes $-CH_2-OH$

(b) $=CH-$ becomes $-CH_2-$

(c) $\equiv C-$ becomes $-CH_2-$

15.46 Based on the number of bonds and the nature of the bonded atoms, state whether each of the following changes is an oxidation or a reduction:

(a)  becomes

(b) $-CH_2-OH$ becomes $=CH_2$

(c)  becomes

15.47 Is the organic reactant oxidized, reduced, or neither in each of the following reactions?

(a) 2-hexene $\xrightarrow[\text{cold OH}^-]{KMnO_4}$ 2,3-dihydroxyhexane

(b) cyclohexane $\xrightarrow[\text{catalyst}]{\Delta}$ benzene + $3H_2$

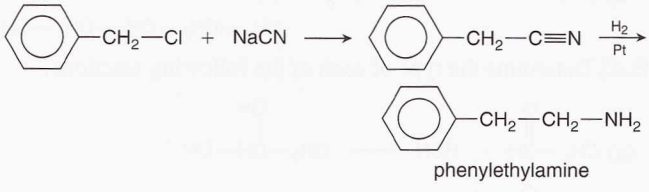
15.48 Is the organic reactant oxidized, reduced, or neither in each of the following reactions?

(a) 1-butyne + H_2 $\xrightarrow{Pt}$ 1-butene

(b) toluene $\xrightarrow[H_3O^+, \Delta]{KMnO_4}$ benzoic acid

Problems in Context

15.49 Phenylethylamine is a natural substance that is structurally similar to amphetamine. It is found in sources as diverse as almond oil and human urine, where it occurs at elevated concentrations as a result of stress and certain forms of schizophrenia. One method of synthesizing the compound for pharmacological and psychiatric studies involves two steps:



phenylethylamine

Classify each step as an addition, elimination, or substitution.

Properties and Reactivities of Common Functional Groups

(Sample Problems 15.4 to 15.7)

Concept Review Questions

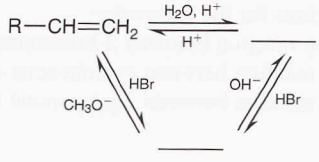
15.50 Compounds with nearly identical molar masses often have very different physical properties. Choose the compound with the higher value for each of the following properties, and explain your choice.

(a) Solubility in water: chloroethane or methylethylamine

(b) Melting point: diethyl ether or 1-butanol

(c) Boiling point: trimethylamine or propylamine

15.51 Fill in each blank with a general formula for the type of compound formed:



15.52 Of the three major types of organic reactions, which do *not* occur readily with benzene? Why?

15.53 Why does the C=O group react differently from the C=C group? Show an example of the difference.

15.54 Many substitution reactions involve an initial electrostatic attraction between reactants. Show where this attraction arises in the formation of an amide from an amine and an ester.

15.55 Although both carboxylic acids and alcohols contain an —OH group, one is acidic in water and the other is not. Explain.

15.56 What reaction type is common to the formation of esters and acid anhydrides? What is the other product?

15.57 Both alcohols and carboxylic acids undergo substitution, but the processes are very different. Explain.

Skill-Building Exercises *(grouped in similar pairs)*

15.58 Name the type of organic compound from the following description of its functional group:

(a) Polar group that has only single bonds and does not include O or N

(b) Group that is polar and has a triple bond

(c) Group that has single and double bonds and is acidic in water

(d) Group that has a double bond and must be at the end of a C chain

15.59 Name the type of organic compound from the following description of its functional group:

(a) N-containing group with single and double bonds

(b) Group that is not polar and has a double bond

(c) Polar group that has a double bond and cannot be at the end of a C chain

(d) Group that has only single bonds and is basic in water

15.60 Circle and name the functional group(s) in each compound:

(a) $CH_3-CH=CH-CH_2-OH$ (b) 
(c)  (d) $N\equiv C-CH_2-C(=O)-CH_3$

(e) 
15.61 Circle and name the functional group(s) in each compound:

(a)  (b) $I-CH_2-CH_2-C\equiv CH$

(c) $CH_2=CH-CH_2-C(=O)-O-CH_3$ (d) $CH_3-NH-C(=O)-C(=O)-O-CH_3$

(e) $CH_3-CH(Br)-CH=CH-CH_2-NH-CH_3$

15.62 Draw all possible alcohols with the formula $C_5H_{12}O$.

15.63 Draw all possible aldehydes and ketones with the formula $C_5H_{10}O$.

15.64 Draw all possible amines with the formula $C_4H_{11}N$.

15.65 Draw all possible carboxylic acids with the formula $C_5H_{10}O_2$.

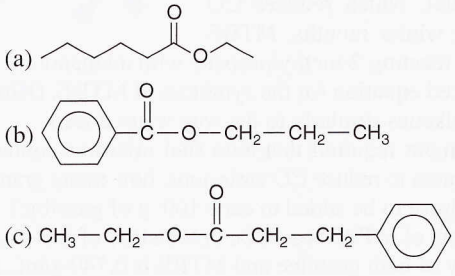
15.66 Draw the product resulting from mild oxidation of (a) 2-butanol; (b) 2-methylpropanal; (c) cyclopentanol.

15.67 Draw the alcohol you'd oxidize to produce (a) 2-methylpropanal; (b) 2-pentanone; (c) 3-methylbutanoic acid.

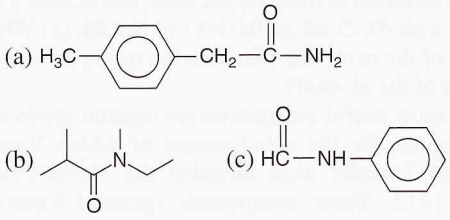
15.68 Draw the organic product formed when the following compounds undergo a substitution reaction:
(a) Acetic acid and methylamine
(b) Butanoic acid and 2-propanol
(c) Formic acid and 2-methyl-1-propanol

15.69 Draw the organic product formed when the following compounds undergo a substitution reaction:
(a) Acetic acid and 1-hexanol
(b) Propanoic acid and dimethylamine
(c) Ethanoic acid and diethylamine

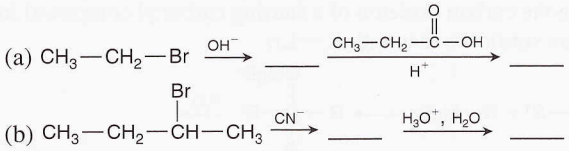
15.70 Draw condensed formulas for the carboxylic acid and alcohol portions of the following esters:



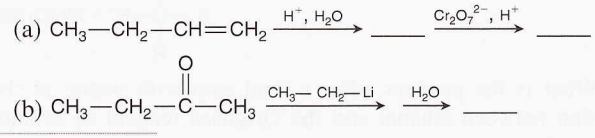
15.71 Draw condensed formulas for the carboxylic acid and amine portions of the following amides:



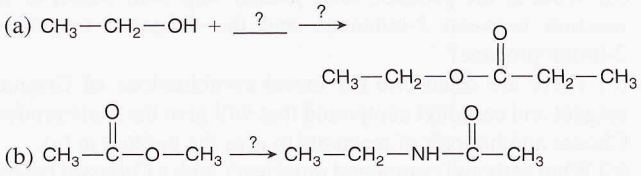
15.72 Fill in the expected organic products:



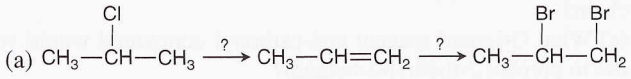
15.73 Fill in the expected organic products:

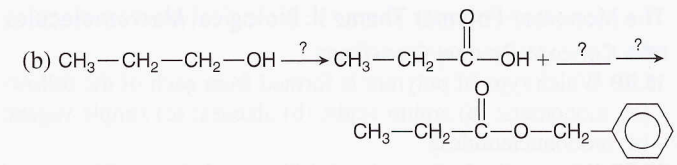


15.74 Supply the missing organic and/or inorganic substances:



15.75 Supply the missing organic and/or inorganic substances:





Problems in Context

15.76 (a) Draw the four isomers of $C_5H_{12}O$ that can be oxidized to an aldehyde. (b) Draw the three isomers of $C_5H_{12}O$ that can be oxidized to a ketone. (c) Draw the isomers of $C_5H_{12}O$ that cannot be easily oxidized to an aldehyde or ketone. (d) Name any isomer that is an alcohol.

15.77 Ethyl formate ($HC(=O)-O-CH_2-CH_3$) is added to foods to give them the flavor of rum. How would you synthesize ethyl formate from ethanol, methanol, and any inorganic reagents?

The Monomer-Polymer Theme I: Synthetic Macromolecules

Concept Review Questions

15.78 Name the reaction processes that lead to the two types of synthetic polymers.

15.79 Which functional group is common to the monomers that make up addition polymers? What makes these polymers different from one another?

15.80 What is a free radical? How is it involved in polymer formation?

15.81 Which intermolecular force is primarily responsible for the different types of polyethylene? Explain.

15.82 Which of the two types of synthetic polymer is more similar chemically to biopolymers? Explain.

15.83 Which two functional groups react to form nylons? Polyesters?

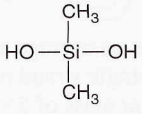
Skill-Building Exercises *(grouped in similar pairs)*

15.84 Draw an abbreviated structure for the following polymers, with brackets around the repeat unit:

(a) Poly(vinyl chloride) (PVC) from 
(b) Polypropylene from 
15.85 Draw an abbreviated structure for the following polymers, with brackets around the repeat unit:

(a) Teflon from 
(b) Polystyrene from 
15.86 Write a balanced equation for the reaction between 1,4-benzenedicarboxylic acid and 1,2-dihydroxyethane to form the polyester Dacron. Draw an abbreviated structure for the polymer, with brackets around the repeat unit.

15.87 Write a balanced equation for the reaction of dihydroxydimethylsilane *(below)* to form the condensation polymer known as Silly Putty.



The Monomer-Polymer Theme II: Biological Macromolecules

Concept Review Questions

15.88 Which type of polymer is formed from each of the following monomers: (a) amino acids; (b) alkenes; (c) simple sugars; (d) mononucleotides?

15.89 What is the key structural difference between fibrous and globular proteins? How is it related, in general, to the proteins' amino acid composition?

15.90 Protein shape, function, and amino acid sequence are interrelated. Which determines which?

15.91 What type of link joins the mononucleotides in each strand of DNA?

15.92 What is base pairing? How does it pertain to DNA structure?

15.93 RNA base sequence, protein amino acid sequence, and DNA base sequence are interrelated. Which determines which in the process of protein synthesis?

Skill-Building Exercises *(grouped in similar pairs)*

15.94 Draw the structure of the R group of (a) alanine; (b) histidine; (c) methionine.

15.95 Draw the structure of the R group of (a) glycine; (b) isoleucine; (c) tyrosine.

15.96 Draw the structure of each of the following tripeptides:
(a) Aspartic acid-histidine-tryptophan
(b) Glycine-cysteine-tyrosine with the charges existing in cell fluid

15.97 Draw the structure of each of the following tripeptides:
(a) Lysine-phenylalanine-threonine
(b) Alanine-leucine-valine with the charges that exist in cell fluid

15.98 Write the sequence of the complementary DNA strand that pairs with each of the following DNA base sequences:
(a) TTAGCC (b) AGACAT

15.99 Write the sequence of the complementary DNA strand that pairs with each of the following DNA base sequences:
(a) GGTTAC (b) CCCGAA

15.100 Write the base sequence of the DNA template from which this RNA sequence was derived: UGUUACGGA. How many amino acids are coded for in this sequence?

15.101 Write the base sequence of the DNA template from which this RNA sequence was derived: GUAUCAAUGAACUUG. How many amino acids are coded for in this sequence?

Problems in Context

15.102 Protein shapes are maintained by a variety of forces that arise from interactions between the amino-acid R groups. Name the amino acid that possesses each R group and the force that could arise in each of the following interactions:

(a) $-CH_2-SH$ with $HS-CH_2-$

(b) $-(CH_2)_4-NH_3^+$ with $^-O-\overset{\overset{O}{\|}}{C}-CH_2-$

(c) $-CH_2-\overset{\overset{O}{\|}}{C}-NH_2$ with $HO-CH_2-$

(d) $-\underset{\underset{CH_3}{|}}{CH}-CH_3$ with 
15.103 Amino acids have an average molar mass of 100 g/mol. How many bases on a single strand of DNA are needed to code for a protein with a molar mass of 5×10^5 g/mol?

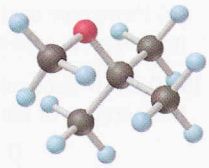
Comprehensive Problems

15.104 Starting with the given organic reactant and any necessary inorganic reagents, explain how you would perform each of the following syntheses:

(a) Starting with $CH_3-CH_2-CH_2-OH$, make $CH_3-\underset{\underset{Br}{|}}{CH}-CH_2-Br$

(b) Starting with CH_3-CH_2-OH, make $CH_3-\overset{\overset{O}{\|}}{C}-O-CH_2-CH_3$

15.105 Ethers (general formula R—O—R′) have many important uses. Until recently, methyl *tert*-butyl ether (MTBE, *right*) was used as an octane booster and fuel additive for gasoline. It increases the oxygen content of the fuel, which reduces CO emissions during winter months. MTBE is synthesized by reacting 2-methylpropene with methanol.



(a) Write a balanced equation for the synthesis of MTBE. (*Hint:* Alcohols add to alkenes similarly to the way water does.)
(b) If the government required that auto fuel mixtures contain 2.7% oxygen by mass to reduce CO emissions, how many grams of MTBE would have to be added to each 100. g of gasoline?
(c) How many liters of MTBE would be in each liter of fuel mixture? (The density of both gasoline and MTBE is 0.740 g/mL.)
(d) How many liters of air (21% O_2 by volume) are needed at 24°C and 1.00 atm to fully combust 1.00 L of MTBE?

15.106 An alcohol is oxidized to a carboxylic acid, and 0.2003 g of the acid is titrated with 45.25 mL of 0.03811 *M* NaOH. (a) What is the molar mass of the acid? (b) What are the molar mass and molecular formula of the alcohol?

15.107 Some of the most useful compounds for organic synthesis are Grignard reagents, for the development of which Victor Grignard and Paul Sabatier were awarded the Nobel Prize in chemistry in 1912. These compounds (general formula R—MgX, where X is a halogen) are made by combining an alkyl halide, R—X, with Mg in ether solvent. They are used to change the carbon skeleton of a starting carbonyl compound in a reaction similar to that with R—Li:

$$R'-\overset{\overset{O}{\|}}{C}-R'' + R-MgBr \longrightarrow R'-\underset{\underset{R}{|}}{\overset{\overset{OMgBr}{|}}{C}}-R'' \xrightarrow{H_2O} R'-\underset{\underset{R}{|}}{\overset{\overset{OH}{|}}{C}}-R'' + Mg(OH)Br$$

(a) What is the product, after a final step with water, of the reaction between ethanal and the Grignard reagent of bromobenzene?
(b) What is the product, after a final step with water, of the reaction between 2-butanone and the Grignard reagent of 2-bromopropane?
(c) There are often two (or more) combinations of Grignard reagent and carbonyl compound that will give the same product. Choose another pair of reactants to give the product in (a).
(d) What carbonyl compound must react with a Grignard reagent to yield a product with the —OH group at the *end* of the carbon chain?
(e) What Grignard reagent and carbonyl compound would you use to prepare 2-methyl-2-butanol?

15.108 A synthesis of 2-butanol was performed by treating 2-bromobutane with hot sodium hydroxide solution. The yield was 60%, indicating that a significant portion of the reactant was converted into a second product. Predict what this other product might be. What simple test would support your prediction?

15.109 Biphenyl consists of two benzene rings connected by a single bond. When Cl atoms substitute for some of the H atoms, polychlorinated biphenyls (PCBs) are formed. There are over 200 different PCBs, but only six with one Cl on each ring. Draw these constitutional isomers.

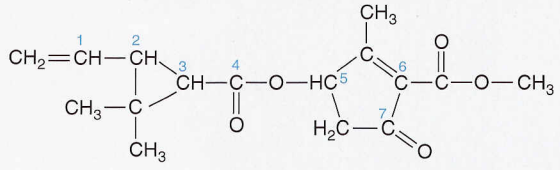
15.110 Cadaverine (1,5-diaminopentane) and putrescine (1,4-diaminobutane) are two compounds that are formed by bacterial action and are responsible for the odor of rotting flesh. Draw their structures. Suggest a series of reactions to synthesize putrescine from 1,2-dibromoethane and any inorganic reagents.

15.111 Pyrethrins, such as jasmolin II *(below)*, are a group of natural compounds synthesized by flowers of the genus *Chrysanthemum* (known as pyrethrum flowers) to act as insecticides.

(a) Circle and name the functional groups in jasmolin II.

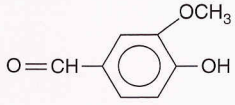
(b) What is the hybridization of the numbered carbons?

(c) Which, if any, of the numbered carbons are chiral centers?



15.112 Compound A is branched and optically active and contains C, H, and O. (a) A 0.500-g sample burns in excess O_2 to yield 1.25 g of CO_2 and 0.613 g of H_2O. Determine the empirical formula. (b) When 0.225 g of compound A vaporizes at 755 torr and 97°C, the vapor occupies 78.0 mL. Determine the molecular formula. (c) Careful oxidation of the compound yields a ketone. Name and draw compound A and circle the chiral center.

15.113 Vanillin *(right)* is a naturally occurring flavoring agent used in many food products. Name each functional group that contains oxygen. Which carbon-oxygen bond is shortest?



15.114 Combustion of gasoline releases almost all of the carbon it contains as CO_2, the major greenhouse gas. Assuming that gasoline is pure octane (d = 0.703 g/mL), how many metric tons of CO_2 are released in a year by an SUV that gets 15 mpg and is driven 18,000 miles?

15.115 Which features of retinal make it so useful as a photon absorber in the visual systems of organisms?

15.116 The polypeptide chain in proteins does not exhibit free rotation because of the partial double-bond character of the peptide bond. Explain this fact with resonance structures.

15.117 Although other nonmetals form many compounds that are structurally analogous to those of carbon, the inorganic compounds are usually more reactive. Predict any missing products and write balanced equations for each reaction:

(a) The decomposition and chlorination of diborane to boron trichloride

(b) The combustion of pentaborane (B_5H_9) in O_2

(c) The addition of water to borazine's double bonds ($B_3N_3H_6$, Figure 14.9B, p. 571). (*Hint:* The —OH group bonds to B.)

(d) The hydrolysis of trisilane (Si_3H_8) to silica (SiO_2) and H_2

(e) The complete halogenation of disilane with Cl_2

(f) The thermal decomposition of H_2S_5 to hydrogen sulfide and sulfur molecules

(g) The hydrolysis of PCl_5

15.118 The genetic code consists of a series of three-base words that each code for a given amino acid.

(a) Using the selections from the genetic code shown below, determine the amino acid sequence coded by the following segment of RNA:

UCCACAGCCUAUAUGGCAAACUUGAAG

AUG = methionine	CCU = proline	CAU = histidine
UGG = tryptophan	AAG = lysine	UAU = tyrosine
GCC = alanine	UUG = leucine	CGG = arginine
UGU = cysteine	AAC = asparagine	ACA = threonine
UCC = serine	GCA = alanine	UCA = serine

(b) What is the complementary DNA sequence from which this RNA sequence was made?

(c) If you were sequencing the DNA fragment in part (b) by the Sanger method, how many complementary chain pieces would you obtain in the tube containing ddATP?

15.119 Citral, the main odor constituent in oil of lemon grass, is used extensively in the flavoring and perfume industries. It occurs naturally as a mixture of the geometric isomers geranial (the *trans* isomer) and neral (the *cis* isomer). Its systematic name is 3,7-dimethyl-2,6-octadienal ("dien" indicates two C=C groups). Draw the structures of geranial and neral.

15.120 Complete hydrolysis of a 100.00-g sample of a peptide gave the following amounts of individual amino acids (molar masses, in g/mol, appear in parentheses):

3.00 g of glycine (75.07)	0.90 g of alanine (89.10)
3.70 g of valine (117.15)	6.90 g of proline (115.13)
7.30 g of serine (105.10)	86.00 g of arginine (174.21)

(a) Why does the total mass of amino acids exceed the mass of peptide? (b) What are the relative numbers of amino acids in the peptide? (c) What is the minimum molar mass of the peptide?

15.121 Aircraft de-icing agents, such as propylene glycol [1,2-propanediol; $CH_3CH(OH)CH_2OH$], are required prior to winter flights, but their presence in runoff depletes O_2 in natural waters (d of propylene glycol = 1.036 g/mL).

(a) Write a balanced equation for the complete oxidation of propylene glycol by O_2.

(b) What is the "theoretical oxygen demand," in grams of O_2 required per gram of propylene glycol oxidized?

(c) What is the theoretical oxygen demand, in grams of O_2 required per liter of solution, of 90.0% by volume propylene glycol solution?

15.122 2-Butanone is reduced by hydride ion donors, such as sodium borohydride ($NaBH_4$), to the alcohol 2-butanol. Even though the alcohol has a chiral center, the product isolated from the redox reaction is not optically active. Explain.

15.123 Sodium propanoate ($CH_3—CH_2—\overset{O}{\overset{\|}{C}}—ONa$) is a common preservative found in breads, cheeses, and pies. How would you synthesize sodium propanoate from 1-propanol and any inorganic reagents?

15.124 Wastewater from a cheese factory has the following composition: 8.0 g/L protein ($C_{16}H_{24}O_5N_4$); 12 g/L carbohydrate (CH_2O); and 2.0 g/L fat ($C_8H_{16}O$). What is the total organic carbon (TOC) of the wastewater in g of C/L?

Temperature and biological activity. The metabolic processes of cold-blooded animals like this thorny devil (*Moloch horridus*) speed up as temperatures rise toward midday. In this chapter, you'll see how the speed of a reaction is influenced by several factors, including temperature, and how we can control them.

Concepts & Skills to Review

before you study this chapter

- influence of temperature on molecular speed and collision frequency (Section 5.6)

Until now we've taken a rather simple approach to chemical change: reactants mix and products form. A balanced equation is an essential quantitative tool for calculating product yields from reactant amounts, but it tells us nothing about three dynamic aspects of the reaction, which are essential to understanding chemical change and which we examine in the next several chapters:

- How fast is the reaction proceeding at a given moment?
- What will the reactant and product concentrations be when the reaction is complete?
- Will the reaction proceed by itself and release energy, or will it require energy to proceed?

This chapter addresses the first of these questions and focuses on the field of *kinetics,* which deals with the speed of a reaction and its mechanism, the stepwise changes that reactants undergo in their conversion to products. Chapters 17 through 19 are concerned with *equilibrium,* the dynamic balance between forward and reverse reactions and how external influences alter reactant and product concentrations. Chapters 20 and 21 present *thermodynamics* and its application to electrochemistry; there, we investigate why reactions occur and how we can put them to use. These central subdisciplines of chemistry apply to all physical and chemical change and, thus, are crucial to our understanding of modern technology, the environment, and the reactions in living things.

Chemical kinetics is the study of *reaction rates,* the changes in concentrations of reactants (or products) as a function of time (Figure 16.1).

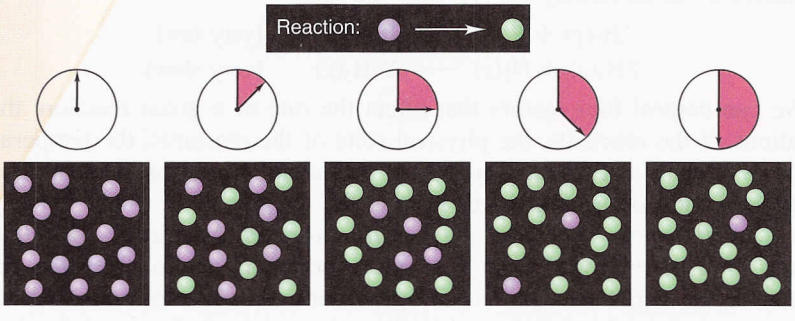

Figure 16.1 Reaction rate: the central focus of chemical kinetics. The rate at which reactant becomes product is the underlying theme of chemical kinetics. As time elapses, reactant *(purple)* decreases and product *(green)* increases.

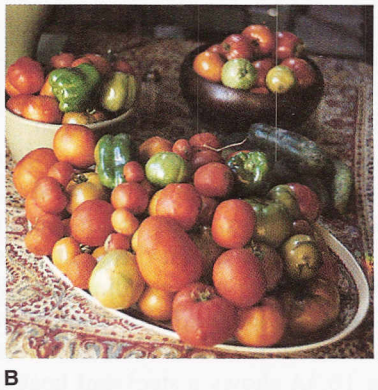
Reactions occur at a wide range of rates (Figure 16.2). Some, like a neutralization, a precipitation, or an explosive redox process, seem to be over as soon as the reactants make contact—in a fraction of a second. Others, such as the reactions involved in cooking or rusting, take a moderate length of time, from minutes to months. Still others take much longer: the reactions that make up the

Figure 16.2 The wide range of reaction rates. Reactions proceed at a wide range of rates. An explosion **(A)** is much faster than the process of ripening **(B),** which is much faster than the process of rusting **(C),** which is much faster than the process of human aging **(D).**

A



B

D

human aging process continue for decades, and those involved in the formation of coal from dead plants take hundreds of millions of years.

Knowing how fast a chemical change occurs can be essential. How quickly a medicine acts or blood clots can make the difference between life and death. How long it takes for cement to harden or polyethylene to form can make the difference between profit and loss. In general, the rates of these diverse processes depend on the same variables, most of which chemists can manipulate to maximize yields within a given time or to slow down an unwanted reaction.

IN THIS CHAPTER . . . We first overview three key factors that affect reaction rate. Then we see how to express rate in the form of a *rate law* and how the components of a rate law are determined experimentally. We focus on the effects of concentration and temperature on rate and examine the models that explain those effects. Only then can we develop a reaction mechanism by noting the steps the reaction goes through and picturing the structure that exists as reactant bonds are breaking and product bonds are forming. Finally, we discuss how catalysts increase reaction rates, highlighting two vital areas—the reactions of a living cell and the depletion of atmospheric ozone.

16.1 FACTORS THAT INFLUENCE REACTION RATE

Let's begin our study of kinetics with a qualitative look at the key factors that affect how fast a reaction proceeds. Under any given set of conditions, *each reaction has its own characteristic rate,* which is determined by the chemical nature of the reactants. At room temperature, for example, hydrogen reacts explosively with fluorine but extremely slowly with nitrogen:

$$H_2(g) + F_2(g) \longrightarrow 2HF(g) \qquad \text{[very fast]}$$
$$3H_2(g) + N_2(g) \longrightarrow 2NH_3(g) \qquad \text{[very slow]}$$

We can control four factors that affect the rate of a given reaction: the concentrations of the reactants, the physical state of the reactants, the temperature at which the reaction occurs, and the use of a catalyst. We'll consider the first three factors here and discuss the fourth later in the chapter.

1. *Concentration: molecules must collide to react.* A major factor influencing the rate of a given reaction is reactant concentration. Consider the reaction between ozone and nitric oxide (nitrogen monoxide) that occurs in the stratosphere, where the oxide is released in the exhaust gases of supersonic aircraft:

$$NO(g) + O_3(g) \longrightarrow NO_2(g) + O_2(g)$$

Imagine what this might look like at the molecular level with the reactants confined in a reaction vessel. Nitric oxide and ozone molecules zoom every which way, crashing into each other and the vessel walls. A reaction between NO and O_3 can occur only when the molecules collide. The more molecules present in the container, the more frequently they collide, and the more often a reaction occurs. Thus, *reaction rate is proportional to the concentration of reactants:*

$$\text{Rate} \propto \text{collision frequency} \propto \text{concentration}$$

In this case, we're looking at a very simple reaction, one in which reactant molecules collide and form product molecules in one step, but even the rates of complex reactions depend on reactant concentration.

2. *Physical state: molecules must mix to collide.* The frequency of collisions between molecules also depends on the physical states of the reactants. When the reactants are in the same phase, as in an aqueous solution, thermal motion brings them into contact. When they are in different phases, contact occurs only at the interface, so vigorous stirring and grinding may be needed. In these cases, *the more finely divided a solid or liquid reactant, the greater its surface area per unit volume, the more contact it makes with the other reactant, and the faster the reaction occurs.* Figure 16.3A shows a steel nail heated in oxygen glowing feebly; in

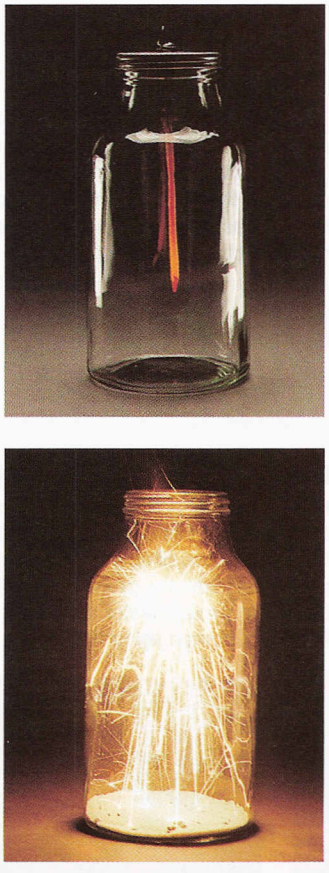

Figure 16.3 The effect of surface area on reaction rate. A, A hot nail glows in O_2. **B,** The same mass of hot steel wool bursts into flame in O_2. The greater surface area per unit volume of the steel wool means that more metal makes contact with O_2, so the reaction is faster.

Figure 16.3B, the same mass of steel wool bursts into flame. For the same reason, you start a campfire with wood chips and thin branches, not logs.

3. *Temperature: molecules must collide with enough energy to react.* Temperature usually has a major effect on the speed of a reaction. Two familiar kitchen appliances employ this effect: a refrigerator slows down chemical processes that spoil food, whereas an oven speeds up other chemical processes that cook it.

Recall that molecules in a sample of gas have a range of speeds, with the most probable speed dependent on the temperature (see Figure 5.14, p. 201). Thus, *at a higher temperature, more collisions occur in a given time*. Even more important, however, is the fact that temperature affects the kinetic energy of the molecules, and thus the *energy* of the collisions. In the jumble of molecules in the reaction of NO and O_3, mentioned previously, most collisions result in the molecules simply recoiling, like billiard balls, with no reaction taking place. However, some collisions occur with so much energy that the molecules react (Figure 16.4). And, at a higher temperature, more of these sufficiently energetic collisions occur. Thus, *raising the temperature increases the reaction rate by increasing the number and, especially, the energy of the collisions:*

$$\text{Rate} \propto \text{collision energy} \propto \text{temperature}$$

The qualitative idea that reaction rate is influenced by the frequency and energy of reactant collisions leads to several quantitative questions: How can we describe the dependence of rate on reactant concentration mathematically? Do all changes in concentration affect the rate to the same extent? Do all rates increase to the same extent with a given rise in temperature? How do reactant molecules use the energy of collision to form product molecules, and is there a way to determine this energy? What do the reactants look like as they are turning into products? We address these questions in the following sections.

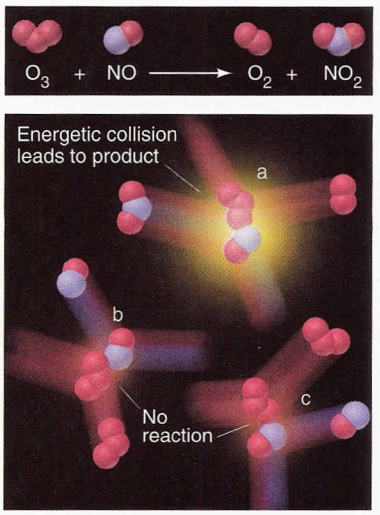

Figure 16.4 Collision energy and reaction rate. The reaction equation is shown in the panel. Although many collisions between NO and O_3 molecules occur, relatively few have enough energy to cause reaction. At this temperature, only collision *a* is energetic enough to lead to product; the reactant molecules in collisions *b* and *c* just bounce off each other.

SECTION SUMMARY

Chemical kinetics deals with reaction rates and the stepwise molecular events by which a reaction occurs. Under a given set of conditions, each reaction has its own rate. Concentration affects rate by influencing the frequency of collisions between reactant molecules. Physical state affects rate by determining the surface area per unit volume of reactant(s). Temperature affects rate by influencing the frequency and, even more importantly, the energy of the reactant collisions.

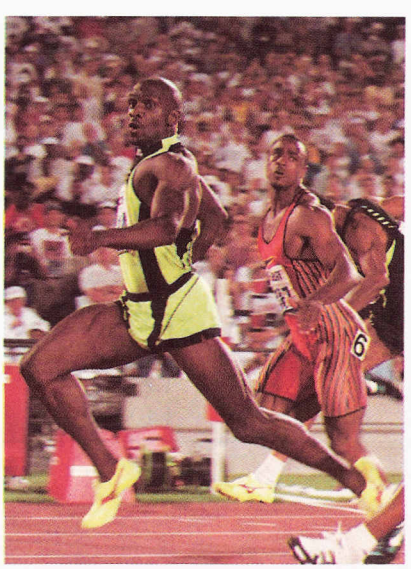
16.2 EXPRESSING THE REACTION RATE

Before we can deal quantitatively with the effects of concentration and temperature on reaction rate, we must express the rate mathematically. A *rate* is a change in some variable per unit of time. The most common examples relate to the rate of motion (speed) of an object, which is the change in its position divided by the change in time. Suppose, for instance, we measure a runner's starting position, x_1, at time t_1 and final position, x_2, at time t_2. The runner's average speed is

$$\text{Rate of motion} = \frac{\text{change in position}}{\text{change in time}} = \frac{x_2 - x_1}{t_2 - t_1} = \frac{\Delta x}{\Delta t}$$

In the case of a chemical change, we are concerned with the **reaction rate,** the changes in concentrations of reactants or products per unit time: *reactant concentrations decrease while product concentrations increase*. Consider a general reaction, A ⟶ B. We quickly measure the starting reactant concentration (conc A_1) at t_1, allow the reaction to proceed, and then quickly measure the reactant concentration again (conc A_2) at t_2. The change in concentration divided by the change in time gives the *average* rate:

$$\text{Rate of reaction} = -\frac{\text{change in concentration of A}}{\text{change in time}} = -\frac{\text{conc } A_2 - \text{conc } A_1}{t_2 - t_1} = -\frac{\Delta(\text{conc A})}{\Delta t}$$



A runner changing position with time

Note the minus sign. By convention, reaction rate is a *positive* number, but conc A_2 will always be *lower* than conc A_1, so the *change in (final − initial) concentration of reactant A is always negative*. We use the minus sign simply to convert the negative change in reactant concentration to a positive value for the rate. Suppose the concentration of A changes from 1.2 mol/L (conc A_1) to 0.75 mol/L (conc A_2) over a 125-s period. The average rate is

$$\text{Rate} = -\frac{0.75\ \text{mol/L} - 1.2\ \text{mol/L}}{125\ \text{s} - 0\ \text{s}} = 3.6\times10^{-3}\ \text{mol/L·s}$$

We use *square brackets,* [ ], *to express concentration in moles per liter.* That is, [A] is the concentration of A in mol/L, so the rate expressed in terms of A is

$$\text{Rate} = -\frac{\Delta[\text{A}]}{\Delta t} \tag{16.1}$$

The rate has units of moles per liter per second (mol L^{-1} s^{-1}, or mol/L·s), or any time unit convenient for the particular reaction (minutes, years, and so on).

If instead we measure the *product* to determine the reaction rate, we find its concentration *increasing* over time. That is, conc B_2 is always *higher* than conc B_1. Thus, the *change* in product concentration, Δ[B], is *positive,* and the reaction rate for A ⟶ B expressed in terms of B is

$$\text{Rate} = \frac{\Delta[\text{B}]}{\Delta t}$$

Average, Instantaneous, and Initial Reaction Rates

Examining the rate of a real reaction reveals an important point: *the rate itself varies with time as the reaction proceeds.* Consider the reversible gas-phase reaction between ethylene and ozone, one of many reactions that can be involved in the formation of photochemical smog:

$$C_2H_4(g) + O_3(g) \rightleftharpoons C_2H_4O(g) + O_2(g)$$

For now, we consider only reactant concentrations. You can see from the equation coefficients that for every molecule of C_2H_4 that reacts, a molecule of O_3 reacts with it. In other words, the concentrations of both reactants decrease at the same rate in this particular reaction:

$$\text{Rate} = -\frac{\Delta[C_2H_4]}{\Delta t} = -\frac{\Delta[O_3]}{\Delta t}$$

By measuring the concentration of either reactant, we can follow the reaction rate.

Suppose we have a known concentration of O_3 in a closed reaction vessel kept at 30°C (303 K). Table 16.1 shows the concentration of O_3 at various times during the first minute after we introduce C_2H_4 gas. The rate over the entire 60.0 s is the total change in concentration divided by the change in time:

$$\text{Rate} = -\frac{\Delta[O_3]}{\Delta t} = -\frac{(1.10\times10^{-5}\ \text{mol/L}) - (3.20\times10^{-5}\ \text{mol/L})}{60.0\ \text{s} - 0.0\ \text{s}} = 3.50\times10^{-7}\ \text{mol/L·s}$$

This calculation gives us the **average rate** over that period; that is, during the first 60.0 s of the reaction, ozone concentration decreases an *average* of 3.50×10^{-7} mol/L each second. However, the average rate does not show that the rate is changing, and it tells us nothing about how fast the ozone concentration is decreasing *at any given instant.*

We can see the rate change during the reaction by calculating the average rate over two shorter periods—one earlier and one later. Between the starting time 0.0 s and 10.0 s, the average rate is

$$\text{Rate} = -\frac{\Delta[O_3]}{\Delta t} = -\frac{(2.42\times10^{-5}\ \text{mol/L}) - (3.20\times10^{-5}\ \text{mol/L})}{10.0\ \text{s} - 0.0\ \text{s}} = 7.80\times10^{-7}\ \text{mol/L·s}$$

Table 16.1 Concentration of O_3 at Various Times in Its Reaction with C_2H_4 at 303 K

Time (s)	Concentration of O_3 (mol/L)
0.0	3.20×10^{-5}
10.0	2.42×10^{-5}
20.0	1.95×10^{-5}
30.0	1.63×10^{-5}
40.0	1.40×10^{-5}
50.0	1.23×10^{-5}
60.0	1.10×10^{-5}

During the last 10.0 s, between 50.0 s and 60.0 s, the average rate is

$$\text{Rate} = -\frac{\Delta[O_3]}{\Delta t} = -\frac{(1.10\times10^{-5}\ \text{mol/L}) - (1.23\times10^{-5}\ \text{mol/L})}{60.0\ \text{s} - 50.0\ \text{s}} = 1.30\times10^{-7}\ \text{mol/L·s}$$

The earlier rate is six times as fast as the later rate. Thus, *the rate decreases during the course of the reaction.* This makes perfect sense from a molecular point of view: as O_3 molecules are used up, fewer of them are present to collide with C_2H_4 molecules, so the rate decreases.

The change in rate can also be seen by plotting the concentrations vs. the times at which they were measured (Figure 16.5). A curve is obtained, which means that the rate changes. *The slope of the straight line ($\Delta y/\Delta x$, that is, $\Delta[O_3]/\Delta t$) joining any two points gives the average rate over that period.*

The shorter the time period we choose, the closer we come to the **instantaneous rate,** the rate at a particular instant during the reaction. *The slope of a line tangent to the curve at a particular point gives the instantaneous rate at that time.* For example, the rate of the reaction of C_2H_4 and O_3 35.0 s after it began is 2.50×10^{-7} mol/L·s, the slope of the line drawn tangent to the curve through the point at which $t = 35.0$ s (line *d* in Figure 16.5). In general, we use the term *reaction rate* to mean the *instantaneous* reaction rate.

As a reaction continues, the product concentrations increase, and so the reverse reaction proceeds more quickly. To find the overall (net) rate, we would have to take both forward and reverse reactions into account and calculate the difference between their rates. A common way to avoid this complication for many reactions is to measure the **initial rate,** the instantaneous rate at the moment the reactants are mixed. Under these conditions, the product concentrations are negligible, so the reverse rate is negligible. Moreover, we know the reactant concentrations from the concentrations and volumes of the solutions we mix together. The initial rate is measured by determining the slope of the line tangent to the curve at $t = 0$ s. In Figure 16.5, the initial rate is 10.0×10^{-7} mol/L·s (line *a*). Unless stated otherwise, we will use initial rate data to determine other kinetic parameters.

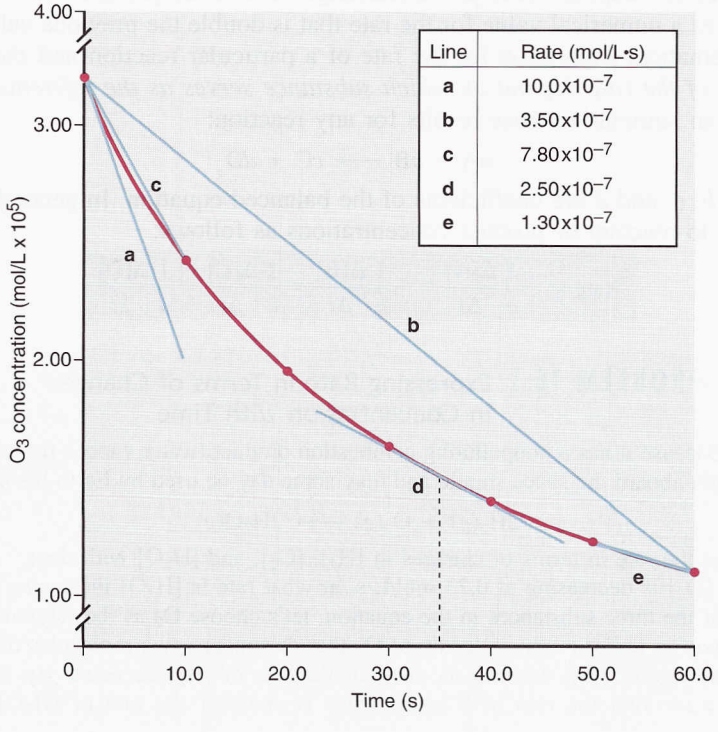


Figure 16.5 The concentration of O_3 vs. time during its reaction with C_2H_4. Plotting the data in Table 16.1 gives a curve because the rate changes during the reaction. The *average* rate over a given period is the slope of a line joining two points along the curve. The slope of line *b* is the average rate over the first 60.0 s of the reaction. The slopes of lines *c* and *e* give the average rate over the first and last 10.0-s intervals, respectively. Line *c* is steeper than line *e* because the average rate over the earlier period is higher. The *instantaneous* rate at 35.0 s is the slope of line *d*, the tangent to the curve at $t = 35.0$ s. The *initial* rate is the slope of line *a*, the tangent to the curve at $t = 0$ s.

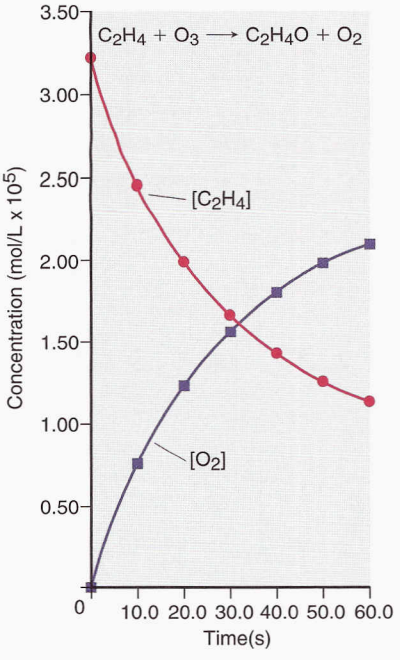

Figure 16.6 Plots of $[C_2H_4]$ and $[O_2]$ vs. time. Measuring reactant concentration, $[C_2H_4]$, and product concentration, $[O_2]$, gives curves of identical shapes but changing in opposite directions. The steep upward (positive) slope of $[O_2]$ early in the reaction mirrors the steep downward (negative) slope of $[C_2H_4]$ because the faster C_2H_4 is used up, the faster O_2 is formed. The curve shapes are identical in this case because the equation coefficients are identical.

Expressing Rate in Terms of Reactant and Product Concentrations

So far, in our discussion of the reaction of C_2H_4 and O_3, we've expressed the rate in terms of the decreasing concentration of O_3. The rate is the same in terms of C_2H_4, but it is exactly the opposite in terms of the products because their concentrations are *increasing*. From the balanced equation, we see that one molecule of C_2H_4O and one of O_2 appear for every molecule of C_2H_4 and of O_3 that disappear. We can express the rate in terms of any of the four substances involved:

$$\text{Rate} = -\frac{\Delta[C_2H_4]}{\Delta t} = -\frac{\Delta[O_3]}{\Delta t} = +\frac{\Delta[C_2H_4O]}{\Delta t} = +\frac{\Delta[O_2]}{\Delta t}$$

Again, note the negative values for the reactants and the positive values for the products (usually written without the plus sign). Figure 16.6 shows a plot of the simultaneous monitoring of one reactant and one product. Because, in this case, product concentration increases at the same rate that reactant concentration decreases, the curves have the same shapes but are inverted.

In the reaction between ethylene and ozone, the reactants disappear and the products appear at the same rate because all the coefficients in the balanced equation are equal. Consider next the reaction between hydrogen and iodine to form hydrogen iodide:

$$H_2(g) + I_2(g) \longrightarrow 2HI(g)$$

For every molecule of H_2 that disappears, one molecule of I_2 disappears and *two* molecules of HI appear. In other words, the rate of $[H_2]$ decrease is the same as the rate of $[I_2]$ decrease, but both are only half the rate of [HI] increase. By referring the change in $[I_2]$ and [HI] to the change in $[H_2]$, we have

$$\text{Rate} = -\frac{\Delta[H_2]}{\Delta t} = -\frac{\Delta[I_2]}{\Delta t} = \frac{1}{2}\frac{\Delta[HI]}{\Delta t}$$

If we refer the change in $[H_2]$ and $[I_2]$ to the change in [HI] instead, we obtain

$$\text{Rate} = \frac{\Delta[HI]}{\Delta t} = -2\frac{\Delta[H_2]}{\Delta t} = -2\frac{\Delta[I_2]}{\Delta t}$$

Notice that this expression is just a rearrangement of the previous one; also note that it gives a numerical value for the rate that is double the previous value. Thus, the mathematical expression for the rate of a particular reaction and *the numerical value of the rate depend on which substance serves as the reference.*

We can summarize these results for any reaction:

$$aA + bB \longrightarrow cC + dD$$

where a, b, c, and d are coefficients of the balanced equation. In general, the rate is related to reactant or product concentrations as follows:

$$\text{Rate} = -\frac{1}{a}\frac{\Delta[A]}{\Delta t} = -\frac{1}{b}\frac{\Delta[B]}{\Delta t} = \frac{1}{c}\frac{\Delta[C]}{\Delta t} = \frac{1}{d}\frac{\Delta[D]}{\Delta t} \qquad (16.2)$$

SAMPLE PROBLEM 16.1 Expressing Rate in Terms of Changes in Concentration with Time

Problem Because it has a nonpolluting combustion product (water vapor), hydrogen gas is used for fuel aboard the space shuttle and may some day be used by Earth-bound engines:

$$2H_2(g) + O_2(g) \longrightarrow 2H_2O(g)$$

(a) Express the rate in terms of changes in $[H_2]$, $[O_2]$, and $[H_2O]$ with time.
(b) When $[O_2]$ is decreasing at 0.23 mol/L·s, at what rate is $[H_2O]$ increasing?

Plan **(a)** Of the three substances in the equation, let's choose O_2 as the reference because its coefficient is 1. For every molecule of O_2 that disappears, two molecules of H_2 disappear, so the rate of $[O_2]$ decrease is one-half the rate of $[H_2]$ decrease. By similar reasoning, we see that the rate of $[O_2]$ decrease is one-half the rate of $[H_2O]$ increase.

(b) Because $[O_2]$ is decreasing, the change in its concentration must be negative. We substitute the negative value into the expression and solve for $\Delta[H_2O]/\Delta t$.

Solution **(a)** Expressing the rate in terms of each component:

$$\text{Rate} = -\frac{1}{2}\frac{\Delta[H_2]}{\Delta t} = -\frac{\Delta[O_2]}{\Delta t} = \frac{1}{2}\frac{\Delta[H_2O]}{\Delta t}$$

(b) Calculating the rate of change of $[H_2O]$:

$$\frac{1}{2}\frac{\Delta[H_2O]}{\Delta t} = -\frac{\Delta[O_2]}{\Delta t} = -(-0.23 \text{ mol/L·s})$$

$$\frac{\Delta[H_2O]}{\Delta t} = 2(0.23 \text{ mol/L·s}) = 0.46 \text{ mol/L·s}$$

Check **(a)** A good check is to use the rate expression to obtain the balanced equation: $[H_2]$ changes twice as fast as $[O_2]$, so two H_2 molecules react for each O_2. $[H_2O]$ changes twice as fast as $[O_2]$, so two H_2O molecules form from each O_2. From this reasoning, we get $2H_2 + O_2 \longrightarrow 2H_2O$. The $[H_2]$ and $[O_2]$ decrease, so they take minus signs; $[H_2O]$ increases, so it takes a plus sign. Another check is to use Equation 16.2, with A = H_2, $a = 2$; B = O_2, $b = 1$; C = H_2O, $c = 2$. Thus,

$$\text{Rate} = -\frac{1}{a}\frac{\Delta[A]}{\Delta t} = -\frac{1}{b}\frac{\Delta[B]}{\Delta t} = \frac{1}{c}\frac{\Delta[C]}{\Delta t}$$

or

$$\text{Rate} = -\frac{1}{2}\frac{\Delta[H_2]}{\Delta t} = -\frac{\Delta[O_2]}{\Delta t} = \frac{1}{2}\frac{\Delta[H_2O]}{\Delta t}$$

(b) Given the rate expression, it makes sense that the numerical value of the rate of $[H_2O]$ increase is twice that of $[O_2]$ decrease.

Comment Thinking through this type of problem at the molecular level is the best approach, but use Equation 16.2 to confirm your answer.

FOLLOW-UP PROBLEM 16.1 **(a)** Balance the following equation and express the rate in terms of the change in concentration with time for each substance:

$$NO(g) + O_2(g) \longrightarrow N_2O_3(g)$$

(b) How fast is $[O_2]$ decreasing when [NO] is decreasing at a rate of 1.60×10^{-4} mol/L·s?

SECTION SUMMARY

The average reaction rate is the change in reactant (or product) concentration over a change in time, Δt. The rate slows as reactants are used up. The instantaneous rate at time t is obtained from the slope of the tangent to a concentration vs. time curve at time t. The initial rate, the instantaneous rate at $t = 0$, occurs when reactants are just mixed and before any product accumulates. The expression for a reaction rate and its numerical value depend on which reaction component is being monitored.

16.3 THE RATE LAW AND ITS COMPONENTS

The centerpiece of any kinetic study is the **rate law** (or **rate equation**) for the reaction in question. The rate law expresses the rate as a function of reactant concentrations, product concentrations, and temperature. Any hypothesis we make about how the reaction occurs on the molecular level must conform to the rate law because it is based on experimental fact.

In this discussion, we generally consider reactions for which the products do not appear in the rate law. In these cases, *the reaction rate depends only on reactant concentrations and temperature*. First, we look at the effect of concentration on rate for reactions occurring at a fixed temperature. For a general reaction,

$$aA + bB + \cdots \longrightarrow cC + dD + \cdots$$

the rate law has the form

$$\text{Rate} = k[A]^m[B]^n \cdots \qquad (16.3)$$

Aside from the concentration terms, [A] and [B], the other parameters in Equation 16.3 require some definition. The proportionality constant k, called the **rate constant,** is specific for a given reaction at a given temperature; it does *not* change as the reaction proceeds. (As you'll see in Section 16.5, k *does* change with temperature and therefore determines how temperature affects the rate.) The exponents m and n, called the **reaction orders,** define how the rate is affected by reactant concentration. Thus, if the rate doubles when [A] doubles, the rate depends on [A] raised to the first power, $[A]^1$, so $m = 1$. Similarly, if the rate quadruples when [B] doubles, the rate depends on [B] raised to the second power, $[B]^2$, so $n = 2$. In another reaction, the rate may not change at all when [A] doubles; in that case, the rate does *not* depend on [A] or, to put it another way, the rate depends on [A] raised to the zero power, $[A]^0$, so $m = 0$. Keep in mind that the coefficients a and b in the general balanced equation are *not* necessarily related in any way to the reaction orders m and n.

A key point to remember is that *the components of the rate law—rate, reaction orders, and rate constant—must be found by experiment;* they cannot be

TOOLS OF THE LABORATORY

Measuring Reaction Rates

Speculation about how a reaction occurs at the molecular level must be based on measurements of reaction rates. There are many experimental approaches, but all must obtain the results quickly and reproducibly. We consider four common methods, with specific examples.

Spectrometric Methods

These methods are used to measure the concentration of a reactant or product that absorbs (or emits) light of a narrow range of wavelengths. The reaction is typically performed *within* the sample compartment of a spectrometer that has been set to measure a wavelength characteristic of one of the species (Figure B16.1; see also Tools of the Laboratory, pp. 269–270). For example, in the reaction of NO and O_3, only NO_2 has a color:

$$NO(g, \text{colorless}) + O_3(g, \text{colorless}) \longrightarrow O_2(g, \text{colorless}) + NO_2(g, \text{brown})$$

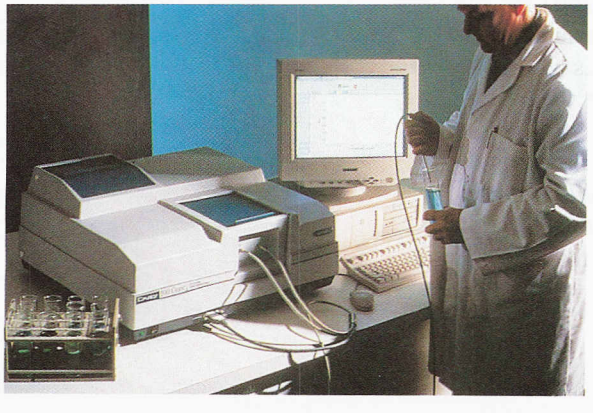
Known amounts of the reactants are injected into a gas sample tube of known volume, and the rate of NO_2 formation is measured by monitoring the color over time. Reactions in aqueous solution are studied similarly.

Conductometric Methods

When nonionic reactants form ionic products, or vice versa, the change in conductivity of the solution over time can be used to measure the rate. Electrodes are immersed in the reaction mixture, and the increase (or decrease) in conductivity correlates with the formation of product (Figure B16.2). Consider the reaction between an organic halide, such as 2-bromo-2-methylpropane, and water:

$$(CH_3)_3C{-}Br(l) + H_2O(l) \longrightarrow (CH_3)_3C{-}OH(l) + H^+(aq) + Br^-(aq)$$

The HBr that forms is a strong acid in water, so it dissociates completely into ions. As time passes, more ions form, so the conductivity of the reaction mixture increases.



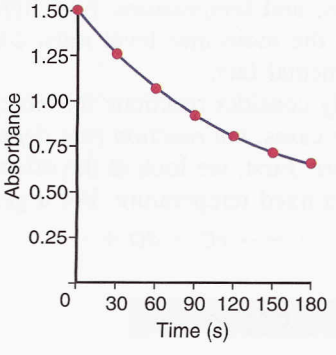


Figure B16.1 Spectrometric monitoring of a reaction. The investigator adds the reactant(s) to the sample tube and immediately places it in the spectrometer. For a reactant (or product) that is colored, rate data are determined from a plot of absorbance (of light of particular wavelength) vs. time. The rate of disappearance of a blue dye is being studied here.

deduced from the reaction stoichiometry. So let's take an experimental approach to finding the components by

1. Using concentration measurements to find the *initial rate*
2. Using initial rates from several experiments to find the *reaction orders*
3. Using these values to calculate the *rate constant*

Once we know the rate law, we can use it to predict the rate for any initial reactant concentrations.

Determining the Initial Rate

In the last section, we showed how initial rates are determined from a plot of concentration vs. time. Because we use initial rate data to determine the reaction orders and rate constant, an accurate experimental method for measuring concentration at various times during the reaction is essential to constructing the rate law. A few of the many techniques used for measuring changes in concentration over time are presented in the Tools of the Laboratory essay.

Figure B16.2 Conductometric monitoring of a reaction. When a reactant mixture differs in conductivity from the product mixture, the change in conductivity is proportional to the reaction rate. This method is usually used when nonionic reactants form ionic products.

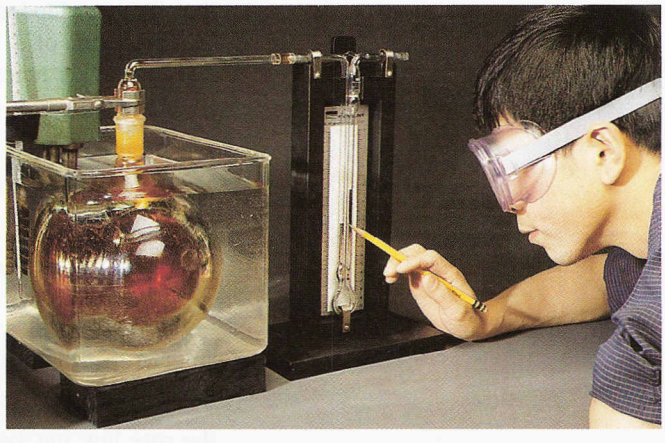

Figure B16.3 Manometric monitoring of a reaction. When a reaction results in a change in the number of moles of gas, the change in pressure with time corresponds to a change in reaction rate. The rate of formation of NO_2 from N_2O_4 is being studied here.

Manometric Methods

If a reaction involves a change in the number of moles of gas, the rate can be determined from the change in pressure (at constant volume and temperature) over time. In practice, a manometer is attached to a reaction vessel of known volume that is immersed in a constant-temperature bath. For example, the reaction between zinc and acetic acid can be monitored by this method:

$$Zn(s) + 2CH_3COOH(aq) \longrightarrow Zn^{2+}(aq) + 2CH_3COO^-(aq) + H_2(g)$$

As H_2 forms, the gas pressure increases. Thus, the reaction rate is directly proportional to the rate of increase of the H_2 gas pressure. In Figure B16.3, this method is being used to study a reaction involving nitrogen dioxide.

Direct Chemical Methods

Rates of slow reactions, or of those that can be easily slowed, are often studied by direct chemical methods. A small, measured portion (called an *aliquot*) of the reaction mixture is removed, and the reaction in this portion is stopped, usually by rapid cooling. The concentration of reactant or product in the aliquot is measured, while the bulk of the reaction mixture continues to react and is sampled later. For example, the earlier reaction between an organic halide and water can also be studied by titration. The reaction rate in an aliquot is slowed by quickly transferring it to a chilled flask in an ice bath. HBr concentration in the aliquot is determined by titrating with standardized NaOH solution. To determine the change in HBr concentration with time, the procedure is repeated at regular intervals during the reaction.

Reaction Order Terminology

Before we see how reaction orders are determined from initial rate data, let's discuss the meaning of reaction order and some important terminology. We speak of a reaction as having an *individual* order "with respect to" or "in" each reactant as well as an *overall* order, which is simply the sum of the individual orders.

In the simplest case, a reaction with a single reactant A, the reaction is *first order* overall if the rate is directly proportional to [A]:

$$\text{Rate} = k[\text{A}]$$

It is *second order* overall if the rate is directly proportional to the square of [A]:

$$\text{Rate} = k[\text{A}]^2$$

And it is *zero order* overall if the rate is *not* dependent on [A] at all, a situation that is quite common in metal-catalyzed and biochemical processes:

$$\text{Rate} = k[\text{A}]^0 = k(1) = k$$

Here are some real examples. For the reaction between nitrogen monoxide and ozone,

$$\text{NO}(g) + \text{O}_3(g) \longrightarrow \text{NO}_2(g) + \text{O}_2(g)$$

the rate law has been experimentally determined to be

$$\text{Rate} = k[\text{NO}][\text{O}_3]$$

This reaction is first order with respect to NO (or first order in NO), which means that the rate depends on NO concentration raised to the first power, that is, $[\text{NO}]^1$ (an exponent of 1 is generally omitted). It is also first order with respect to O_3, or $[\text{O}_3]^1$. This reaction is second order overall ($1 + 1 = 2$).

Now consider a different gas-phase reaction:

$$2\text{NO}(g) + 2\text{H}_2(g) \longrightarrow \text{N}_2(g) + 2\text{H}_2\text{O}(g)$$

The rate law for this reaction has been determined to be

$$\text{Rate} = k[\text{NO}]^2[\text{H}_2]$$

The reaction is second order in NO and first order in H_2, so it is third order overall.

Finally, for the hydrolysis of 2-bromo-2-methylpropane, which we just considered in the Tools of the Laboratory essay,

$$(\text{CH}_3)_3\text{C—Br}(l) + \text{H}_2\text{O}(l) \longrightarrow (\text{CH}_3)_3\text{C—OH}(l) + \text{H}^+(aq) + \text{Br}^-(aq)$$

the rate law has been found to be

$$\text{Rate} = k[(\text{CH}_3)_3\text{CBr}]$$

This reaction is first order in 2-bromo-2-methylpropane. Note that the concentration of H_2O does not even appear in the rate law. Thus, the reaction is zero order with respect to H_2O ($[\text{H}_2\text{O}]^0$). This means that the rate does not depend on the concentration of H_2O. We can also write the rate law as

$$\text{Rate} = k[(\text{CH}_3)_3\text{CBr}][\text{H}_2\text{O}]^0$$

Overall, this is a first-order reaction.

These examples demonstrate a major point: *reaction orders* ***cannot*** *be deduced from the balanced equation.* For the reaction between NO and H_2 and for the hydrolysis of 2-bromo-2-methylpropane, the reaction orders in the rate laws do *not* correspond to the coefficients of the balanced equations. Reaction orders *must* be determined from rate data.

Reaction orders are usually positive integers or zero, but they can also be fractional or negative. For the reaction

$$\text{CHCl}_3(g) + \text{Cl}_2(g) \longrightarrow \text{CCl}_4(g) + \text{HCl}(g)$$

a fractional order appears in the rate law:

$$\text{Rate} = k[CHCl_3][Cl_2]^{1/2}$$

This reaction order means that the rate depends on the square root of the Cl_2 concentration. For example, if the initial Cl_2 concentration is increased by a factor of 4, while the initial $CHCl_3$ concentration is kept the same, the rate increases by a factor of 2, the square root of the change in $[Cl_2]$. A negative exponent means that the rate *decreases* when the concentration of that component increases. Negative orders are often seen for reactions whose rate laws include products. For example, for the atmospheric reaction

$$2O_3(g) \rightleftharpoons 3O_2(g)$$

the rate law has been shown to be

$$\text{Rate} = k[O_3]^2[O_2]^{-1} = k\frac{[O_3]^2}{[O_2]}$$

If the O_2 concentration doubles, the reaction proceeds half as fast.

SAMPLE PROBLEM 16.2 Determining Reaction Order from Rate Laws

Problem For each of the following reactions, use the given rate law to determine the reaction order with respect to each reactant and the overall order:

(a) $2NO(g) + O_2(g) \longrightarrow 2NO_2(g)$; rate $= k[NO]^2[O_2]$

(b) $CH_3CHO(g) \longrightarrow CH_4(g) + CO(g)$; rate $= k[CH_3CHO]^{3/2}$

(c) $H_2O_2(aq) + 3I^-(aq) + 2H^+(aq) \longrightarrow I_3^-(aq) + 2H_2O(l)$; rate $= k[H_2O_2][I^-]$

Plan We inspect the exponents in the rate law, *not* the coefficients of the balanced equation, to find the individual orders, and then take their sum to find the overall reaction order.

Solution **(a)** The exponent of [NO] is 2, so the reaction is second order with respect to NO, first order with respect to O_2, and third order overall.

(b) The reaction is $\frac{3}{2}$ order in CH_3CHO and $\frac{3}{2}$ order overall.

(c) The reaction is first order in H_2O_2, first order in I^-, and second order overall.

The reactant H^+ does not appear in the rate law, so the reaction is zero order in H^+.

Check Be sure that each reactant has an order and that the sum of the individual orders gives the overall order.

FOLLOW-UP PROBLEM 16.2 Experiment shows that the reaction

$$5Br^-(aq) + BrO_3^-(aq) + 6H^+(aq) \longrightarrow 3Br_2(l) + 3H_2O(l)$$

obeys this rate law: rate $= k[Br^-][BrO_3^-][H^+]^2$. What are the reaction orders in each reactant and the overall reaction order?

Determining Reaction Orders

Sample Problem 16.2 shows how to find the reaction orders from a known rate law. Now let's see how they are found from data *before* the rate law is known. Consider the reaction between oxygen and nitrogen monoxide, a key step in the formation of acid rain and in the industrial production of nitric acid:

$$O_2(g) + 2NO(g) \longrightarrow 2NO_2(g)$$

The rate law, expressed in general form, is

$$\text{Rate} = k[O_2]^m[NO]^n$$

To find the reaction orders, *we run a series of experiments, starting each one with a different set of reactant concentrations and obtaining an initial rate in each case.*

Table 16.2 Initial Rates for a Series of Experiments with the Reaction Between O_2 and NO

Experiment	Initial Reactant Concentrations (mol/L)		Initial Rate (mol/L·s)
	O_2	NO	
1	1.10×10^{-2}	1.30×10^{-2}	3.21×10^{-3}
2	2.20×10^{-2}	1.30×10^{-2}	6.40×10^{-3}
3	1.10×10^{-2}	2.60×10^{-2}	12.8×10^{-3}
4	3.30×10^{-2}	1.30×10^{-2}	9.60×10^{-3}
5	1.10×10^{-2}	3.90×10^{-2}	28.8×10^{-3}

Table 16.2 shows experiments that change one reactant concentration while keeping the other constant. If we compare experiments 1 and 2, we see the effect of doubling $[O_2]$ on the rate. First, we take the ratio of their rate laws:

$$\frac{\text{Rate 2}}{\text{Rate 1}} = \frac{k[O_2]_2^m [NO]_2^n}{k[O_2]_1^m [NO]_1^n}$$

where $[O_2]_2$ is the O_2 concentration for experiment 2, $[NO]_1$ is the NO concentration for experiment 1, and so forth. Because k is a constant and [NO] does not change between these two experiments, these quantities cancel:

$$\frac{\text{Rate 2}}{\text{Rate 1}} = \frac{[O_2]_2^m}{[O_2]_1^m} = \left(\frac{[O_2]_2}{[O_2]_1}\right)^m$$

Substituting the values from Table 16.2, we obtain

$$\frac{6.40\times10^{-3}\ \text{mol/L·s}}{3.21\times10^{-3}\ \text{mol/L·s}} = \left(\frac{2.20\times10^{-2}\ \text{mol/L}}{1.10\times10^{-2}\ \text{mol/L}}\right)^m$$

Dividing, we obtain

$$1.99 = (2.00)^m$$

Rounding to one significant figure gives

$$2 = 2^m; \quad \text{therefore,} \quad m = 1$$

The reaction is first order in O_2: when $[O_2]$ doubles, the rate doubles.

To find the order with respect to NO, we compare experiments 3 and 1, in which $[O_2]$ is held constant and [NO] is doubled:

$$\frac{\text{Rate 3}}{\text{Rate 1}} = \frac{k[O_2]_3^m [NO]_3^n}{k[O_2]_1^m [NO]_1^n}$$

As before, k is constant, and in this pair of experiments $[O_2]$ does not change, so these quantities cancel:

$$\frac{\text{Rate 3}}{\text{Rate 1}} = \left(\frac{[NO]_3}{[NO]_1}\right)^n$$

The actual values give

$$\frac{12.8\times10^{-3}\ \text{mol/L·s}}{3.21\times10^{-3}\ \text{mol/L·s}} = \left(\frac{2.60\times10^{-2}\ \text{mol/L}}{1.30\times10^{-2}\ \text{mol/L}}\right)^n$$

Dividing, we obtain

$$3.99 = (2.00)^n$$

Rounding gives

$$4 = 2^n; \quad \text{therefore,} \quad n = 2$$

The reaction is second order in NO: when [NO] doubles, the rate quadruples. Thus, the rate law is

$$\text{Rate} = k[O_2][NO]^2$$

You may want to use experiment 1 in combination with experiments 4 and 5 to check this result.

SAMPLE PROBLEM 16.3 Determining Reaction Orders from Initial Rate Data

Problem Many gaseous reactions occur in car engines and exhaust systems. One of these is

$$NO_2(g) + CO(g) \longrightarrow NO(g) + CO_2(g) \qquad \text{rate} = k[NO_2]^m[CO]^n$$

Use the following data to determine the individual and overall reaction orders:

Experiment	Initial Rate (mol/L·s)	Initial $[NO_2]$ (mol/L)	Initial [CO] (mol/L)
1	0.0050	0.10	0.10
2	0.080	0.40	0.10
3	0.0050	0.10	0.20

Plan We need to solve the general rate law for the reaction orders m and n. To solve for each exponent, we proceed as in the text, taking the ratio of the rate laws for two experiments in which only the reactant in question changes.

Solution Calculating m in $[NO_2]^m$: We take the ratio of the rate laws for experiments 1 and 2, in which $[NO_2]$ varies but [CO] is constant:

$$\frac{\text{Rate 2}}{\text{Rate 1}} = \frac{k[NO_2]_2^m[CO]_2^n}{k[NO_2]_1^m[CO]_1^n} = \left(\frac{[NO_2]_2}{[NO_2]_1}\right)^m \quad \text{or} \quad \frac{0.080 \text{ mol/L·s}}{0.0050 \text{ mol/L·s}} = \left(\frac{0.40 \text{ mol/L}}{0.10 \text{ mol/L}}\right)^m$$

This gives $16 = 4.0^m$, so $m = 2.0$. The reaction is second order in NO_2.

Calculating n in $[CO]^n$: We take the ratio of the rate laws for experiments 1 and 3, in which [CO] varies but $[NO_2]$ is constant:

$$\frac{\text{Rate 3}}{\text{Rate 1}} = \frac{k[NO_2]_3^2[CO]_3^n}{k[NO_2]_1^2[CO]_1^n} = \left(\frac{[CO]_3}{[CO]_1}\right)^n \quad \text{or} \quad \frac{0.0050 \text{ mol/L·s}}{0.0050 \text{ mol/L·s}} = \left(\frac{0.20 \text{ mol/L}}{0.10 \text{ mol/L}}\right)^n$$

We have $1.0 = (2.0)^n$, so $n = 0$. The rate does not change when [CO] varies, so the reaction is zero order in CO.

Therefore, the rate law is

$$\text{Rate} = k[NO_2]^2[CO]^0 = k[NO_2]^2(1) = k[NO_2]^2$$

The reaction is second order overall.

Check A good check is to reason through the orders. If $m = 1$, quadrupling $[NO_2]$ would quadruple the rate; but the rate *more* than quadruples, so $m > 1$. If $m = 2$, quadrupling $[NO_2]$ would increase the rate by a factor of 16 (4^2). The ratio of rates is $0.080/0.005 = 16$, so $m = 2$. In contrast, increasing [CO] has no effect on the rate, which can happen only if $[CO]^n = 1$, so $n = 0$.

FOLLOW-UP PROBLEM 16.3 Find the rate law and the overall reaction order for the reaction $H_2 + I_2 \longrightarrow 2HI$ from the following data at 450°C:

Experiment	Initial Rate (mol/L·s)	Initial $[H_2]$ (mol/L)	Initial $[I_2]$ (mol/L)
1	1.9×10^{-23}	0.0113	0.0011
2	1.1×10^{-22}	0.0220	0.0033
3	9.3×10^{-23}	0.0550	0.0011
4	1.9×10^{-22}	0.0220	0.0056

Determining the Rate Constant

With the rate, reactant concentrations, and reaction orders known, the sole remaining unknown in the rate law is the rate constant, k. The rate constant is specific for a particular reaction *at a particular temperature*. The experiments with the reaction of O_2 and NO were run at the same temperature, so we can use data from any to solve for k. From experiment 1 in Table 16.2, for instance, we obtain

$$k = \frac{\text{rate 1}}{[O_2]_1[NO]_1^2} = \frac{3.21\times10^{-3} \text{ mol/L·s}}{(1.10\times10^{-2} \text{ mol/L})(1.30\times10^{-2} \text{ mol/L})^2}$$

$$= \frac{3.21\times10^{-3} \text{ mol/L·s}}{1.86\times10^{-6} \text{ mol}^3/\text{L}^3} = 1.73\times10^3 \text{ L}^2/\text{mol}^2\text{·s}$$

Table 16.3 Units of the Rate Constant *k* for Several Overall Reaction Orders

Overall Reaction Order	Units of *k* (*t* in seconds)
0	mol/L·s (or mol L^{-1} s^{-1})
1	1/s (or s^{-1})
2	L/mol·s (or L mol^{-1} s^{-1})
3	L^2/mol^2·s (or L^2 mol^{-2} s^{-1})

General formula:

$$\text{Units of } k = \frac{\left(\frac{\text{L}}{\text{mol}}\right)^{\text{order}-1}}{\text{unit of } t}$$

Always check that the values of k for a series are constant within experimental error. To three significant figures, the average value of k for the five experiments in Table 16.2 is 1.72×10^3 L^2/mol^2·s.

Note the units for the rate constant. With concentrations in mol/L and the reaction rate in units of mol/L·time, the units for k depend on the order of the reaction and, of course, the time unit. The units for k in our example, L^2/mol^2·s, are required to give a rate with units of mol/L·s:

$$\frac{\text{mol}}{\text{L·s}} = \frac{\text{L}^2}{\text{mol}^2\text{·s}} \times \frac{\text{mol}}{\text{L}} \times \left(\frac{\text{mol}}{\text{L}}\right)^2$$

The rate constant will *always* have these units for an overall third-order reaction with the time unit in seconds. Table 16.3 shows the units of k for some common overall reaction orders, but you can always determine the units mathematically.

SECTION SUMMARY

An experimentally determined rate law shows how the rate of a reaction depends on concentration. If we consider only initial rates, the rate law often takes this form: rate $= k[A]^m[B]^n \cdots$. With an accurate method for obtaining initial rates, reaction orders are determined experimentally by comparing rates for different initial concentrations, that is, by performing several experiments and varying the concentration of one reactant at a time to see its effect on the rate. With rate, concentrations, and reaction orders known, the rate constant is the only remaining unknown in the rate law, so it can be calculated.

16.4 INTEGRATED RATE LAWS: CONCENTRATION CHANGES OVER TIME

Notice that the rate laws we've developed so far do not include time as a variable. They tell us the rate or concentration at a given instant, allowing us to answer a critical question, "How fast is the reaction proceeding at the moment when y moles per liter of A are reacting with z moles per liter of B?" However, by employing different forms of the rate laws, called **integrated rate laws,** we can consider the time factor and answer other questions, such as "How long will it take for x moles per liter of A to be used up?" and "What is the concentration of A after y minutes of reaction?"

Integrated Rate Laws for First-, Second-, and Zero-Order Reactions

Consider a simple first-order reaction, A ⟶ B. (Because first- and second-order reactions are more common, we'll discuss them before zero-order reactions.) As we discussed previously, the rate can be expressed as the change in the concentration of A divided by the change in time:

$$\text{Rate} = -\frac{\Delta[\text{A}]}{\Delta t}$$

It can also be expressed in terms of the rate law:

$$\text{Rate} = k[\text{A}]$$

Setting these different expressions equal to each other gives

$$-\frac{\Delta[\text{A}]}{\Delta t} = k[\text{A}]$$

Through the methods of calculus, this expression is integrated over time to obtain the integrated rate law for a first-order reaction:

$$\ln\frac{[\text{A}]_0}{[\text{A}]_t} = kt \quad \text{(first-order reaction; rate} = k[\text{A}]) \tag{16.4}$$

where ln is the natural logarithm, $[A]_0$ is the concentration of A at $t = 0$, and $[A]_t$ is the concentration of A at any time t during an experiment. In mathematical terms, $\ln \frac{a}{b} = \ln a - \ln b$, so we have

$$\ln [A]_0 - \ln [A]_t = kt$$

For a general second-order reaction, the expression including time is quite complex, so let's consider the case in which the rate law contains only one reactant. Setting the rate expressions equal to each other gives

$$\text{Rate} = -\frac{\Delta[A]}{\Delta t} = k[A]^2$$

Integrating over time gives the integrated rate law for a second-order reaction involving one reactant:

$$\frac{1}{[A]_t} - \frac{1}{[A]_0} = kt \quad \text{(second-order reaction; rate} = k[A]^2\text{)} \tag{16.5}$$

For a zero-order reaction, we have

$$\text{Rate} = -\frac{\Delta[A]}{\Delta t} = k[A]^0$$

Integrating over time gives the integrated rate law for a zero-order reaction:

$$[A]_t - [A]_0 = -kt \quad \text{(zero-order reaction; rate} = k[A]^0 = k\text{)} \tag{16.6}$$

Sample Problem 16.4 shows one way integrated rate laws are applied.

SAMPLE PROBLEM 16.4 Determining the Reactant Concentration at a Given Time

Problem At 1000°C, cyclobutane (C_4H_8) decomposes in a first-order reaction, with the very high rate constant of 87 s^{-1}, to two molecules of ethylene (C_2H_4).
(a) If the initial C_4H_8 concentration is 2.00 *M*, what is the concentration after 0.010 s?
(b) What fraction of C_4H_8 has decomposed in this time?

Plan **(a)** We must find the concentration of cyclobutane at time t, $[C_4H_8]_t$. The problem tells us this is a first-order reaction, so we use the integrated first-order rate law:

$$\ln \frac{[C_4H_8]_0}{[C_4H_8]_t} = kt$$

We know k (87 s^{-1}), t (0.010 s), and $[C_4H_8]_0$ (2.00 *M*), so we can solve for $[C_4H_8]_t$.
(b) The fraction decomposed is the concentration that has decomposed divided by the initial concentration:

$$\text{Fraction decomposed} = \frac{[C_4H_8]_0 - [C_4H_8]_t}{[C_4H_8]_0}$$

Solution **(a)** Substituting the data into the integrated rate law:

$$\ln \frac{2.00 \text{ mol/L}}{[C_4H_8]_t} = (87 \text{ s}^{-1})(0.010 \text{ s}) = 0.87$$

Taking the antilog of both sides:

$$\frac{2.00 \text{ mol/L}}{[C_4H_8]_t} = e^{0.87} = 2.4$$

Solving for $[C_4H_8]_t$:

$$[C_4H_8]_t = \frac{2.00 \text{ mol/L}}{2.4} = 0.83 \text{ mol/L}$$

(b) Finding the fraction that has decomposed after 0.010 s:

$$\frac{[C_4H_8]_0 - [C_4H_8]_t}{[C_4H_8]_0} = \frac{2.00 \text{ mol/L} - 0.83 \text{ mol/L}}{2.00 \text{ mol/L}} = 0.58$$

Check The concentration remaining after 0.010 s (0.83 mol/L) is less than the starting concentration (2.00 mol/L), which makes sense. Raising e to an exponent slightly less than 1 should give a number (2.4) slightly less than the value of e (2.718). Moreover, the final result makes sense: a high rate constant indicates a fast reaction, so it's not surprising that so much decomposes in such a short time.

Comment Integrated rate laws are also used to solve for the time it takes to reach a certain reactant concentration, as in the follow-up problem.

FOLLOW-UP PROBLEM 16.4 At 25°C, hydrogen iodide breaks down very slowly to hydrogen and iodine: rate $= k[\text{HI}]^2$. The rate constant at 25°C is 2.4×10^{-21} L/mol·s. If 0.0100 mol of HI(g) is placed in a 1.0-L container, how long will it take for the concentration of HI to reach 0.00900 mol/L (10.0% reacted)?

Determining the Reaction Order from the Integrated Rate Law

Suppose you don't know the rate law for a reaction and don't have the initial rate data needed to determine the reaction orders (which we did have in Sample Problem 16.3). Another method for finding reaction orders is a graphical technique that uses concentration and time data directly.

An integrated rate law can be rearranged into the form of an equation for a straight line, $y = mx + b$, where m is the slope and b is the y-axis intercept. For a first-order reaction, we have

$$\ln [\text{A}]_0 - \ln [\text{A}]_t = kt$$

Rearranging and changing signs gives

$$\ln [\text{A}]_t = -kt + \ln [\text{A}]_0$$
$$y = mx + b$$

Therefore, a plot of $\ln [\text{A}]_t$ vs. time gives a straight line with slope $= -k$ and y intercept $= \ln [\text{A}]_0$ (Figure 16.7A).

For a simple second-order reaction, we have

$$\frac{1}{[\text{A}]_t} - \frac{1}{[\text{A}]_0} = kt$$

Rearranging gives

$$\frac{1}{[\text{A}]_t} = kt + \frac{1}{[\text{A}]_0}$$
$$y = mx + b$$

In this case, a plot of $1/[\text{A}]_t$ vs. time gives a straight line with slope $= k$ and y intercept $= 1/[\text{A}]_0$ (Figure 16.7B).

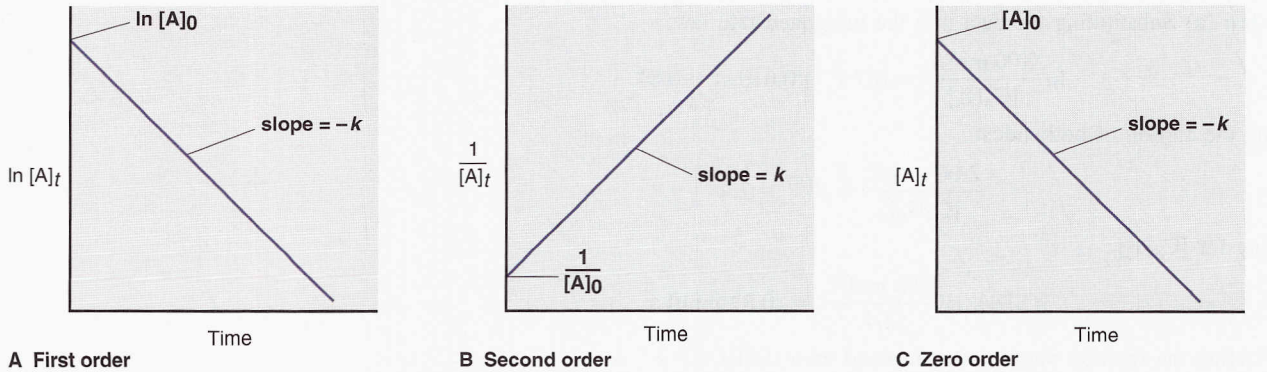

Figure 16.7 Integrated rate laws and reaction orders. A, Plot of $\ln [\text{A}]_t$ vs. time gives a straight line for a reaction that is first order in A. **B,** Plot of $1/[\text{A}]_t$ vs. time gives a straight line for a reaction that is second order in A. **C,** Plot of $[\text{A}]_t$ vs. time gives a straight line for a reaction that is zero order in A.

For a zero-order reaction, we have

$$[A]_t - [A]_0 = -kt$$

Rearranging gives

$$[A]_t = -kt + [A]_0$$
$$y = mx + b$$

Thus, a plot of $[A]_t$ vs. time gives a straight line with slope $= -k$ and y intercept $= [A]_0$ (Figure 16.7C).

Therefore, some trial-and-error graphical plotting is required to find the reaction order from the concentration and time data:

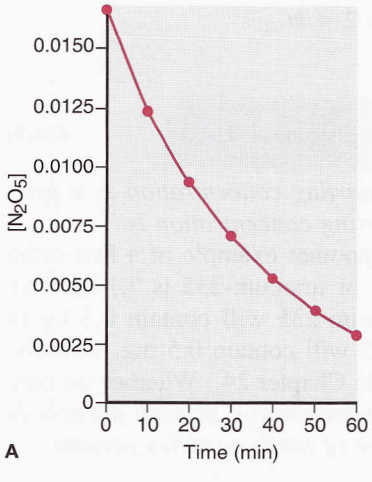
- If you obtain a straight line when you plot ln [reactant] vs. time, the reaction is *first order* with respect to that reactant.
- If you obtain a straight line when you plot 1/[reactant] vs. time, the reaction is *second order* with respect to that reactant.
- If you obtain a straight line when you plot [reactant] vs. time, the reaction is *zero order* with respect to that reactant.

Figure 16.8 shows how this approach is used to determine the order for the decomposition of N_2O_5. Since the plot of ln $[N_2O_5]$ *is* linear and the plot of $1/[N_2O_5]$ *is not,* the decomposition of N_2O_5 must be first order in N_2O_5.

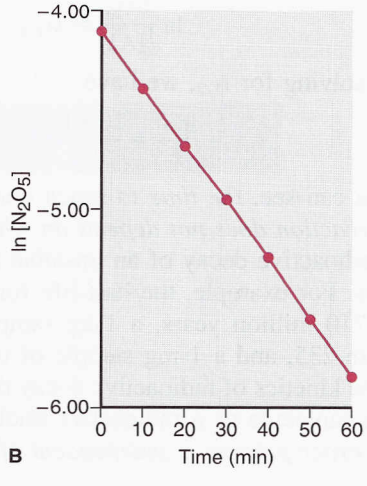
Reaction Half-Life

The **half-life** ($t_{1/2}$) of a reaction is the time required for the reactant concentration to reach half its initial value. A half-life is expressed in time units appropriate for a given reaction and is characteristic of that reaction at a given temperature.

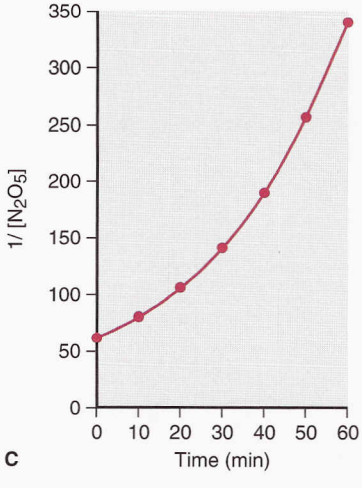
At fixed conditions, *the half-life of a first-order reaction is a constant, independent of reactant concentration.* For example, the half-life for the first-order decomposition of N_2O_5 at 45°C is 24.0 min. The meaning of this value is that if



A



B



C

Time (min)	$[N_2O_5]$	ln $[N_2O_5]$	$1/[N_2O_5]$
0	0.0165	−4.104	60.6
10	0.0124	−4.390	80.6
20	0.0093	−4.68	1.1×10^2
30	0.0071	−4.95	1.4×10^2
40	0.0053	−5.24	1.9×10^2
50	0.0039	−5.55	2.6×10^2
60	0.0029	−5.84	3.4×10^2

Figure 16.8 Graphical determination of the reaction order for the decomposition of N_2O_5. A table of time and concentration data for determining reaction order appears below the graphs. **A,** A plot of $[N_2O_5]$ vs. time is curved, indicating that the reaction is *not* zero order in N_2O_5. **B,** A plot of ln $[N_2O_5]$ vs. time gives a straight line, indicating that the reaction *is* first order in N_2O_5. **C,** A plot of $1/[N_2O_5]$ vs. time is curved, indicating that the reaction is *not* second order in N_2O_5. Plots A and C support the conclusion from plot B.

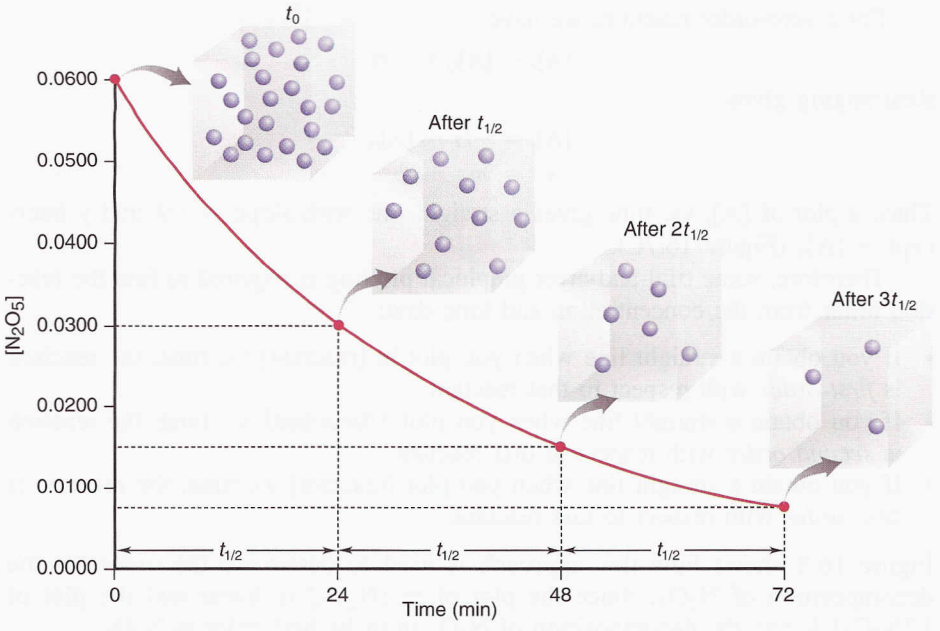


Figure 16.9 A plot of $[N_2O_5]$ vs. time for three half-lives. During each half-life, the concentration is halved (T = 45°C and $[N_2O_5]_0$ = 0.0600 mol/L). The blow-up volumes, with N_2O_5 molecules as colored spheres, show that after three half-lives, $\frac{1}{2} \times \frac{1}{2} \times \frac{1}{2} = \frac{1}{8}$ of the original concentration remains.

we start with, say, 0.0600 mol/L of N_2O_5 at 45°C, after 24 min (one half-life), 0.0300 mol/L has been consumed and 0.0300 mol/L remains; after 48 min (two half-lives), 0.0150 mol/L remains; after 72 min (three half-lives), 0.0075 mol/L remains, and so forth (Figure 16.9).

We can see from the integrated rate law why the half-life of a first-order reaction is independent of concentration:

$$\ln \frac{[A]_0}{[A]_t} = kt$$

After one half-life, $t = t_{1/2}$, and $[A]_t = \frac{1}{2}[A]_0$. Substituting, we obtain

$$\ln \frac{[A]_0}{\frac{1}{2}[A]_0} = kt_{1/2} \qquad \text{or} \qquad \ln 2 = kt_{1/2}$$

Then, solving for $t_{1/2}$, we have

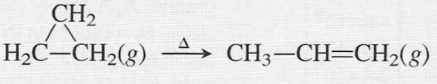
$$t_{1/2} = \frac{\ln 2}{k} = \frac{0.693}{k} \quad \text{(first-order process; rate} = k[A]) \tag{16.7}$$

As you can see, *the time to reach one-half the starting concentration in a first-order reaction does not depend on what that starting concentration is.*

Radioactive decay of an unstable nucleus is another example of a first-order process. For example, the half-life for the decay of uranium-235 is 7.1×10^8 yr. After 710 million years, a 1-kg sample of uranium-235 will contain 0.5 kg of uranium-235, and a 1-mg sample of uranium-235 will contain 0.5 mg. (We discuss the kinetics of radioactive decay thoroughly in Chapter 24.) Whether we consider a molecule or a radioactive nucleus, the *decomposition of each particle in a first-order process is independent of the number of other particles present.*

SAMPLE PROBLEM 16.5 Determining the Half-Life of a First-Order Reaction

Problem Cyclopropane is the smallest cyclic hydrocarbon. Because its 60° bond angles reduce orbital overlap, its bonds are weak. As a result, it is thermally unstable and rearranges to propene at 1000°C via the following first-order reaction:



The rate constant is 9.2 s^{-1}. **(a)** What is the half-life of the reaction? **(b)** How long does it take for the concentration of cyclopropane to reach one-quarter of the initial value?

Plan **(a)** The cyclopropane rearrangement is first order, so to find $t_{1/2}$ we use Equation 16.7 and substitute for k (9.2 s^{-1}). **(b)** Each half-life decreases the concentration to one-half of its initial value, so two half-lives decrease it to one-quarter.

Solution **(a)** Solving for $t_{1/2}$:

$$t_{1/2} = \frac{\ln 2}{k} = \frac{0.693}{9.2\ s^{-1}} = 0.075\ s$$

It takes 0.075 s for half the cyclopropane to form propene at this temperature.

(b) Finding the time to reach one-quarter of the initial concentration:

$$\text{Time} = 2(t_{1/2}) = 2(0.075\ s) = 0.15\ s$$

Check For (a), rounding gives 0.7/9 s^{-1} = 0.08 s, so the answer seems correct.

FOLLOW-UP PROBLEM 16.5 Iodine-123 is used to study thyroid gland function. This radioactive isotope breaks down in a first-order process with a half-life of 13.1 h. What is the rate constant for the process?

In contrast to the half-life of a first-order reaction, the half-life of a second-order reaction *does* depend on reactant concentration:

$$t_{1/2} = \frac{1}{k[A]_0} \quad \text{(second-order process; rate} = k[A]^2\text{)}$$

Note that here *the half-life is **inversely** proportional to the initial reactant concentration*. This relationship means that a second-order reaction with a high initial reactant concentration has a shorter half-life, and one with a low initial reactant concentration has a longer half-life. Therefore, *as a second-order reaction proceeds, the half-life increases.*

In contrast to the half-life of a second-order reaction, *the half-life of a zero-order reaction is **directly** proportional to the initial reactant concentration:*

$$t_{1/2} = \frac{[A]_0}{2k} \quad \text{(zero-order process; rate} = k\text{)}$$

Thus, if a zero-order reaction begins with a high reactant concentration, it has a longer half-life than if it begins with a low reactant concentration. Table 16.4 summarizes the essential features of zero-, first-, and second-order reactions.

Table 16.4 An Overview of Zero-Order, First-Order, and Simple Second-Order Reactions

	Zero Order	First Order	Second Order
Rate law	rate = k	rate = $k[A]$	rate = $k[A]^2$
Units for k	mol/L·s	1/s	L/mol·s
Integrated rate law in straight-line form	$[A]_t = -kt + [A]_0$	$\ln [A]_t = -kt + \ln [A]_0$	$1/[A]_t = kt + 1/[A]_0$
Plot for straight line	$[A]_t$ vs. time	$\ln [A]_t$ vs. time	$1/[A]_t$ vs. time
Slope, y intercept	$-k$, $[A]_0$	$-k$, $\ln [A]_0$	k, $1/[A]_0$
Half-life	$[A]_0/2k$	$(\ln 2)/k$	$1/k[A]_0$

SECTION SUMMARY

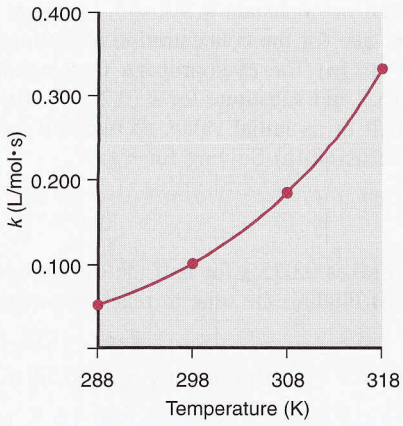
Integrated rate laws are used to find either the time needed to reach a certain concentration of reactant or the concentration present after a given time. Rearrangements of the integrated rate laws allow us to determine reaction orders and rate constants graphically. The half-life is the time needed for the reaction to consume half the reactant; for first-order reactions, it is independent of concentration.

Figure 16.10 **Dependence of the rate constant on temperature. A,** In the hydrolysis of an ester, when reactant concentrations are held constant and temperature increases, the rate and rate constant increase. Note the near doubling of k with each rise of 10 K (10°C). **B,** A plot of rate constant vs. temperature for this reaction shows an exponentially increasing curve.

A

Exp't	[Ester]	[H_2O]	T (K)	Rate (mol/L·s)	k (L/mol·s)
1	0.100	0.200	288	1.04×10^{-3}	0.0521
2	0.100	0.200	298	2.02×10^{-3}	0.101
3	0.100	0.200	308	3.68×10^{-3}	0.184
4	0.100	0.200	318	6.64×10^{-3}	0.332

B



16.5 THE EFFECT OF TEMPERATURE ON REACTION RATE

Temperature often has a major effect on reaction rate. As Figure 16.10A shows for a common organic reaction (hydrolysis, or reaction with water, of an ester), when reactant concentrations are held constant, the rate nearly doubles with each rise in temperature of 10 K (or 10°C). In fact, for many reactions near room temperature, an increase of 10°C causes a doubling or tripling of the rate.

Aside from mammals and birds, most animals—all reptiles and many species of amphibians, insects, and fish—absorb heat from the external environment to maintain metabolic and physical activity. For example, lizards and crocodiles bask in the sun or lie in the shade to regulate their internal reaction rates.

How does the rate law express this effect of temperature? If we collect concentration and time data for the same reaction run at *different* temperatures (T), and then solve each rate expression for k, we find that k increases as T increases. In other words, *temperature affects the rate by affecting the rate constant.* A plot of k vs. T gives a curve that increases exponentially (Figure 16.10B).

These results are consistent with studies made in 1889 by the Swedish chemist Svante Arrhenius, who discovered a key relationship between T and k. In its modern form, the **Arrhenius equation** is

$$k = Ae^{-E_a/RT} \qquad (16.8)$$

where k is the rate constant, e is the base of natural logarithms, T is the absolute temperature, and R is the universal gas constant. We'll discuss the meaning of A, which is related to the orientation of the colliding molecules, in the next section. The E_a term is the **activation energy** of the reaction, which Arrhenius considered the *minimum energy* the molecules must have to react; we'll explore its meaning in the next section as well. This negative exponential relationship between T and k means that *as T increases, the negative exponent becomes smaller, so the value of k becomes larger, which means that the rate increases:*

$$\text{Higher } T \Longrightarrow \text{larger } k \Longrightarrow \text{increased rate}$$

We can calculate E_a from the Arrhenius equation by taking the natural logarithm of both sides and recasting the equation into an equation for a straight line:

$$\ln k = \ln A - \frac{E_a}{R}\left(\frac{1}{T}\right)$$

$$y = b + mx$$

A plot of ln k vs. $1/T$ gives a straight line whose slope is $-E_a/R$ and whose y intercept is ln A (Figure 16.11). Therefore, with the constant R known, we can determine E_a graphically from a series of k values at different temperatures.

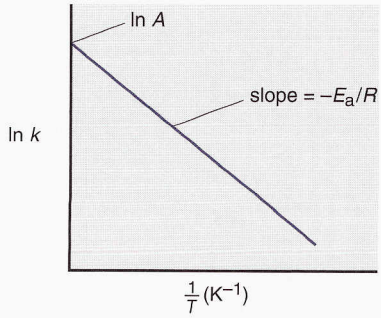


Figure 16.11 **Graphical determination of the activation energy.** A plot of ln k vs. $1/T$ gives a straight line with slope = $-E_a/R$.

Because the relationship between ln k and $1/T$ is linear, we can use a simpler method to find E_a if we know the rate constants at two temperatures, T_2 and T_1:

$$\ln k_2 = \ln A - \frac{E_a}{R}\left(\frac{1}{T_2}\right) \qquad \ln k_1 = \ln A - \frac{E_a}{R}\left(\frac{1}{T_1}\right)$$

When we subtract ln k_1 from ln k_2, the term ln A drops out and the other terms can be rearranged to give

$$\ln \frac{k_2}{k_1} = -\frac{E_a}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right) \tag{16.9}$$

From this, we can solve for E_a.

The Significance of *R* The importance of R extends beyond the study of gases (or osmotic pressure). By expressing pressure and volume in more fundamental quantities, we obtain dimensions for energy, E:

$$P = \frac{\text{force}}{\text{area}} = \frac{\text{force}}{(\text{length})^2} \qquad V = (\text{length})^3$$

Thus,

$$PV = \frac{\text{force}}{(\text{length})^2} \times (\text{length})^3$$
$$= \text{force} \times \text{length}$$

Energy is used when a force moves an object over a distance. Thus, E = force × distance (or length), so

$$PV = \text{force} \times \text{length} = E$$

Solving for R in the ideal gas law and substituting for PV, we obtain

$$R = \frac{PV}{nT} = \frac{E}{\text{amount} \times T}$$

Thus, R is the proportionality constant that relates the energy, amount (mol), and temperature of any chemical system.

SAMPLE PROBLEM 16.6 Determining the Energy of Activation

Problem The decomposition of hydrogen iodide,

$$2HI(g) \longrightarrow H_2(g) + I_2(g)$$

has rate constants of 9.51×10^{-9} L/mol·s at 500. K and 1.10×10^{-5} L/mol·s at 600. K. Find E_a.

Plan We are given the rate constants, k_1 and k_2, at two temperatures, T_1 and T_2, so we substitute into Equation 16.9 and solve for E_a.

Solution Rearranging Equation 16.9 to solve for E_a:

$$\ln \frac{k_2}{k_1} = -\frac{E_a}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

$$E_a = -R\left(\ln \frac{k_2}{k_1}\right)\left(\frac{1}{T_2} - \frac{1}{T_1}\right)^{-1}$$

$$= -(8.314 \text{ J/mol·K})\left(\ln \frac{1.10\times10^{-5} \text{ L/mol·s}}{9.51\times10^{-9} \text{ L/mol·s}}\right)\left(\frac{1}{600. \text{ K}} - \frac{1}{500. \text{ K}}\right)^{-1}$$

$$= 1.76\times10^5 \text{ J/mol} = 1.76\times10^2 \text{ kJ/mol}$$

Comment Be sure to retain the same number of significant figures in $1/T$ as you have in T, or a significant error could be introduced. Round to the correct number of significant figures only at the final answer. On most pocket calculators, the expression $(1/T_2 - 1/T_1)$ is entered as follows: $(T_2)(1/x) - (T_1)(1/x) =$.

FOLLOW-UP PROBLEM 16.6 The reaction $2NOCl(g) \longrightarrow 2NO(g) + Cl_2(g)$ has an E_a of 1.00×10^2 kJ/mol and a rate constant of 0.286 L/mol·s at 500. K. What is the rate constant at 490. K?

In this section and the previous two, we discussed a series of experimental and mathematical methods for the study of reaction kinetics. Figure 16.12 is a useful summary of this information. Note that the integrated rate law provides an alternative method for obtaining reaction orders and the rate constant.

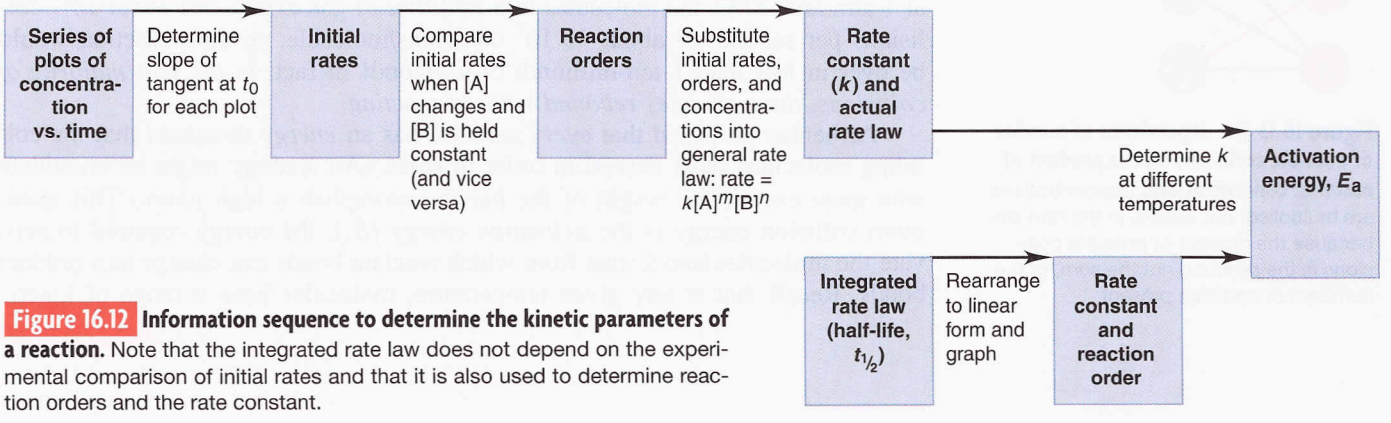

Figure 16.12 Information sequence to determine the kinetic parameters of a reaction. Note that the integrated rate law does not depend on the experimental comparison of initial rates and that it is also used to determine reaction orders and the rate constant.

SECTION SUMMARY

As the Arrhenius equation shows, rate increases with temperature because a temperature rise increases the rate constant. The activation energy, E_a, the minimum energy needed for a reaction to occur, can be determined graphically from k values at different T values.

16.6 EXPLAINING THE EFFECTS OF CONCENTRATION AND TEMPERATURE

The Arrhenius equation was developed empirically from the observations of many reactions. It took more than 30 years for models to appear that could explain the effects of concentration and temperature on reaction rate. The two major models we consider here highlight different aspects of the reaction process but are completely compatible. *Collision theory* views the reaction rate as the result of particles colliding with a certain frequency and minimum energy. *Transition state theory* offers a close-up view of how the energy of a collision converts reactant to product.

Collision Theory: Basis of the Rate Law

The basic tenet of **collision theory** is that reactant particles—atoms, molecules, and ions—must collide with each other to react. Therefore, the number of collisions per unit time provides an upper limit on how fast a reaction can take place. The model restricts itself to simple one-step reactions in which two particles collide and form products: A + B ⟶ products. With its emphasis on collisions between three-dimensional particles, this model elegantly explains why reactant concentrations are multiplied together in the rate law, how temperature affects the rate, and what influence molecular structure has on rate.

Why Concentrations Are Multiplied in the Rate Law If particles must collide to react, the laws of probability tell us why the rate depends on the *product* of the reactant concentrations, not their sum. Imagine that you have only two particles of A and two of B confined in a reaction vessel. Figure 16.13 shows that four A-B collisions are possible. If you add another particle of A, there can be six A-B collisions (3 × 2), not five (3 + 2); add another particle of B, and there can be nine A-B collisions (3 × 3), not six (3 + 3). Thus, collision theory is consistent with the observation that concentrations are *multiplied* in the rate law.

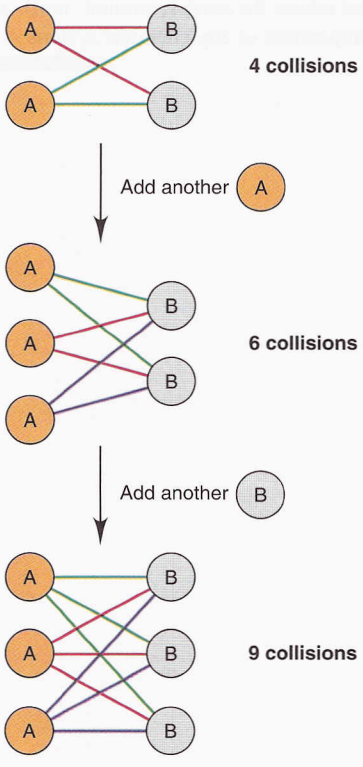

Figure 16.13 The dependence of number of possible collisions on the product of reactant concentrations. Concentrations are multiplied, not added, in the rate law because the number of possible collisions is the *product,* not the sum, of the numbers of particles present.

How Temperature Affects Rate: The Importance of Activation Energy Increasing the temperature of a reaction increases the average speed of particles and therefore their collision frequency. But collision frequency cannot be the only factor affecting rate, or every gaseous reaction would be almost instantaneous: after all, at 1 atm and 20°C, the molecules in a milliliter of gas experience about 10^{27} collisions per second, or about 4×10^{7} collisions/molecule, so their reaction would be over in less than 1 ten-millionth of a second! In fact, *in the vast majority of collisions, the molecules rebound without reacting.*

Arrhenius proposed that every reaction has an *energy threshold* that the colliding molecules must exceed in order to react. (An analogy might be an athlete who must exceed the height of the bar to accomplish a high jump.) This minimum collision energy is the *activation energy* (E_a), the energy required to activate the molecules into a state from which reactant bonds can change into product bonds. Recall that at any given temperature, molecules have a range of kinetic

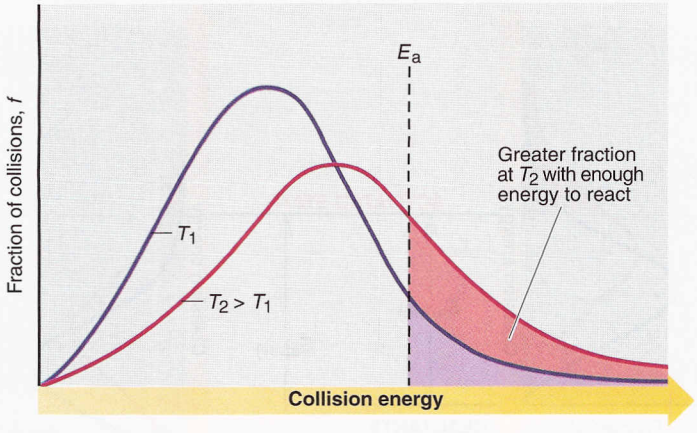

Figure 16.14 The effect of temperature on the distribution of collision energies. At the higher temperature, T_2, a larger fraction of collisions occur with enough energy to exceed E_a.

Table 16.5 The Effect of E_a and T on the Fraction (f) of Collisions with Sufficient Energy to Allow Reaction

E_a (kJ/mol)	f (at T = 298 K)
50	1.70×10^{-9}
75	7.03×10^{-14}
100	2.90×10^{-18}
T	**f (at E_a = 50 kJ/mol)**
25°C (298 K)	1.70×10^{-9}
35°C (308 K)	3.29×10^{-9}
45°C (318 K)	6.12×10^{-9}

energies; thus, their collisions have a range of energies as well. According to collision theory, *only those collisions with enough energy to exceed E_a can lead to reaction.*

We noted earlier that many reactions near room temperature approximately double or triple their rates with a 10°C rise in temperature. Is the rate increase due to a higher number of collisions? Actually, this has only a minor effect. Calculations show that a 10°C rise increases the average molecular speed by only 2%. If an increase in speed is the only effect of temperature and if the speed of each colliding molecule increases by 2%, we should observe only a 4% increase in rate. Far more important is that *the temperature rise enlarges the fraction of collisions with enough energy to exceed the activation energy.* This key point is shown in Figure 16.14.

At a given temperature, the fraction f of molecular collisions with energy greater than or equal to the activation energy E_a is given by

$$f = e^{-E_a/RT}$$

where e is the base of natural logarithms, T is the absolute temperature, and R is the universal gas constant. [Notice that the right side of this equation is the central component in the Arrhenius equation (Equation 16.8).] *The magnitudes of both E_a and T affect the fraction of sufficiently energetic collisions.* In the top portion of Table 16.5, you can see the effect on this fraction of increasing E_a at a fixed temperature. Note how much the fraction shrinks with a 25-kJ/mol increase in activation energy. (As the height of the bar is raised, fewer athletes can accomplish the jump.) In the bottom portion of the table, you can see the effect on the fraction of increasing T at a fixed E_a of 50 kJ/mol, a typical value for many reactions. Note that the fraction nearly doubles for a 10°C increase. Doubling the fraction doubles the rate constant, which doubles the reaction rate.

A reversible reaction has two activation energies (Figure 16.15). The activation energy for the forward reaction, $E_{a(fwd)}$, is the energy difference between the activated state and the reactants; the activation energy for the reverse reaction, $E_{a(rev)}$, is the energy difference between the activated state and the products. The figure shows an energy-level diagram for an exothermic reaction, so the products are at a lower energy than the reactants, and $E_{a(fwd)}$ is less than $E_{a(rev)}$.

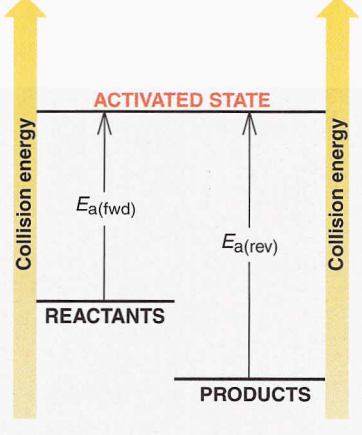

Figure 16.15 Energy-level diagram for a reaction. For molecules to react, they must collide with enough energy to reach an activated state. This minimum collision energy is the energy of activation, E_a. A reaction can occur in either direction, so the diagram shows two activation energies. Here, the forward reaction is exothermic because $E_{a(fwd)} < E_{a(rev)}$.

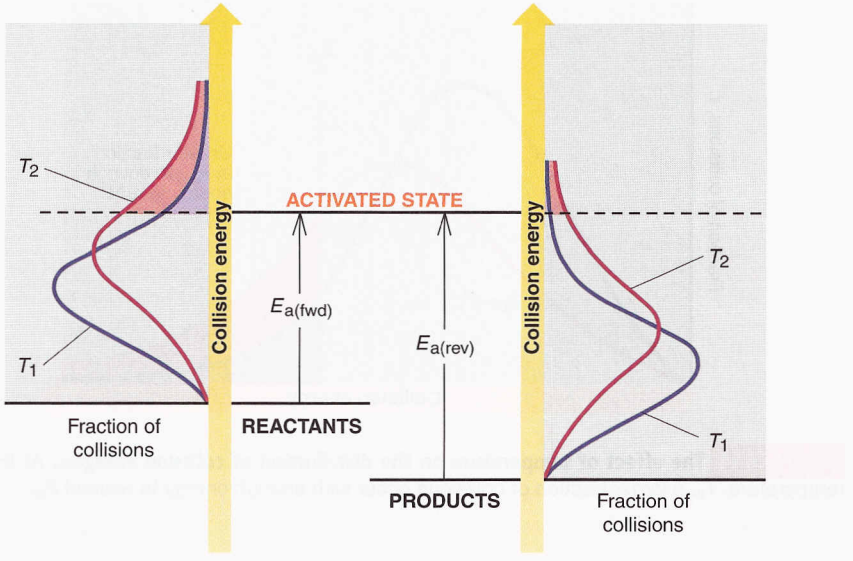

Figure 16.16 An energy-level diagram of the fraction of collisions whose energy exceeds E_a. When Figure 16.14 is aligned vertically on the left and right axes of Figure 16.15, we see that

- In either direction, the fraction of collisions with energy exceeding E_a is larger at the higher T.
- In an *exothermic* reaction at any temperature, the fraction of collisions with energy exceeding $E_{a(fwd)}$ is larger than the fraction exceeding $E_{a(rev)}$.

By turning the collision-energy distribution curve of Figure 16.14 vertically and aligning it on both sides of Figure 16.15, we obtain Figure 16.16, which shows how temperature affects the fraction of collisions that have energy exceeding the activation energy for both the forward and reverse reactions. Several ideas are illustrated in this composite figure:

- In both reaction directions, a larger fraction of collisions exceeds the activation energy at the higher temperature, T_2: higher T increases reaction rate.
- For an *exothermic* process (forward reaction here) at any temperature, the fraction of reactant collisions with energy exceeding $E_{a(fwd)}$ is *larger* than the fraction of product collisions with energy exceeding $E_{a(rev)}$; thus, the forward reaction is faster. On the other hand, in an *endothermic* process (reverse reaction here), $E_{a(fwd)}$ is greater than $E_{a(rev)}$, so the fraction of product collisions with energy exceeding $E_{a(rev)}$ is larger, and the reverse reaction is faster.

These conclusions are consistent with the Arrhenius equation; that is, *the larger the E_a, the smaller the value of k, and the slower the reaction:*

$$\text{Larger } E_a \Longrightarrow \text{smaller } k \Longrightarrow \text{decreased rate}$$

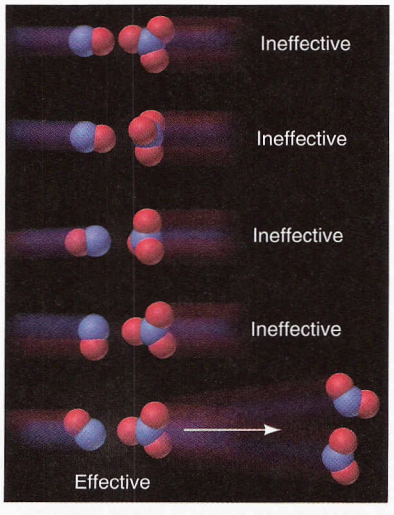

Figure 16.17 The importance of molecular orientation to an effective collision. Only one of the five orientations shown for the collision between NO and NO_3 has the correct orientation to lead to product. In the effective orientation, contact occurs between the atoms that will become bonded in the product.

How Molecular Structure Affects Rate You've seen that the enormous number of collisions per second is greatly reduced when we count only those with enough energy to react. However, even this tiny fraction of the total collisions does not reveal the true number of **effective collisions,** those that actually lead to product. In addition to colliding with enough energy, *the molecules must collide so that the reacting atoms make contact.* In other words, a collision must have enough energy *and* a particular *molecular orientation* to be an effective collision.

In the Arrhenius equation, the effect of molecular orientation is contained in the term A:

$$k = Ae^{-E_a/RT}$$

This term is called the **frequency factor,** the product of the collision frequency Z and an *orientation probability factor, p,* which is specific for each reaction: $A = pZ$. The factor p is related to the structural complexity of the colliding particles. You can think of it as the ratio of effectively oriented collisions to all possible collisions. For example, Figure 16.17 shows a few of the possible collision orientations for the following simple gaseous reaction:

$$NO(g) + NO_3(g) \longrightarrow 2NO_2(g)$$

Of the five collisions shown, only one has an orientation in which the N of NO makes contact with an O of NO_3. Actually, the orientation probability factor (p value) for this reaction is 0.006: only 6 collisions in every 1000 (1 in 167) have an orientation that can lead to reaction.

Collisions between individual atoms have p values near 1: almost no matter how they hit, as long as the collision has enough energy, the particles react. In such cases, the rate constant depends only on the frequency and energy of the collisions. At the other extreme are biochemical reactions, in which the reactants are often two small molecules that can react only when they collide with a specific tiny region of a giant molecule—a protein or nucleic acid. The orientation probability factor for these reactions is often less than 10^{-6}: fewer than one in a million sufficiently energetic collisions leads to product. The fact that countless such biochemical reactions are occurring right now, as you read this sentence, helps make the point that the number of collisions per second is truly astounding.

Transition State Theory: Molecular Nature of the Activated Complex

Collision theory is a simple, easy to visualize model, but it provides no insight about why the activation energy is crucial and how the activated molecules look. To understand these aspects of the process, we turn to **transition state theory,** which focuses on the high-energy species that forms through an effective collision.

Visualizing the Transition State Recall from our discussion of energy changes (Chapter 6) that the internal energy of a system is the sum of its kinetic and potential energies. Two molecules that are far apart but speeding toward each other have high kinetic energy and low potential energy. As the molecules get closer, some kinetic energy is converted to potential energy as the electron clouds repel each other. At the moment of a head-on collision, the molecules stop, and their kinetic energy is converted to the potential energy of the collision. *If this potential energy is less than the activation energy, the molecules recoil,* bouncing off each other like billiard balls. Repulsions decrease, speeds increase, and the molecules zoom apart without reacting.

The tiny fraction of molecules that are oriented effectively *and* moving at the highest speed behave differently. *Their kinetic energy pushes them together with enough force to overcome repulsions and react.* Nuclei in one atom attract electrons in another; atomic orbitals overlap and electron density shifts; some bonds lengthen and weaken while others start to form. If we could watch this process in slow motion, we would see the reactant molecules gradually change their bonds and shapes as they turn into product molecules. At some point during this smooth transformation, what exists is *neither reactant nor product but a transitional species with partial bonds.* This species is extremely unstable (has very high potential energy) and exists only at the instant when the reacting system is highest in energy. It is called the **transition state,** or **activated complex,** and it forms only if the molecules collide in an effective orientation *and* with energy equal to or greater than the activation energy. Thus, *the activation energy is the quantity needed to stretch and deform bonds in order to reach the transition state.*

Because transition states *cannot* be isolated, our knowledge of them, until recently, came from reasoning and studies of analogous, more stable species. This situation is changing rapidly due to the pioneering work of Ahmed H. Zewail, who received the 1999 Nobel Prize in chemistry. He used lasers pulsing on the same femtosecond (10^{-15}) time scale as bond vibrations to observe the detailed changes occurring when transition states form and decompose.

Consider the reaction between methyl bromide and hydroxide ion:

$$CH_3Br + OH^- \longrightarrow CH_3OH + Br^-$$

The electronegative bromine makes the carbon of methyl bromide partially positive. If the reactants are moving toward each other fast enough and are oriented

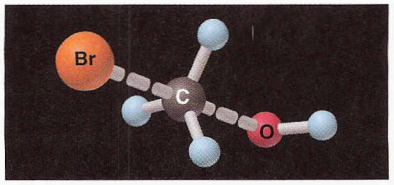

Figure 16.18 Nature of the transition state in the reaction between CH_3Br and OH^-. Note the partial (elongated) C—O and C—Br bonds and the trigonal bipyramidal shape of the transition state of this reaction.

effectively when they collide, the negatively charged oxygen in OH^- approaches the carbon with enough energy to begin forming a C—O bond, which causes the C—Br bond to weaken. In the transition state (Figure 16.18), C is surrounded by five atoms (trigonal bipyramidal), which never occurs in its stable compounds. This high-energy species has three normal C—H bonds and two partial bonds, one from C to O and the other from C to Br. Reaching this transition state is no guarantee that the reaction will proceed to products. A transition state can change in either direction: if the C—O bond continues to shorten and strengthen, products form; however, if the C—Br bond becomes shorter and stronger again, the transition state reverts to reactants.

Depicting the Change with Reaction Energy Diagrams A useful way to depict the events we just described is with a **reaction energy diagram,** which shows the potential energy of the system during the reaction as a smooth curve. Figure 16.19 shows the reaction energy diagram for the reaction of CH_3Br and OH^-, with an electron density relief map, structural formula, and molecular-scale view at various points during the change.

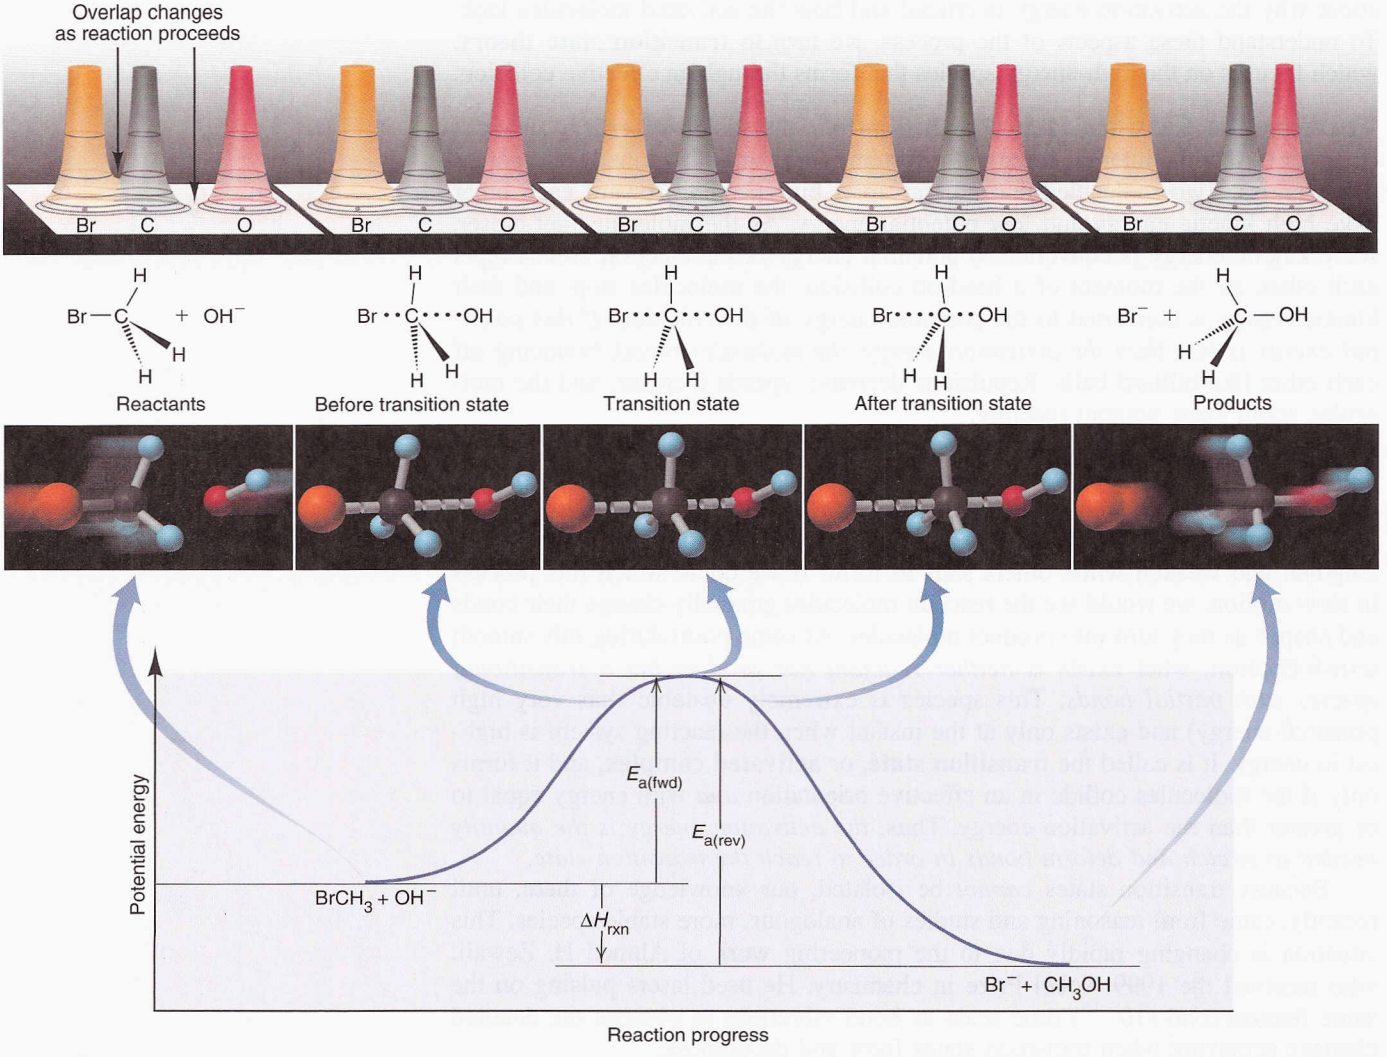

Figure 16.19 Reaction energy diagram for the reaction between CH_3Br and OH^-. A plot of potential energy vs. reaction progress shows the relative energy levels of reactants, products, and transition state joined by a curved line, as well as the activation energies of the forward and reverse reactions and the heat of reaction. The electron density relief maps, structural formulas, and molecular-scale views depict the change at five points. Note the gradual bond forming and bond breaking as the system goes through the transition state.

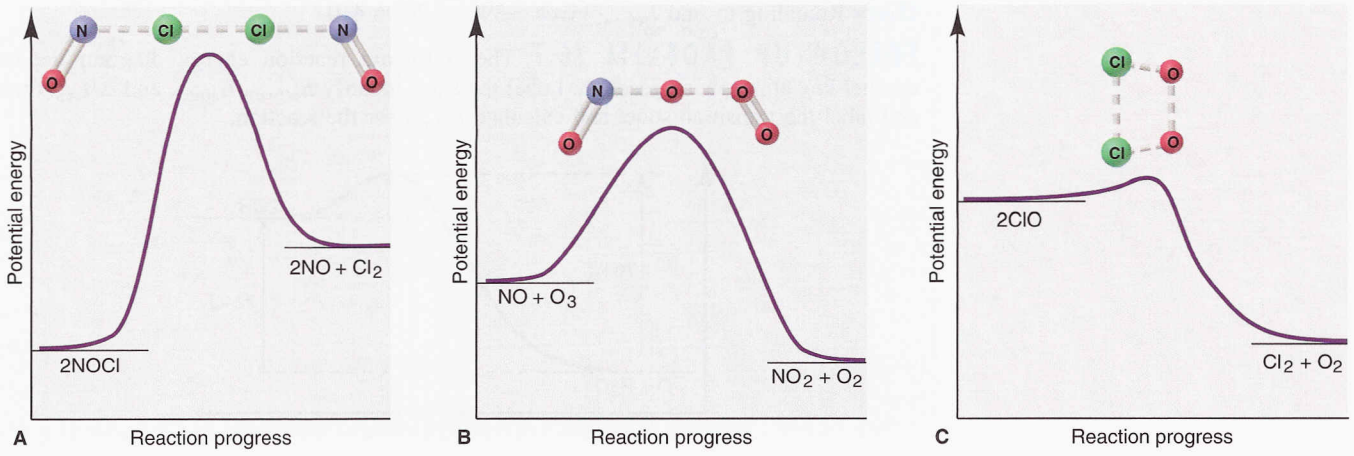

Figure 16.20 Reaction energy diagrams and possible transition states for three reactions.
A, $2NOCl(g) \longrightarrow 2NO(g) + Cl_2(g)$ (Despite the formula NOCl, the atom sequence is ClNO.)
B, $NO(g) + O_3(g) \longrightarrow NO_2(g) + O_2(g)$
C, $2ClO(g) \longrightarrow Cl_2(g) + O_2(g)$
Note that reaction A is endothermic, B and C are exothermic, and C has a very small $E_{a(fwd)}$.

The horizontal axis, labeled "Reaction progress," means reactants change to products from left to right. This reaction is exothermic, so reactants are higher in energy than products. This difference reflects the change in bond energies, which appears as the heat of reaction, ΔH_{rxn}. The diagram also shows activation energies for the forward and reverse reactions; in this case, $E_{a(fwd)}$ is less than $E_{a(rev)}$.

Transition state theory proposes that *every reaction (and every step in an overall reaction) goes through its own transition state,* from which it can continue in either direction. We imagine how a transition state might look by examining the reactant and product bonds that change. Figure 16.20 depicts reaction energy diagrams for three simple reactions. Note that the shape of the postulated transition state in each case is based on a collision orientation between atoms that become bonded to form the product.

SAMPLE PROBLEM 16.7 Drawing Reaction Energy Diagrams and Transition States

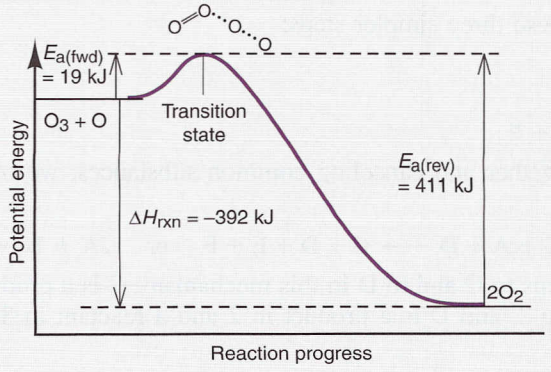
Problem A key reaction in the upper atmosphere is

$$O_3(g) + O(g) \longrightarrow 2O_2(g)$$

The $E_{a(fwd)}$ is 19 kJ, and the ΔH_{rxn} for the reaction as written is −392 kJ. Draw a reaction energy diagram for this reaction, postulate a transition state, and calculate $E_{a(rev)}$.

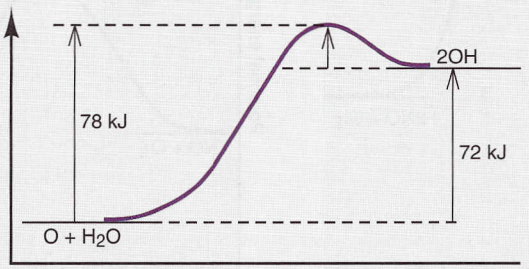
Plan The reaction is highly exothermic ($\Delta H_{rxn} = -392$ kJ), so the products are much lower in energy than the reactants. The small $E_{a(fwd)}$ (19 kJ) means the energy of the reactants lies slightly below that of the transition state. To reach the transition state from the products requires energy equal to ΔH_{rxn} plus $E_{a(fwd)}$; thus, $E_{a(rev)} = \Delta H_{rxn} + E_{a(fwd)}$. To postulate the transition state, we sketch the species and note that one of the bonds in O_3 weakens, and this partially bonded O begins forming a bond to the separate O atom.

Solution The reaction energy diagram (not drawn to scale), with transition state, is



Check Rounding to find $E_{a(rev)}$ gives ~390 + 20 = 410.

FOLLOW-UP PROBLEM 16.7 The following reaction energy diagram depicts another key atmospheric reaction. Label the axes, identify $E_{a(fwd)}$, $E_{a(rev)}$, and ΔH_{rxn}, draw and label the transition state, and calculate $E_{a(rev)}$ for the reaction.



SECTION SUMMARY

According to collision theory, reactant particles must collide to react, and the number of collisions depends on the product of the reactant concentrations. At higher temperatures, more collisions have enough energy to exceed the activation energy (E_a). The relative E_a values for the forward and the reverse reactions depend on whether the overall reaction is exothermic or endothermic. Molecules must collide with an effective orientation for reaction to occur, so structural complexity decreases rate.

Transition state theory pictures the kinetic energy of the particles changing to potential energy during a collision. Given a sufficiently energetic collision and an effective molecular orientation, the reactant species become an unstable transition state, which either forms product(s) or reverts to reactant(s). Reaction energy diagrams depict the changing energy of the chemical system as it progresses from reactants through transition state(s) to products.

16.7 REACTION MECHANISMS: STEPS IN THE OVERALL REACTION

Imagine trying to figure out how a car works just by examining the body, wheels, and dashboard. It can't be done—you need to look under the hood and inside the engine to see how the parts fit together and function. Similarly, because our main purpose is to know how a reaction works *at the molecular level,* examining the overall balanced equation is not much help—we must "look under the yield arrow and inside the reaction" to see how reactants change into products.

When we do so, we find that most reactions occur through a **reaction mechanism,** a sequence of single reaction steps that sum to the overall reaction. For example, a possible mechanism for the overall reaction

$$2A + B \longrightarrow E + F$$

might involve these three simpler steps:

(1) $A + B \longrightarrow C$
(2) $C + A \longrightarrow D$
(3) $D \longrightarrow E + F$

Adding them together and canceling common substances, we obtain the overall equation:

$$A + B + \cancel{C} + A + \cancel{D} \longrightarrow \cancel{C} + \cancel{D} + E + F \quad \text{or} \quad 2A + B \longrightarrow E + F$$

Note what happens to C and to D in this mechanism. C is a product in step 1 and a reactant in step 2, and D is a product in 2 and a reactant in 3. Each functions

as a **reaction intermediate,** a substance that is formed and used up during the overall reaction. Reaction intermediates do not appear in the overall balanced equation but are absolutely essential for the reaction to occur. They are usually unstable relative to the reactants and products but are far more stable than transition states (activated complexes). Reaction intermediates are molecules with normal bonds and are sometimes stable enough to be isolated.

Chemists *propose* a reaction mechanism to explain how a particular reaction might occur, and then they *test* the mechanism. This section focuses on the nature of the individual steps and how they fit together to give a rate law consistent with experimental results.

Elementary Reactions and Molecularity

The individual steps, which together make up the proposed reaction mechanism, are called **elementary reactions** (or **elementary steps**). Each describes a *single molecular event,* such as one particle decomposing or two particles colliding and combining. *An elementary step is **not** made up of simpler steps.*

An elementary step is characterized by its **molecularity,** the number of *reactant* particles involved in the step. Consider the mechanism for the breakdown of ozone in the stratosphere. The overall reaction is

$$2O_3(g) \longrightarrow 3O_2(g)$$

A two-step mechanism has been proposed for this reaction. Notice that the two steps sum to the overall reaction. The first elementary step is a **unimolecular reaction,** one that involves the decomposition or rearrangement of a single particle:

(1) $O_3(g) \longrightarrow O_2(g) + O(g)$

The second step is a **bimolecular reaction,** one in which two particles react:

(2) $O_3(g) + O(g) \longrightarrow 2O_2(g)$

Some *termolecular* elementary steps occur, but they are extremely rare because the probability of three particles colliding simultaneously with enough energy and with an effective orientation is very small. Higher molecularities are not known. Unless evidence exists to the contrary, it makes good chemical sense to propose only unimolecular or bimolecular reactions as the elementary steps in a reaction mechanism.

The rate law for an elementary reaction, unlike that for an overall reaction, *can* be deduced from the reaction stoichiometry. An elementary reaction occurs in one step, so its rate must be proportional to the product of the reactant concentrations. Therefore, *we use the equation coefficients as the reaction orders in the rate law for an elementary step; that is, reaction order equals molecularity* (Table 16.6). Remember that this statement holds *only* when we know that the reaction is elementary; you've already seen that for an overall reaction, the reaction orders must be determined experimentally.

Table 16.6 Rate Laws for General Elementary Steps

Elementary Step	Molecularity	Rate Law
$A \longrightarrow$ product	Unimolecular	Rate $= k[A]$
$2A \longrightarrow$ product	Bimolecular	Rate $= k[A]^2$
$A + B \longrightarrow$ product	Bimolecular	Rate $= k[A][B]$
$2A + B \longrightarrow$ product	Termolecular	Rate $= k[A]^2[B]$

SAMPLE PROBLEM 16.8 Determining Molecularity and Rate Laws for Elementary Steps

Problem The following two reactions are proposed as elementary steps in the mechanism for an overall reaction:

(1) $NO_2Cl(g) \longrightarrow NO_2(g) + Cl(g)$

(2) $NO_2Cl(g) + Cl(g) \longrightarrow NO_2(g) + Cl_2(g)$

(a) Write the overall balanced equation.

(b) Determine the molecularity of each step.

(c) Write the rate law for each step.

Plan We find the overall equation from the sum of the elementary steps. The molecularity of each step equals the total number of reactant particles. We write the rate law for each step using the molecularities as reaction orders.

Solution **(a)** Writing the overall balanced equation:

$$\begin{array}{r} NO_2Cl(g) \longrightarrow NO_2(g) + Cl(g) \\ NO_2Cl(g) + Cl(g) \longrightarrow NO_2(g) + Cl_2(g) \\ \hline NO_2Cl(g) + NO_2Cl(g) + \cancel{Cl(g)} \longrightarrow NO_2(g) + \cancel{Cl(g)} + NO_2(g) + Cl_2(g) \\ 2NO_2Cl(g) \longrightarrow 2NO_2(g) + Cl_2(g) \end{array}$$

(b) Determining the molecularity of each step: The first elementary step has only one reactant, NO_2Cl, so it is unimolecular. The second elementary step has two reactants, NO_2Cl and Cl, so it is bimolecular.

(c) Writing rate laws for the elementary reactions:

(1) $\text{Rate}_1 = k_1[NO_2Cl]$

(2) $\text{Rate}_2 = k_2[NO_2Cl][Cl]$

Check In part (a), be sure the equation is balanced; in part (c), be sure the substances in brackets are the reactants of each elementary step.

FOLLOW-UP PROBLEM 16.8 The following elementary steps constitute a proposed mechanism for a reaction:

(1) $2NO(g) \longrightarrow N_2O_2(g)$

(2) $2H_2(g) \longrightarrow 4H(g)$

(3) $N_2O_2(g) + H(g) \longrightarrow N_2O(g) + HO(g)$

(4) $2HO(g) + 2H(g) \longrightarrow 2H_2O(g)$

(5) $H(g) + N_2O(g) \longrightarrow HO(g) + N_2(g)$

(a) Write the balanced equation for the overall reaction.

(b) Determine the molecularity of each step.

(c) Write the rate law for each step.

Sleeping Through the Rate-Determining Step Baking bread provides a macroscopic example of a rate-limiting step. The five steps for making a loaf of tasty French bread are (1) mixing the ingredients (15 min), (2) kneading the dough (10 min), (3) letting the dough rise in a refrigerator (400 min), (4) shaping the loaf (2 min), and (5) baking the loaf (25 min). Obviously, the dough-rising step limits how fast a baker can produce a loaf because it is so much slower than the other steps. Keenly aware of the baking "reaction mechanism," bakers let the dough rise overnight, which allows them to sleep through the rate-determining step.

The Rate-Determining Step of a Reaction Mechanism

All the elementary steps in a mechanism do not have the same rate. Usually, one of the elementary steps is much slower than the others, so it limits how fast the overall reaction proceeds. This step is called the **rate-determining step** (or **rate-limiting step**).

Because the rate-determining step limits the rate of the overall reaction, its rate law represents the rate law for the overall reaction. Consider the reaction between nitrogen dioxide and carbon monoxide:

$$NO_2(g) + CO(g) \longrightarrow NO(g) + CO_2(g)$$

If the overall reaction were an elementary reaction—that is, if the mechanism consisted of only one step—we could immediately write the overall rate law as

$$\text{Rate} = k[NO_2][CO]$$

However, as you saw in Sample Problem 16.3, experiment shows that the actual rate law is

$$\text{Rate} = k[NO_2]^2$$

From this, we know immediately that the reaction shown cannot be elementary.

A proposed two-step mechanism is

(1) $NO_2(g) + NO_2(g) \longrightarrow NO_3(g) + NO(g)$ [slow; rate determining]
(2) $NO_3(g) + CO(g) \longrightarrow NO_2(g) + CO_2(g)$ [fast]

Note that NO_3 functions as a reaction intermediate in the mechanism. Rate laws for these elementary steps are

(1) $\text{Rate}_1 = k_1[NO_2][NO_2] = k_1[NO_2]^2$
(2) $\text{Rate}_2 = k_2[NO_3][CO]$

Note that if $k_1 = k$, *the rate law for the rate-determining step (step 1) is identical to the experimental rate law.* The first step is so slow compared with the second that the overall reaction takes essentially as long as the first step. Here you can see that one reason that a reactant (in this case, CO) has a reaction order of zero is that it takes part in the reaction only *after* the rate-determining step.

Correlating the Mechanism with the Rate Law

Conjuring up a reasonable reaction mechanism is one of the most exciting aspects of chemical kinetics and can be a classic example of the use of the scientific method. We use observations and data from rate experiments to hypothesize what the individual steps might be and then test our hypothesis by gathering further evidence. If the evidence supports it, we continue to apply that mechanism; if not, we propose a new one. However, *we can never prove, just from data, that a particular mechanism represents the actual chemical change.*

Regardless of the elementary steps proposed for a mechanism, they must meet three criteria:

1. *The elementary steps must add up to the overall balanced equation.* We cannot wind up with more (or fewer) reactants or products than are present in the balanced equation.
2. *The elementary steps must be physically reasonable.* As we noted, most steps should involve one reactant particle (unimolecular) or two (bimolecular). Steps with three reactant particles (termolecular) are very unlikely.
3. *The mechanism must correlate with the rate law.* Most importantly, a mechanism must support the experimental facts shown by the rate law, not the other way around.

Let's see how the mechanisms of several reactions conform to these criteria and how the elementary steps fit together.

Mechanisms with a Slow Initial Step We've already seen one mechanism with a rate-determining first step—that for the reaction of NO_2 and CO. Another example is the reaction between nitrogen dioxide and fluorine gas:

$$2NO_2(g) + F_2(g) \longrightarrow 2NO_2F(g)$$

The experimental rate law is first order in NO_2 and in F_2:

$$\text{Rate} = k[NO_2][F_2]$$

The accepted mechanism for the reaction is

(1) $NO_2(g) + F_2(g) \longrightarrow NO_2F(g) + F(g)$ [slow; rate determining]
(2) $NO_2(g) + F(g) \longrightarrow NO_2F(g)$ [fast]

Molecules of reactant and product appear in both elementary steps. The free fluorine atom is a reaction intermediate.

Does this mechanism meet the three crucial criteria?

1. The elementary reactions sum to the balanced equation:

$$NO_2(g) + NO_2(g) + F_2(g) + \cancel{F(g)} \longrightarrow NO_2F(g) + NO_2F(g) + \cancel{F(g)}$$

or $$2NO_2(g) + F_2(g) \longrightarrow 2NO_2F(g)$$

2. Both steps are bimolecular, so they are chemically reasonable.

3. The mechanism gives the rate law for the overall equation. To show this, we write the rate laws for the elementary steps:

   (1) $\text{Rate}_1 = k_1[NO_2][F_2]$

   (2) $\text{Rate}_2 = k_2[NO_2][F]$

Step 1 is the rate-determining step and therefore gives the overall rate law, with $k_1 = k$. Because the second molecule of NO_2 appears in the step that follows the rate-determining step, it does not appear in the overall rate law. Thus, we see that *the overall rate law includes only species active in the reaction up to and including those in the rate-determining step.* This point was also illustrated by the mechanism for NO_2 and CO shown earlier. Carbon monoxide was absent from the overall rate law because it appeared *after* the rate-determining step.

Figure 16.21 is a reaction energy diagram for the reaction of NO_2 and F_2. Note that

- *Each step in the mechanism has its own transition state.* (Note that only one molecule of NO_2 reacts in step 1, and only the first transition state is depicted.)
- The F atom intermediate is a reactive, unstable species (as you know from halogen chemistry), so it is higher in energy than the reactants or product.
- The first step is slower (rate limiting), so its activation energy is *larger* than that of the second step.
- The overall reaction is exothermic, so the product is lower in energy than the reactants.

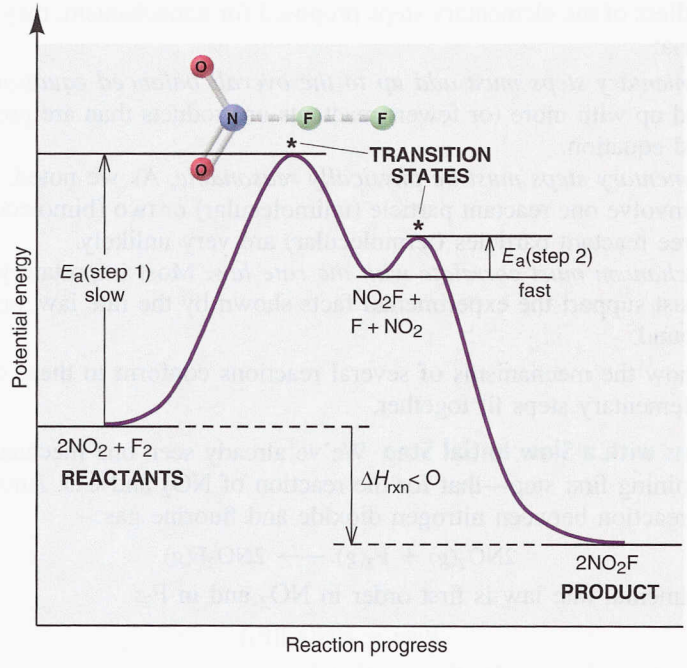


Figure 16.21 Reaction energy diagram for the two-step reaction of NO_2 and F_2. Each step in the mechanism has its own transition state. The proposed transition state is shown for step 1. Reactants for the second step are the F atom intermediate and the second molecule of NO_2. Note that the first step is slower (higher E_a). The overall reaction is exothermic ($\Delta H_{rxn} < 0$).

Mechanisms with a Fast Initial Step If the rate-limiting step in a mechanism is *not* the initial step, it acts as a bottleneck later in the reaction sequence. As a result, the product of a fast initial step builds up and starts reverting to reactant, while waiting for the slow step to remove it. With time, the product of the initial step is changing back to reactant as fast as it is forming. In other words, the *fast initial step reaches equilibrium.* As you'll see, this situation allows us to fit the mechanism to the overall rate law.

Consider once again the oxidation of nitric oxide:

$$2NO(g) + O_2(g) \longrightarrow 2NO_2(g)$$

The experimentally determined rate law is

$$\text{Rate} = k[\text{NO}]^2[\text{O}_2]$$

and a proposed mechanism is

(1) $\text{NO}(g) + \text{O}_2(g) \rightleftharpoons \text{NO}_3(g)$ [fast, reversible]

(2) $\text{NO}_3(g) + \text{NO}(g) \longrightarrow 2\text{NO}_2(g)$ [slow; rate determining]

Note that, with cancellation of the reaction intermediate NO_3, the first criterion is met because the sum of the steps gives the overall equation. Also note that the second criterion is met because both steps are bimolecular.

To meet the third criterion (that the mechanism conforms to the overall rate law), we first write rate laws for the elementary steps:

(1) $\text{Rate}_{1(\text{fwd})} = k_1[\text{NO}][\text{O}_2]$

$\text{Rate}_{1(\text{rev})} = k_{-1}[\text{NO}_3]$

where k_{-1} is the rate constant for the reverse reaction.

(2) $\text{Rate}_2 = k_2[\text{NO}_3][\text{NO}]$

Now we must show that the rate law for the rate-determining step (step 2) gives the overall rate law. As written, it does not, because it contains the intermediate NO_3, and *an overall rate law can include only reactants (and products).* Therefore, we must eliminate $[NO_3]$ from the step 2 rate law. To do so, we express $[NO_3]$ in terms of reactants. Step 1 reaches equilibrium when the forward and reverse rates are equal:

$$\text{Rate}_{1(\text{fwd})} = \text{Rate}_{1(\text{rev})} \quad \text{or} \quad k_1[\text{NO}][\text{O}_2] = k_{-1}[\text{NO}_3]$$

To express $[NO_3]$ in terms of reactants, we isolate it algebraically:

$$[\text{NO}_3] = \frac{k_1}{k_{-1}}[\text{NO}][\text{O}_2]$$

Then, substituting for $[NO_3]$ in the rate law for step 2, we obtain

$$\text{Rate}_2 = k_2[\text{NO}_3][\text{NO}] = k_2\left(\frac{k_1}{k_{-1}}[\text{NO}][\text{O}_2]\right)[\text{NO}] = \frac{k_2k_1}{k_{-1}}[\text{NO}]^2[\text{O}_2]$$

This rate law is identical to the overall rate law, with $k = \dfrac{k_2k_1}{k_{-1}}$.

Thus, to test the validity of a mechanism with a fast initial, reversible step:

1. Write rate laws for both directions of the fast step and for the slow step.
2. Show the slow step's rate law is equivalent to the overall rate law, by *expressing [intermediate] in terms of [reactant]:* set the forward rate law of the fast, reversible step equal to the reverse rate law, and solve for [intermediate].
3. Substitute the expression for [intermediate] into the rate law for the slow step to obtain the overall rate law.

Several end-of-chapter problems, including 16.72 and 16.73, provide additional examples of this approach.

SECTION SUMMARY

The mechanisms of most common reactions consist of two or more elementary steps, reactions that occur in one step and depict a single chemical change. The molecularity of an elementary step equals the number of reactant particles and is the same as the reaction order of its rate law. Unimolecular and bimolecular steps are common. The rate-determining, or rate-limiting (slowest), step determines how fast the overall reaction occurs, and its rate law represents the overall rate law. Reaction intermediates are species that form in one step and react in a later one. The steps in a proposed mechanism must add up to the overall reaction, be physically reasonable, and conform to the overall rate law. If a fast step precedes a slow step, the fast step reaches equilibrium, and the concentrations of intermediates in the rate law of the slow step must be expressed in terms of reactants.

16.8 CATALYSIS: SPEEDING UP A CHEMICAL REACTION

There are many situations in which the rate of a reaction must be increased for it to be useful. In an industrial process, for example, a higher rate often determines whether a new product can be made economically. Sometimes, we can speed up a reaction sufficiently with a higher temperature, but energy is costly and many substances are heat sensitive and easily decomposed. Alternatively, we can often employ a **catalyst,** a substance that increases the rate *without* being consumed in the reaction. Because catalysts are not consumed, only very small, nonstoichiometric quantities are generally required. Nevertheless, these substances are employed in so many important processes that several million tons of industrial catalysts are produced annually in the United States alone! Nature is the master designer and user of catalysts. Even the simplest bacterium employs thousands of biological catalysts, known as *enzymes,* to speed up its cellular reactions. Every organism relies on enzymes to sustain life.

Each catalyst has its own specific way of functioning, but in general, *a catalyst effects a lower activation energy, which in turn makes the rate constant larger and the rate higher.* Two important points stand out in Figure 16.22:

- A catalyst speeds up the forward *and* reverse reactions. A reaction with a catalyst *does not yield more product* than one without a catalyst, but it yields the product *more quickly.*
- A catalyst effects a *lower activation energy* by providing a *different mechanism* for the reaction, a new, lower energy pathway.

Consider a general *uncatalyzed* reaction that proceeds by a one-step mechanism involving a bimolecular collision:

$$A + B \longrightarrow \text{product} \qquad \text{[slower]}$$

In the *catalyzed* reaction, a reactant molecule interacts with the catalyst, so the mechanism might involve a two-step pathway:

$$A + \text{catalyst} \longrightarrow C \qquad \text{[faster]}$$
$$C + B \longrightarrow \text{product} + \text{catalyst} \qquad \text{[faster]}$$

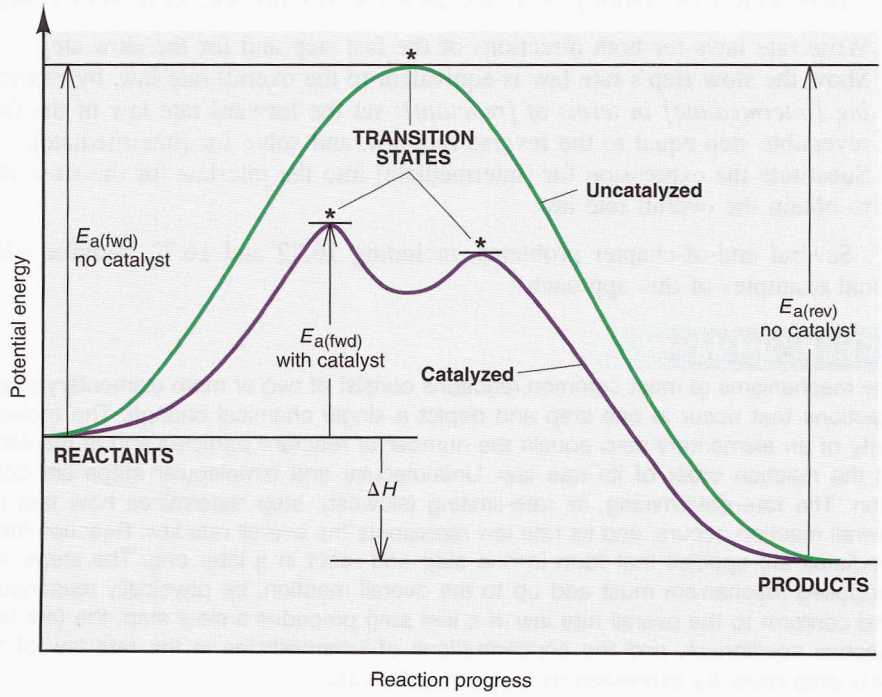

Figure 16.22 Reaction energy diagram for a catalyzed and an uncatalyzed process. A catalyst speeds a reaction by providing a new, lower energy pathway, in this case by replacing the one-step mechanism with a two-step mechanism. Both forward and reverse rates are increased to the same extent, so *a catalyst does not affect the overall reaction yield.* (The only activation energy shown for the catalyzed reaction is the larger one for the forward direction.)

Note that *the catalyst is not consumed,* as its definition requires. Rather, it is used and then regenerated, and the activation energies of both steps are lower than the activation energy of the uncatalyzed pathway.

There are two general categories of catalyst—homogeneous catalysts and heterogeneous catalysts—based on whether the catalyst is in the same phase as the reactant and product.

Homogeneous Catalysis

A **homogeneous catalyst** exists in solution with the reaction mixture. All homogeneous catalysts are gases, liquids, or soluble solids. Some industrial processes that employ these catalysts are shown in Table 16.7 *(top)*.

A thoroughly studied example of homogeneous catalysis is the hydrolysis of an organic ester (RCOOR′), a reaction we examined in Section 15.4:

$$R{-}\overset{\overset{O}{\|}}{C}{-}O{-}R' + H_2O \rightleftharpoons R{-}\overset{\overset{O}{\|}}{C}{-}OH + R'{-}OH$$

Here R and R′ are hydrocarbon groups, $R{-}\overset{\overset{O}{\|}}{C}{-}OH$ is a carboxylic acid, and R′—OH is an alcohol. The reaction rate is low at room temperature but can be increased greatly by adding a small amount of strong acid, which provides H^+ ion, the catalyst in the reaction; strong bases, which supply OH^- ions, also speed ester hydrolysis, but by a slightly different mechanism.

In the first step of the acid-catalyzed reaction (Figure 16.23), the H^+ of a hydronium ion forms a bond to the double-bonded O atom. From the resonance forms, we see that the bonding of H^+ then makes the C atom more positive, which *increases its attraction* for the partially negative O atom of water. In effect, H^+ increases the likelihood that the bonding of water, which is the rate-determining step, will take place. Several steps later, a water molecule, acting as a base, removes the H^+ and returns it to solution. Thus, H^+ acts as a catalyst because it speeds up the reaction but is not itself consumed: it is used up in one step and re-formed in another.

Table 16.7 Some Modern Processes That Employ Catalysts

Reactants	Catalyst	Product	Use
Homogeneous			
Propylene, oxidizer	Mo(VI) complexes	Propylene oxide	Polyurethane foams; polyesters
Methanol, CO	$[Rh(CO)_2I_2]^-$	Acetic acid	Poly(vinyl acetate) coatings; poly(vinyl alcohol)
Butadiene, HCN	Ni/P compounds	Adiponitrile	Nylons (fibers, plastics)
α-Olefins, CO, H_2	Rh/P compounds	Aldehydes	Plasticizers, lubricants
Heterogeneous			
Ethylene, O_2	Silver, cesium chloride on alumina	Ethylene oxide	Polyesters, ethylene glycol, lubricants
Propylene, NH_3, O_2	Bismuth molybdates	Acrylonitrile	Plastics, fibers, resins
Ethylene	Organochromium and titanium halides on silica	High-density polyethylene	Molded products

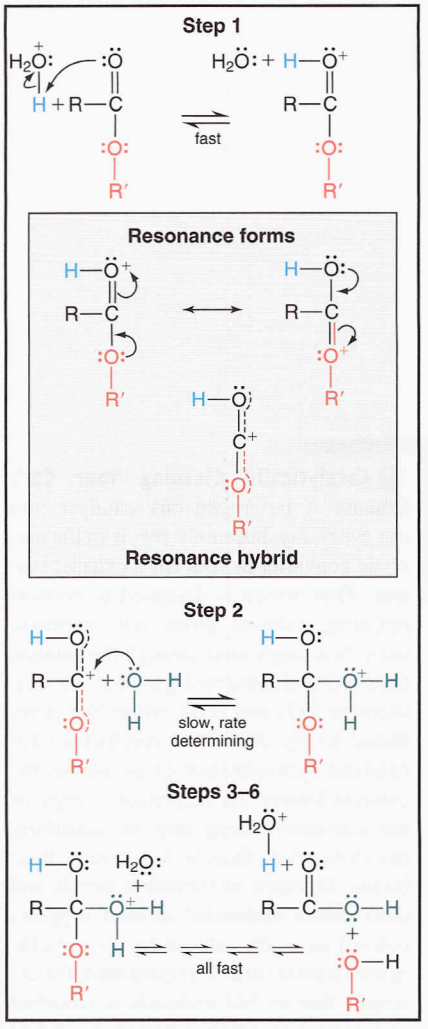

Figure 16.23 Mechanism for the catalyzed hydrolysis of an organic ester. In step 1, the catalytic H^+ ion binds to the electron-rich oxygen. The resonance hybrid of this product *(see gray panel)* shows the C atom is more positive than it would ordinarily be. The enhanced charge on C attracts the partially negative O of water more strongly, increasing the fraction of effective collisions and thus speeding up step 2, the rate-determining step. Loss of R′OH and removal of H^+ by water occur in a final series of fast steps.

Many digestive enzymes, which catalyze the hydrolysis of proteins, fats, and carbohydrates during the digestion of foods, employ very similar mechanisms. The difference is that the acids or bases that speed these reactions are not the strong inorganic reagents used in the lab, but rather specific amino-acid side chains of the enzymes that release or abstract H^+ ions.

Heterogeneous Catalysis

A **heterogeneous catalyst** speeds up a reaction that occurs in a separate phase. The catalyst is most often a solid interacting with gaseous or liquid reactants. Because reaction occurs on the solid's surface, heterogeneous catalysts usually have enormous surface areas for contact, between 1 and 500 m^2/g. Interestingly, many reactions that occur on a metal surface, such as the decomposition of HI on gold and the decomposition of N_2O on platinum, are zero order because the rate-determining step occurs on the surface itself. Thus, despite an enormous surface area, once the reactant gas covers the surface, increasing the reactant concentration cannot increase the rate. Table 16.7 *(bottom)* lists some polymer manufacturing processes that employ heterogeneous catalysts.

One of the most important examples of heterogeneous catalysis is the addition of H_2 to the C=C bonds of organic compounds to form C—C bonds. The petroleum, plastics, and food industries frequently use catalytic **hydrogenation.** The conversion of vegetable oil into margarine is one example.

The simplest hydrogenation converts ethylene to ethane:

$$H_2C{=}CH_2(g) + H_2(g) \longrightarrow H_3C{-}CH_3(g)$$

In the absence of a catalyst, the reaction occurs very slowly. At high H_2 pressure in the presence of finely divided Ni, Pd, or Pt, the reaction becomes rapid even at ordinary temperatures. These Group 8B(10) metals catalyze by *chemically adsorbing the reactants onto their surface* (Figure 16.24). The H_2 lands and splits into separate H atoms chemically bound to the solid catalyst's metal atoms (catM):

$$H{-}H(g) + 2\text{catM}(s) \longrightarrow 2\text{catM}{-}H \text{ (H atoms bound to metal surface)}$$

Then, C_2H_4 adsorbs and reacts with two H atoms, one at a time, to form C_2H_6. The H—H bond breakage is the rate-determining step in the overall process, and interaction with the catalyst's surface provides the low-E_a step as part of an alternative reaction mechanism.

Two Chemical Connections essays follow. The first introduces the remarkable abilities of the catalytic enzymes inside you, and the second discusses how catalysis operates in the depletion of stratospheric ozone.

Catalytically Cleaning Your Car's Exhaust A heterogeneous catalyst you use every day, but rarely see, is in the catalytic converter in your car's exhaust system. This device is designed to convert polluting exhaust gases into nontoxic ones. In a single pass through the catalyst bed, CO and unburned gasoline are oxidized to CO_2 and H_2O, while NO is reduced to N_2. As in the mechanism for catalytic hydrogenation of an alkene, the catalyst lowers the activation energy of the rate-determining step by adsorbing the molecules, thereby weakening their bonds. Mixtures of transition metals and their oxides embedded in inert supports convert as much exhaust gas as possible in the shortest time. It is estimated, for example, that an NO molecule is adsorbed and split into catalyst-bound N and O atoms in less than 2×10^{-12} s!

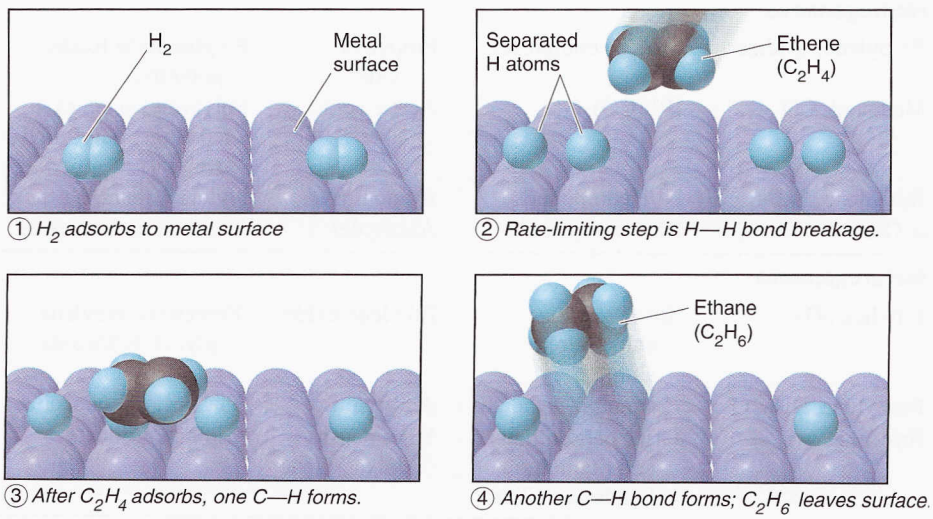

Figure 16.24 The metal-catalyzed hydrogenation of ethylene.

CHEMICAL CONNECTIONS to Enzymology

Kinetics and Function of Biological Catalysts

Within every living cell, thousands of individual reactions occur. Many involve complex chemical changes, yet they take place in dilute solution at ordinary temperatures and pressures. The rate of each reaction responds smoothly to momentary or permanent changes in other reaction rates, various signals from other cells, and environmental stresses. Virtually every reaction in this marvelous chemical harmony is catalyzed by its own specific **enzyme,** a protein catalyst whose function has been perfected through evolution.

Enzymes have complex three-dimensional shapes and molar masses ranging from about 15,000 to 1,000,000 g/mol (Section 15.6). At a specific region on an enzyme's surface is its **active site,** a crevice whose shape results from the shapes of the amino acid side chains (R groups) directly involved in catalyzing the reaction (also see Figure B10.4, p. 391). When the reactant molecules, called the **substrates** of the reaction, collide with the active site, the chemical change is initiated. The active site makes up only a small part of the enzyme's surface—like a tiny hollow carved into a mountainside—and often includes amino acid R groups from distant regions of the molecular chain that lie near each other because of the folding of the protein's backbone, as depicted in Figure B16.4. In most cases, *substrates bind to the active site through intermolecular forces:* H bonds, dipole forces, and other weak attractions.

(continued)

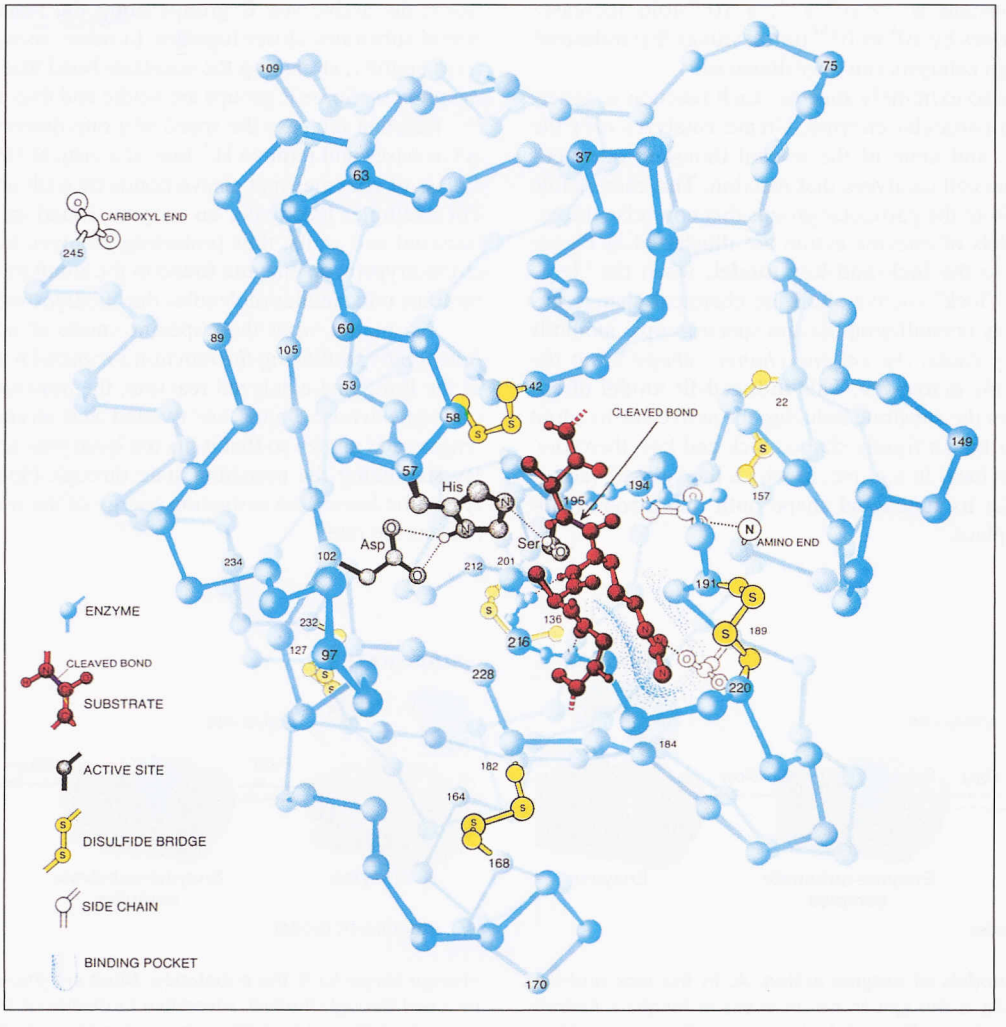

Figure B16.4 The widely separated amino acid groups that form an active site. The amino acids in chymotrypsin, a digestive enzyme, are shown as linked spheres and numbered consecutively from the beginning of the chain. The R groups of the active-site amino acids 57 (histidine, His), 102 (aspartic acid, Asp), and 195 (serine, Ser) are shown because they play a crucial role in the enzyme-catalyzed reaction. Part of the substrate molecule lies within the active site's crevice (binding pocket) to anchor it during reaction. (Illustration by Irving Geis. Rights owned by Howard Hughes Medical Institute. Not to be used without permission.)

An enzyme has features of both a homogeneous and a heterogeneous catalyst. Most enzymes are enormous compared with their substrates, and they are often found embedded within membranes of larger cell parts. Thus, like a heterogeneous catalyst, an enzyme provides an active surface on which a reactant is immobilized temporarily, waiting for its reaction partner to land nearby. Like a homogeneous catalyst, the enzyme's amino acid R groups interact actively with the substrates in multistep sequences involving intermediates.

Enzymes are incredibly *efficient* catalysts. Consider the hydrolysis of urea as an example:

$$(NH_2)_2C{=}O(aq) + 2H_2O(l) + H^+(aq) \longrightarrow 2NH_4^+(aq) + HCO_3^-(aq)$$

In water at room temperature, the rate constant for the uncatalyzed reaction is approximately 3×10^{-10} s^{-1}. Under the same conditions in the presence of the enzyme *urease* (pronounced "*yur*-ee-ase"), the rate constant is 3×10^{4} s^{-1}, a 10^{14}-fold increase! Enzymes increase rates by 10^8 to 10^{20} times, values that industrial chemists who design catalysts can only dream of.

Enzymes are also extremely *specific:* each reaction is generally catalyzed by a particular enzyme. Urease catalyzes *only* the hydrolysis of urea, and none of the several thousand other enzymes present in the cell catalyzes that reaction. This remarkable specificity results from the particular groups that comprise the active site. Two models of enzyme action are illustrated in Figure B16.5. According to the **lock-and-key model,** when the "key" (substrate) fits the "lock" (active site), the chemical change begins. However, x-ray crystallographic and spectroscopic methods show that, in many cases, *the enzyme changes shape when the substrate lands at the active site.* This **induced-fit model** of enzyme action pictures the substrate inducing the active site to adopt a perfect fit. Rather than a rigidly shaped lock and key, therefore, we should picture a hand in a glove, in which the "glove" (active site) does not attain its functional shape until the "hand" (substrate) moves into place.

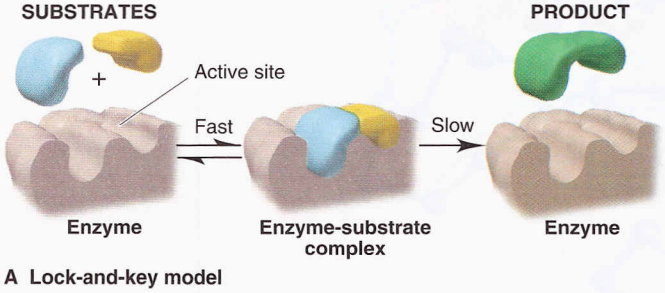
The kinetics of enzyme catalysis has many features in common with that of ordinary catalysis. In an uncatalyzed reaction, the rate is affected by the concentrations of the reactants; in a catalyzed reaction, the rate is affected by the *concentration of reactant bound to catalyst.* In the enzyme-catalyzed case, substrate (S) and enzyme (E) form an intermediate **enzyme-substrate complex (ES),** whose concentration determines the rate of product (P) formation. The steps common to virtually all enzyme-catalyzed reactions are

(1) $E + S \rightleftharpoons ES$ [fast, reversible]
(2) $ES \longrightarrow E + P$ [slow; rate determining]

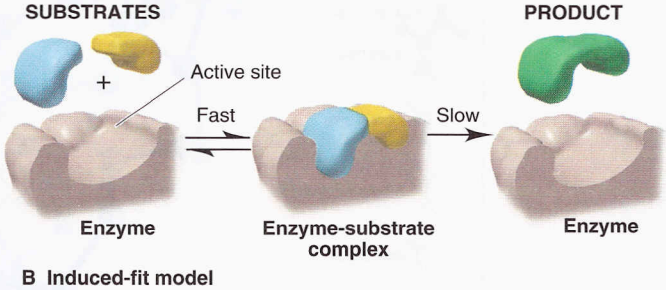
Thus, rate = k[ES]. When all the available enzyme molecules are bound to substrate and exist as ES, increasing [S] has no effect on rate and the process is zero order. To cite one very common example, the breakdown of ethanol in the body is zero order.

Enzymes employ a variety of catalytic mechanisms. In some cases, the active site R groups bring the reacting atoms of the bound substrates closer together. In other cases, the groups move apart slightly, stretching the substrate bond that is to be broken in the process. Some R groups are acidic and thus are able to provide H^+ ions that increase the speed of a rate-determining step; others act as bases and remove H^+ ions at a critical step. *Hydrolases* are a class of enzymes that cleave bonds by such *acid-base catalysis.* For example, lysozyme, an enzyme found in tears, hydrolyzes bacterial cell walls, thus protecting the eyes from microbes, and chymotrypsin, an enzyme found in the small intestine, hydrolyzes proteins into smaller molecules during digestion.

No matter what their specific mode of action, *all enzymes function by stabilizing the reaction's transition state.* For instance, in the lysozyme-catalyzed reaction, the transition state is a sugar molecule whose bonds are twisted and stretched into unusual lengths and angles so that it fits the lysozyme active site perfectly. By stabilizing the transition state through binding it effectively, lysozyme lowers the activation energy of the reaction and thus increases the rate.



A Lock-and-key model



B Induced-fit model

Figure B16.5 Two models of enzyme action. A, In the lock-and-key model, the active site is thought to be an exact fit for the substrate shapes. **B,** In the induced-fit model, the active site is thought to change shape to fit the substrates. Most enzyme-catalyzed reactions proceed through the fast, reversible formation of an enzyme-substrate complex, followed by a slow conversion to product and free enzyme.

CHEMICAL CONNECTIONS to Atmospheric Science

Depletion of the Earth's Ozone Layer

Both homogeneous and heterogeneous catalysts play key roles in one of today's most serious environmental concerns—the depletion of ozone from the stratosphere. The stratospheric ozone layer absorbs UV radiation with wavelengths between 280 and 320 nm emitted by the Sun that would otherwise reach Earth's surface. This radiation (called UV-B) has enough energy to break bonds in deoxyribonucleic acid (DNA) and thereby damage genes. Depletion of stratospheric ozone could significantly increase risks to human health from UV-B, particularly a higher incidence of skin cancer and cataracts (loss of transparency of the lens of the eye). Plant life, especially the simpler forms at the base of the food chain, may also be damaged.

Historically, stratospheric ozone concentration varied seasonally but remained nearly constant from year to year through a series of atmospheric reactions. Oxygen atoms formed from dissociation of O_2 by UV radiation with wavelengths less than 242 nm react with O_2 to form O_3, and with O_3 to regenerate O_2:

$$O_2 \xrightarrow{UV} 2O$$
$$O + O_2 \longrightarrow O_3 \qquad \text{[ozone formation]}$$
$$O + O_3 \longrightarrow 2O_2 \qquad \text{[ozone breakdown]}$$

However, research by Paul J. Crutzen, Mario J. Molina, and F. Sherwood Rowland, for which they received the Nobel Prize in chemistry in 1995, revealed that industrially produced chlorofluorocarbons (CFCs) shifted this balance by catalyzing the breakdown reaction.

CFCs were widely used as aerosol propellants, foam blowing agents, and air-conditioning coolants, so large quantities were released into the atmosphere. Unreactive in the troposphere, CFC molecules gradually reach the stratosphere, where they encounter UV radiation that can split them and release chlorine atoms:

$$CF_2Cl_2 \xrightarrow{UV} CF_2Cl\cdot + Cl\cdot$$

(The dots are unpaired electrons resulting from bond cleavage.)

Like many species with unpaired electrons (free radicals), atomic Cl is very reactive. The Cl atoms react with stratospheric ozone to produce an intermediate, chlorine monoxide (ClO·), which then reacts with free O atoms to regenerate Cl atoms:

$$O_3 + Cl\cdot \longrightarrow ClO\cdot + O_2$$
$$ClO\cdot + O \longrightarrow \cdot Cl + O_2$$

The sum of these steps is the ozone breakdown reaction:

$$O_3 + \cdot\cancel{Cl} + \cdot\cancel{ClO} + O \longrightarrow \cdot\cancel{ClO} + O_2 + \cdot\cancel{Cl} + O_2$$

or

$$O_3 + O \longrightarrow 2O_2$$

Within a region low in ozone, the concentration of O atoms is also low, so Cl atoms are regenerated from ClO:

$$2\,ClO\cdot \longrightarrow ClOOCl$$
$$ClOOCl + \text{light} \longrightarrow Cl\cdot + \cdot OOCl$$
$$ClOO\cdot + \text{light} \longrightarrow Cl\cdot + O_2$$

Thus, the overall process converts two O_3 to three O_2 molecules.

Note that the Cl atom acts as a homogeneous catalyst: it exists in the same phase as the reactants, speeds up the process via a different mechanism, and is regenerated. The problem is that each Cl atom has a stratospheric half-life of about 2 years, during which time it speeds the breakdown of about 100,000 ozone molecules. Bromine is a more effective catalyst, but much less ends up in the stratosphere. Halons, used as fire suppressants, and methyl bromide, an agricultural insecticide, are the main anthropogenic (human-made) sources of stratospheric bromine.

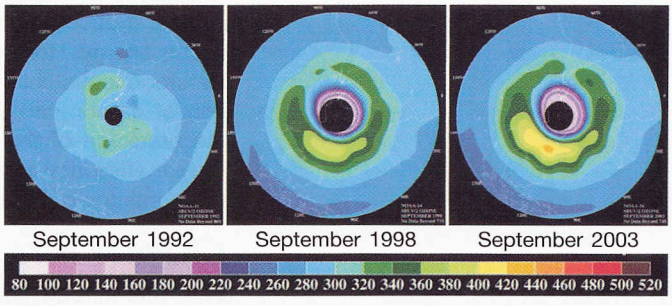


Figure B16.6 The increasing size of the Antarctic ozone hole. Satellite images show changes in ozone concentration over the South Pole for September 1992, 1998, and 2003. Note the increasing size of the "hole" in the ozone layer (indicated by the four leftmost colors in the key; the black circle is an instrument artifact). Since 1995, data show a similar thinning, though not yet as severe, over the North Pole.

A variety of Cl-containing species cause the Antarctic *ozone hole*, the severe reduction of stratospheric ozone over the Antarctic region when the Sun rises after the long winter darkness. Measurements of high [ClO·] over Antarctica are consistent with the breakdown mechanism. Atmospheric scientists have documented more than 80% ozone depletion over the South Pole (Figure B16.6). The ozone hole enlarges by heterogeneous catalysis involving polar stratospheric clouds. The clouds provide a surface for reactions that convert inactive chlorine compounds, such as HCl and chlorine nitrate ($ClONO_2$), to substances, such as Cl_2, that are cleaved by UV radiation to Cl atoms. Heterogeneous catalysis also occurs on fine particles in the stratosphere. Dust from the eruption of Mt. Pinatubo in 1991 reduced stratospheric ozone for 2 years. There is ozone thinning over the North Pole, and NASA has also documented the loss of stratospheric ozone at middle latitudes, such as over the United States. So far, both of these losses occur to a lower extent and at a lower rate.

The Montreal Protocol in 1987 and later amendments curtailed growth in production of CFCs and set dates for phasing out these and other chlorinated and brominated compounds, such as CCl_4, CCl_3CH_3, and CH_3Br. Another change was replacement of CFC aerosol propellants by hydrocarbons, such as isobutane, $(CH_3)_3CH$. Replacement of CFCs in refrigeration units is more difficult, because it will require changes in equipment. The first replacements for CFCs were hydrochlorofluorocarbons (HCFCs), such as CHF_2Cl. These deplete ozone less than CFCs do because they have relatively short tropospheric lifetimes due to abstraction of H atoms by hydroxyl radicals (·OH):

$$CHF_2Cl + \cdot OH \longrightarrow H_2O + \cdot CF_2Cl$$

After this initial attack, further degradation occurs rapidly.

HCFCs will be phased out by 2040 and replaced by hydrofluorocarbons (HFCs, which contain only C, H, and F) in devices such as car air conditioners. HFCs are preferable to CFCs or HCFCs because fluorine is a poor catalyst of ozone breakdown. Nevertheless, because of the long lifetimes of CFCs and the ongoing emissions of HCFCs until their phase-out, full recovery of the ozone layer may take another century! The good news is that tropospheric halogen levels have already begun to fall.

SECTION SUMMARY

A catalyst is a substance that increases the rate of a reaction without being consumed. It accomplishes this by providing an alternative mechanism with a lower activation energy. Homogeneous catalysts function in the same phase as the reactants. Heterogeneous catalysts act in a different phase from the reactants. The hydrogenation of carbon-carbon double bonds takes place on a solid catalyst, which speeds the breakage of the H—H bond in H_2. Enzymes are biological catalysts with spectacular efficiency and specificity. Chlorine atoms derived from CFC molecules catalyze the breakdown of stratospheric ozone.

Chapter Perspective

With this introduction to chemical kinetics, we have begun to explore the dynamic inner workings of chemical change. Variations in reaction rate are observed with concentration and temperature changes, which operate on the molecular level through the frequency and energetics of particle collisions and the details of reactant structure. Kinetics allows us to speculate about the molecular pathway of a reaction. Modern industry and biochemistry depend on its principles. However, speed and yield are very different aspects of a reaction. In Chapter 17, we'll see how opposing reaction rates give rise to the equilibrium state and examine how much product has formed once the net reaction stops.

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. How reaction rate depends on concentration, physical state, and temperature (Section 16.1)
2. The meaning of reaction rate in terms of changing concentrations over time (Section 16.2)
3. How the rate can be expressed in terms of reactant or product concentrations (Section 16.2)
4. The distinction between average and instantaneous rate and why the instantaneous rate changes during the reaction (Section 16.2)
5. The interpretation of reaction rate in terms of reactant and product concentrations (Section 16.2)
6. The experimental basis of the rate law and the information needed to determine it—initial rate data, reaction orders, and rate constant (Section 16.3)
7. The importance of reaction order in determining the rate (Section 16.3)
8. How reaction order is determined from initial rates at different concentrations (Section 16.3)
9. How integrated rate laws show the dependence of concentration on time (Section 16.4)
10. What reaction half-life means and why it is constant for a first-order reaction (Section 16.4)
11. Activation energy and the effect of temperature on the rate constant (Arrhenius equation) (Section 16.5)
12. Why concentrations are multiplied in the rate law (Section 16.6)
13. How temperature affects rate by influencing collision energy and, thus, the fraction of collisions with energy exceeding the activation energy (Section 16.6)
14. Why molecular orientation and complexity influence the number of effective collisions and the rate (Section 16.6)
15. The transition state as the momentary species between reactants and products whose formation requires the activation energy (Section 16.6)
16. How an elementary step represents a single molecular event and its molecularity equals the number of colliding particles (Section 16.7)
17. How a reaction mechanism consists of several elementary steps, with the slowest step determining the overall rate (Section 16.7)
18. The criteria for a valid reaction mechanism (Section 16.7)
19. How a catalyst speeds a reaction by lowering the activation energy (Section 16.8)
20. The distinction between homogeneous and heterogeneous catalysis (Section 16.8)

Master These Skills

1. Calculating instantaneous rate from the slope of a tangent to a concentration vs. time plot (Section 16.2)
2. Expressing reaction rate in terms of changes in concentration over time (SP 16.1)
3. Determining reaction order from a known rate law (SP 16.2)
4. Determining reaction order from changes in initial rate with concentration (SP 16.3)
5. Calculating the rate constant and its units (Section 16.3)
6. Using an integrated rate law to find concentration at a given time or the time to reach a given concentration (SP 16.4)
7. Determining reaction order graphically with a rearranged integrated rate law (Section 16.4)
8. Determining the half-life of a first-order reaction (SP 16.5)
9. Using a form of the Arrhenius equation to calculate the activation energy (SP 16.6)

Learning Objectives *(continued)*

10. Using reaction energy diagrams to depict the energy changes during a reaction (SP 16.7)
11. Postulating a transition state for a simple reaction (SP 16.7)
12. Determining the molecularity and rate law for an elementary step (SP 16.8)
13. Constructing a mechanism with either a slow or a fast initial step (Section 16.7)

Key Equations and Relationships

16.1 Expressing reaction rate in terms of reactant A (676):

$$\text{Rate} = -\frac{\Delta[\text{A}]}{\Delta t}$$

16.2 Expressing the rate of a general reaction (678):

$$a\text{A} + b\text{B} \longrightarrow c\text{C} + d\text{D}$$

$$\text{Rate} = -\frac{1}{a}\frac{\Delta[\text{A}]}{\Delta t} = -\frac{1}{b}\frac{\Delta[\text{B}]}{\Delta t} = \frac{1}{c}\frac{\Delta[\text{C}]}{\Delta t} = \frac{1}{d}\frac{\Delta[\text{D}]}{\Delta t}$$

16.3 Writing a general rate law (for a case not involving products) (679):

$$\text{Rate} = k[\text{A}]^m[\text{B}]^n \cdots$$

16.4 Calculating the time to reach a given [A] in a first-order reaction (rate = k[A]) (686):

$$\ln\frac{[\text{A}]_0}{[\text{A}]_t} = kt$$

16.5 Calculating the time to reach a given [A] in a simple second-order reaction (rate = $k[\text{A}]^2$) (687):

$$\frac{1}{[\text{A}]_t} - \frac{1}{[\text{A}]_0} = kt$$

16.6 Calculating the time to reach a given [A] in a zero-order reaction (rate = k) (687):

$$[\text{A}]_t - [\text{A}]_0 = -kt$$

16.7 Finding the half-life of a first-order process (690):

$$t_{1/2} = \frac{\ln 2}{k} = \frac{0.693}{k}$$

16.8 Relating the rate constant to the temperature (Arrhenius equation) (692):

$$k = Ae^{-E_a/RT}$$

16.9 Calculating the activation energy (rearranged form of Arrhenius equation) (693):

$$\ln\frac{k_2}{k_1} = -\frac{E_a}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

Brief Solutions to Follow-up Problems

16.1 (a) $4NO(g) + O_2(g) \longrightarrow 2N_2O_3(g)$;

$$\text{rate} = -\frac{\Delta[O_2]}{\Delta t} = -\frac{1}{4}\frac{\Delta[NO]}{\Delta t} = \frac{1}{2}\frac{\Delta[N_2O_3]}{\Delta t}$$

(b) $$-\frac{\Delta[O_2]}{\Delta t} = -\frac{1}{4}\frac{\Delta[NO]}{\Delta t}$$

$$= -\frac{1}{4}(-1.60\times10^{-4}\ \text{mol/L·s}) = 4.00\times10^{-5}\ \text{mol/L·s}$$

16.2 First order in Br^-, first order in BrO_3^-, second order in H^+, fourth order overall.

16.3 Rate $= k[H_2]^m[I_2]^n$. From experiments 1 and 3, $m = 1$. From experiments 2 and 4, $n = 1$.
Therefore, rate $= k[H_2][I_2]$; second order overall.

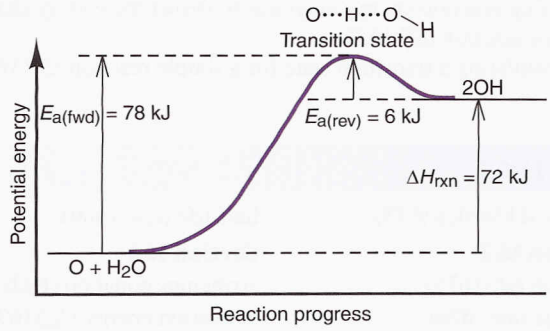
16.4 $1/[HI]_1 - 1/[HI]_0 = kt$;
$111\ \text{L/mol} - 100\ \text{L/mol} = (2.4\times10^{-21}\ \text{L/mol·s})(t)$
$t = 4.6\times10^{21}$ s (or 1.5×10^{14} yr)

16.5 $t_{1/2} = (\ln 2)/k$; $k = 0.693/13.1\ \text{h} = 5.29\times10^{-2}\ \text{h}^{-1}$

16.6 $$\ln\frac{0.286\ \text{L/mol·s}}{k_1} = -\frac{1.00\times10^5\ \text{J/mol}}{8.314\ \text{J/mol·K}} \times \left(\frac{1}{500.\ \text{K}} - \frac{1}{490.\ \text{K}}\right) = 0.491$$

$$k_1 = 0.175\ \text{L/mol·s}$$

16.7



16.8 (a) Balanced equation:
$2NO(g) + 2H_2(g) \longrightarrow N_2(g) + 2H_2O(g)$
(b) Step 2 is unimolecular. All others are bimolecular.
(c) $\text{Rate}_1 = k_1[NO]^2$; $\text{rate}_2 = k_2[H_2]$; $\text{rate}_3 = k_3[N_2O_2][H]$; $\text{rate}_4 = k_4[HO][H]$; $\text{rate}_5 = k_5[H][N_2O]$.

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

Factors That Influence Reaction Rate

Concept Review Questions

16.1 What variable of a chemical reaction is measured over time to obtain the reaction rate?

16.2 How does an increase in pressure affect the rate of a gas-phase reaction? Explain.

16.3 A reaction is carried out with water as the solvent. How does the addition of more water to the reaction vessel affect the rate of the reaction? Explain.

16.4 A gas reacts with a solid that is present in large chunks. Then the reaction is run again with the solid pulverized. How does the increase in the surface area of the solid affect the rate of its reaction with the gas? Explain.

16.5 How does an increase in temperature affect the rate of a reaction? Explain the two factors involved.

16.6 In a kinetics experiment, a chemist places crystals of iodine in a closed reaction vessel, introduces a given quantity of hydrogen gas, and obtains data to calculate the rate of hydrogen iodide formation. In a second experiment, she uses the same amounts of iodine and hydrogen, but she first warms the flask to 130°C, a temperature above the sublimation point of iodine. In which of these two experiments does the reaction proceed at a higher rate? Explain.

Expressing the Reaction Rate

(Sample Problem 16.1)

Concept Review Questions

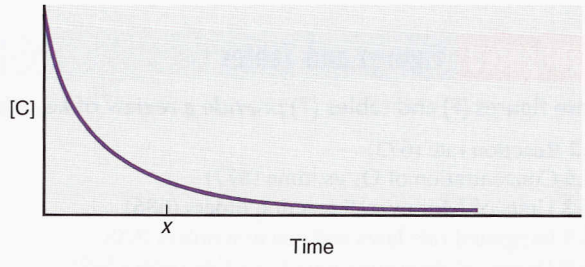
16.7 Define *reaction rate*. Assuming constant temperature and a closed reaction vessel, why does the rate change with time?

16.8 (a) What is the difference between an average rate and an instantaneous rate? (b) What is the difference between an initial rate and an instantaneous rate?

16.9 Give two reasons to measure initial rates in a kinetics study.

16.10 For the reaction $A(g) \longrightarrow B(g)$, sketch two curves on the same set of axes that show
(a) The formation of product as a function of time
(b) The consumption of reactant as a function of time

16.11 For the reaction $C(g) \longrightarrow D(g)$, [C] vs. time is plotted:



How do you determine each of the following?
(a) The average rate over the entire experiment
(b) The reaction rate at time x
(c) The initial reaction rate
(d) Would the values in parts (a), (b), and (c) be different if you plotted [D] vs. time? Explain.

Skill-Building Exercises *(grouped in similar pairs)*

16.12 The compound AX_2 decomposes according to the equation $2AX_2(g) \longrightarrow 2AX(g) + X_2(g)$. In one experiment, $[AX_2]$ was measured at various times and these data were obtained:

Time (s)	$[AX_2]$ (mol/L)
0.0	0.0500
2.0	0.0448
6.0	0.0300
8.0	0.0249
10.0	0.0209
20.0	0.0088

(a) Find the average rate over the entire experiment.
(b) Is the initial rate higher or lower than the rate in part (a)? Use graphical methods to estimate the initial rate.

16.13 (a) Use the data from Problem 16.12 to calculate the average rate from 8.0 to 20.0 s.
(b) Is the rate at exactly 5.0 s higher or lower than the rate in part (a)? Use graphical methods to estimate the rate at 5.0 s.

16.14 Express the rate of reaction in terms of the change in concentration of each of the reactants and products:

$$2A(g) \longrightarrow B(g) + C(g)$$

When [C] is increasing at 2 mol/L·s, how fast is [A] decreasing?

16.15 Express the rate of reaction in terms of the change in concentration of each of the reactants and products:

$$D(g) \longrightarrow \tfrac{3}{2}E(g) + \tfrac{5}{2}F(g)$$

When [E] is increasing at 0.25 mol/L·s, how fast is [F] increasing?

16.16 Express the rate of reaction in terms of the change in concentration of each of the reactants and products:

$$A(g) + 2B(g) \longrightarrow C(g)$$

When [B] is decreasing at 0.5 mol/L·s, how fast is [A] decreasing?

16.17 Express the rate of reaction in terms of the change in concentration of each of the reactants and products:

$$2D(g) + 3E(g) + F(g) \longrightarrow 2G(g) + H(g)$$

When [D] is decreasing at 0.1 mol/L·s, how fast is [H] increasing?

16.18 Reaction rate is expressed in terms of changes in concentration of reactants and products. Write a balanced equation for

$$\text{Rate} = -\frac{1}{2}\frac{\Delta[N_2O_5]}{\Delta t} = \frac{1}{4}\frac{\Delta[NO_2]}{\Delta t} = \frac{\Delta[O_2]}{\Delta t}$$

16.19 Reaction rate is expressed in terms of changes in concentration of reactants and products. Write a balanced equation for

$$\text{Rate} = -\frac{\Delta[CH_4]}{\Delta t} = -\frac{1}{2}\frac{\Delta[O_2]}{\Delta t} = \frac{1}{2}\frac{\Delta[H_2O]}{\Delta t} = \frac{\Delta[CO_2]}{\Delta t}$$

Problems in Context

16.20 The decomposition of nitrosyl bromide is followed manometrically because the number of moles of gas changes; it cannot be followed colorimetrically because both NOBr and Br_2 are reddish brown:

$$2NOBr(g) \longrightarrow 2NO(g) + Br_2(g)$$

Use the data in the next column to answer the following:
(a) Determine the average rate over the entire experiment.
(b) Determine the average rate between 2.00 and 4.00 s.
(c) Use graphical methods to estimate the initial reaction rate.
(d) Use graphical methods to estimate the rate at 7.00 s.
(e) At what time does the instantaneous rate equal the average rate over the entire experiment?

Time (s)	[NOBr] (mol/L)
0.00	0.0100
2.00	0.0071
4.00	0.0055
6.00	0.0045
8.00	0.0038
10.00	0.0033

16.21 The formation of ammonia is one of the most important processes in the chemical industry:

$$N_2(g) + 3H_2(g) \longrightarrow 2NH_3(g)$$

Express the rate in terms of changes in $[N_2]$, $[H_2]$, and $[NH_3]$.

16.22 Just as the depletion of stratospheric ozone threatens life on Earth today, its accumulation was one of the crucial processes that allowed life to develop in prehistoric times:

$$3O_2(g) \longrightarrow 2O_3(g)$$

(a) Express the reaction rate in terms of $[O_2]$ and $[O_3]$.
(b) At a given instant, the reaction rate in terms of $[O_2]$ is 2.17×10^{-5} mol/L·s. What is it in terms of $[O_3]$?

The Rate Law and Its Components

(Sample Problems 16.2 and 16.3)

Concept Review Questions

16.23 The rate law for the general reaction

$$aA + bB + \cdots \longrightarrow cC + dD + \cdots$$

is rate $= k[A]^m[B]^n \cdots$.
(a) Explain the meaning of k.
(b) Explain the meanings of m and n. Does $m = a$ and $n = b$? Explain.
(c) If the reaction is first order in A and second order in B, and time is measured in minutes (min), what are the units for k?

16.24 You are studying the reaction

$$A_2(g) + B_2(g) \longrightarrow 2AB(g)$$

to determine its rate law. Assuming that you have a valid experimental procedure for obtaining $[A_2]$ and $[B_2]$ at various times, explain how you determine (a) the initial rate, (b) the reaction orders, and (c) the rate constant.

16.25 By what factor does the rate change in each of the following cases (assuming constant temperature)?
(a) A reaction is first order in reactant A, and [A] is doubled.
(b) A reaction is second order in reactant B, and [B] is halved.
(c) A reaction is second order in reactant C, and [C] is tripled.

Skill-Building Exercises *(grouped in similar pairs)*

16.26 Give the individual reaction orders for all substances and the overall reaction order from the following rate law:

$$\text{Rate} = k[BrO_3^-][Br^-][H^+]^2$$

16.27 Give the individual reaction orders for all substances and the overall reaction order from the following rate law:

$$\text{Rate} = k\frac{[O_3]^2}{[O_2]}$$

16.28 By what factor does the rate in Problem 16.26 change if each of the following changes occurs: (a) $[BrO_3^-]$ is doubled; (b) $[Br^-]$ is halved; (c) $[H^+]$ is quadrupled?

16.29 By what factor does the rate in Problem 16.27 change if each of the following changes occurs: (a) $[O_3]$ is doubled; (b) $[O_2]$ is doubled; (c) $[O_2]$ is halved?

16.30 Give the individual reaction orders for all substances and the overall reaction order from this rate law:

$$\text{Rate} = k[NO_2]^2[Cl_2]$$

16.31 Give the individual reaction orders for all substances and the overall reaction order from this rate law:

$$\text{Rate} = k\frac{[HNO_2]^4}{[NO]^2}$$

16.32 By what factor does the rate in Problem 16.30 change if each of the following changes occurs: (a) $[NO_2]$ is tripled; (b) $[NO_2]$ and $[Cl_2]$ are doubled; (c) $[Cl_2]$ is halved?

16.33 By what factor does the rate in Problem 16.31 change if each of the following changes occurs: (a) $[HNO_2]$ is doubled; (b) [NO] is doubled; (c) $[HNO_2]$ is halved?

16.34 For the reaction

$$4A(g) + 3B(g) \longrightarrow 2C(g)$$

the following data were obtained at constant temperature:

Experiment	Initial [A] (mol/L)	Initial [B] (mol/L)	Initial Rate (mol/L·min)
1	0.100	0.100	5.00
2	0.300	0.100	45.0
3	0.100	0.200	10.0
4	0.300	0.200	90.0

(a) What is the order with respect to each reactant? (b) Write the rate law. (c) Calculate k (using the data from experiment 1).

16.35 For the reaction

$$A(g) + B(g) + C(g) \longrightarrow D(g)$$

the following data were obtained at constant temperature:

Exp't	Initial [A] (mol/L)	Initial [B] (mol/L)	Initial [C] (mol/L)	Initial Rate (mol/L·s)
1	0.0500	0.0500	0.0100	6.25×10^{-3}
2	0.1000	0.0500	0.0100	1.25×10^{-2}
3	0.1000	0.1000	0.0100	5.00×10^{-2}
4	0.0500	0.0500	0.0200	6.25×10^{-3}

(a) What is the order with respect to each reactant? (b) Write the rate law. (c) Calculate k (using the data from experiment 1).

16.36 Without consulting Table 16.3, give the units of the rate constants for reactions with the following overall orders: (a) first order; (b) second order; (c) third order; (d) $\frac{5}{2}$ order.

16.37 Give the overall reaction order that corresponds to a rate constant with each of the following units: (a) mol/L·s; (b) yr^{-1}; (c) $(mol/L)^{1/2}\cdot s^{-1}$; (d) $(mol/L)^{-5/2}\cdot min^{-1}$.

Problems in Context

16.38 Phosgene is a toxic gas prepared by the reaction of carbon monoxide with chlorine:

$$CO(g) + Cl_2(g) \longrightarrow COCl_2(g)$$

These data were obtained in a kinetics study of its formation:

Experiment	Initial [CO] (mol/L)	Initial $[Cl_2]$ (mol/L)	Initial Rate (mol/L·s)
1	1.00	0.100	1.29×10^{-29}
2	0.100	0.100	1.33×10^{-30}
3	0.100	1.00	1.30×10^{-29}
4	0.100	0.0100	1.32×10^{-31}

(a) Write the rate law for the formation of phosgene.
(b) Calculate the average value of the rate constant.

Integrated Rate Laws: Concentration Changes over Time

(Sample Problems 16.4 and 16.5)

Concept Review Questions

16.39 How are integrated rate laws used to determine reaction order? What is the order in reactant if a plot of
(a) The natural logarithm of [reactant] vs. time is linear?
(b) The inverse of [reactant] vs. time is linear?
(c) [Reactant] vs. time is linear?

16.40 Define the *half-life* of a reaction. Explain on the molecular level why the half-life of a first-order reaction is constant.

Skill-Building Exercises *(grouped in similar pairs)*

16.41 For the simple decomposition reaction

$$AB(g) \longrightarrow A(g) + B(g)$$

rate $= k[AB]^2$ and $k = 0.2$ L/mol·s. How long will it take for [AB] to reach $\frac{1}{3}$ of its initial concentration of 1.50 M?

16.42 For the reaction in Problem 16.41, what is [AB] after 10.0 s?

16.43 In a first-order decomposition reaction, 50.0% of a compound decomposes in 10.5 min. (a) What is the rate constant of the reaction? (b) How long does it take for 75.0% of the compound to decompose?

16.44 A decomposition reaction has a rate constant of 0.0012 yr^{-1}. (a) What is the half-life of the reaction? (b) How long does it take for [reactant] to reach 12.5% of its original value?

Problems in Context

16.45 In a study of ammonia production, an industrial chemist discovers that the compound decomposes to its elements N_2 and H_2 in a first-order process. She collects the following data:

Time (s)	0	1.000	2.000
$[NH_3]$ (mol/L)	4.000	3.986	3.974

(a) Use graphical methods to determine the rate constant.
(b) What is the half-life for ammonia decomposition?

The Effect of Temperature on Reaction Rate

(Sample Problem 16.6)

Concept Review Questions

16.46 Use the exponential term in the Arrhenius equation to explain how temperature affects reaction rate.

16.47 How is the activation energy determined from the Arrhenius equation?

16.48 (a) Graph the relationship between k (y axis) and T (x axis). (b) Graph the relationship between ln k (y axis) and $1/T$ (x axis). How is the activation energy determined from this graph?

Skill-Building Exercises *(grouped in similar pairs)*

16.49 The rate constant of a reaction is $4.7\times10^{-3}\ s^{-1}$ at 25°C, and the activation energy is 33.6 kJ/mol. What is k at 75°C?

16.50 The rate constant of a reaction is 4.50×10^{-5} L/mol·s at 195°C and 3.20×10^{-3} L/mol·s at 258°C. What is the activation energy of the reaction?

Problems in Context

16.51 Understanding the high-temperature formation and breakdown of the nitrogen oxides is essential for controlling the pollutants generated from power plants and cars. The first-order breakdown of dinitrogen monoxide to its elements has rate constants of 0.76/s at 727°C and 0.87/s at 757°C. What is the activation energy of this reaction?

Explaining the Effects of Concentration and Temperature
(Sample Problem 16.7)

Concept Review Questions

16.52 What is the central idea of collision theory? How does this idea explain the effect of concentration on reaction rate?

16.53 Is collision frequency the only factor affecting rate? Explain.

16.54 Arrhenius proposed that each reaction has an energy threshold that must be reached for the particles to react. The kinetic theory of gases proposes that the average kinetic energy of the particles is proportional to the absolute temperature. How do these concepts relate to the effect of temperature on rate?

16.55 (a) For a reaction with a given E_a, how does an increase in T affect the rate? (b) For a reaction at a given T, how does a decrease in E_a affect the rate?

16.56 In the reaction AB + CD $\rightleftharpoons$ EF, 4×10^{-5} mol of AB molecules collide with 4×10^{-5} mol of CD molecules. Will 4×10^{-5} mol of EF form? Explain.

16.57 Assuming the activation energies are equal, which of the following reactions will occur at a higher rate at 50°C? Explain:

$$NH_3(g) + HCl(g) \longrightarrow NH_4Cl(s)$$
$$N(CH_3)_3(g) + HCl(g) \longrightarrow (CH_3)_3NHCl(s)$$

Skill-Building Exercises *(grouped in similar pairs)*

16.58 For the reaction $A(g) + B(g) \longrightarrow AB(g)$, how many unique collisions between A and B are possible if there are four particles of A and three particles of B present in the vessel?

16.59 For the reaction $A(g) + B(g) \longrightarrow AB(g)$, how many unique collisions between A and B are possible if 1.01 mol of $A(g)$ and 2.12 mol of $B(g)$ are present in the vessel?

16.60 At 25°C, what is the fraction of collisions with energy equal to or greater than an activation energy of 100. kJ/mol?

16.61 If the temperature in Problem 16.60 is increased to 50.°C, by what factor does the fraction of collisions with energy equal to or greater than the activation energy change?

16.62 For the reaction ABC + D $\rightleftharpoons$ AB + CD, $\Delta H^0_{rxn} = -55$ kJ/mol and $E_{a(fwd)} = 215$ kJ/mol. Assuming a one-step reaction, (a) draw a reaction energy diagram; (b) calculate $E_{a(rev)}$; and (c) sketch a possible transition state if ABC is V-shaped.

16.63 For the reaction $A_2 + B_2 \longrightarrow 2AB$, $E_{a(fwd)} = 125$ kJ/mol and $E_{a(rev)} = 85$ kJ/mol. Assuming the reaction occurs in one step, (a) draw a reaction energy diagram; (b) calculate ΔH^0_{rxn}; and (c) sketch a possible transition state.

Problems in Context

16.64 Aqua regia, a mixture of HCl and HNO_3, has been used since alchemical times to dissolve many metals, including gold. Its orange color is due to the presence of nitrosyl chloride. Consider this one-step reaction for the formation of this compound:

$$NO(g) + Cl_2(g) \longrightarrow NOCl(g) + Cl(g) \qquad \Delta H^0 = 83 \text{ kJ}$$

(a) Draw a reaction energy diagram, given $E_{a(fwd)}$ is 86 kJ/mol.
(b) Calculate $E_{a(rev)}$.
(c) Sketch a possible transition state for the reaction. (*Note:* The atom sequence of nitrosyl chloride is Cl—N—O.)

Reaction Mechanisms: Steps in the Overall Reaction
(Sample Problem 16.8)

Concept Review Questions

16.65 Is the rate of an overall reaction lower, higher, or equal to the average rate of the individual steps? Explain.

16.66 Explain why the coefficients of an elementary step equal the reaction orders of its rate law but those of an overall reaction do not.

16.67 Is it possible for more than one mechanism to be consistent with the rate law of a given reaction? Explain.

16.68 What is the difference between a reaction intermediate and a transition state?

16.69 Why is a bimolecular step more reasonable physically than a termolecular step?

16.70 If a slow step precedes a fast step in a two-step mechanism, do the substances in the fast step appear in the rate law? Explain.

16.71 If a fast step precedes a slow step in a two-step mechanism, how is the fast step affected? How is this effect used to determine the validity of the mechanism?

Skill-Building Exercises *(grouped in similar pairs)*

16.72 The proposed mechanism for a reaction is

(1) $A(g) + B(g) \rightleftharpoons X(g)$ [fast]
(2) $X(g) + C(g) \longrightarrow Y(g)$ [slow]
(3) $Y(g) \longrightarrow D(g)$ [fast]

(a) What is the overall equation?
(b) Identify the intermediate(s), if any.
(c) What are the molecularity and the rate law for each step?
(d) Is the mechanism consistent with the actual rate law: rate = $k[A][B][C]$?
(e) Is the following one-step mechanism equally valid: $A(g) + B(g) + C(g) \longrightarrow D(g)$?

16.73 Consider the following mechanism:

(1) $ClO^-(aq) + H_2O(l) \rightleftharpoons HClO(aq) + OH^-(aq)$ [fast]
(2) $I^-(aq) + HClO(aq) \longrightarrow HIO(aq) + Cl^-(aq)$ [slow]
(3) $OH^-(aq) + HIO(aq) \longrightarrow H_2O(l) + IO^-(aq)$ [fast]

(a) What is the overall equation?
(b) Identify the intermediate(s), if any.
(c) What are the molecularity and the rate law for each step?
(d) Is the mechanism consistent with the actual rate law: rate = $k[ClO^-][I^-]$?

Problems in Context

16.74 In a study of nitrosyl halides, a chemist proposes the following mechanism for the synthesis of nitrosyl bromide:

$$NO(g) + Br_2(g) \rightleftharpoons NOBr_2(g) \quad \text{[fast]}$$
$$NOBr_2(g) + NO(g) \longrightarrow 2NOBr(g) \quad \text{[slow]}$$

If the rate law is rate = $k[NO]^2[Br_2]$, is the proposed mechanism valid? If so, show that it satisfies the three criteria for validity.

16.75 The rate law for $2NO(g) + O_2(g) \longrightarrow 2NO_2(g)$ is rate = $k[NO]^2[O_2]$. In addition to the mechanism in the text, the following ones have been proposed:

I $2NO(g) + O_2(g) \longrightarrow 2NO_2(g)$

II $2NO(g) \rightleftharpoons N_2O_2(g)$ [fast]
$N_2O_2(g) + O_2(g) \longrightarrow 2NO_2(g)$ [slow]

III $2NO(g) \rightleftharpoons N_2(g) + O_2(g)$ [fast]
$N_2(g) + 2O_2(g) \longrightarrow 2NO_2(g)$ [slow]

(a) Which of these mechanisms is consistent with the rate law?
(b) Which is most reasonable chemically? Why?

Catalysis: Speeding Up a Chemical Reaction

Concept Review Questions

16.76 Consider the reaction $N_2O(g) \xrightarrow{Au} N_2(g) + \frac{1}{2}O_2(g)$.
(a) Is the gold a homogeneous or a heterogeneous catalyst?
(b) On the same set of axes, sketch the reaction energy diagrams for the catalyzed and the uncatalyzed reactions.

16.77 Does a catalyst increase reaction rate by the same means as a rise in temperature does? Explain.

16.78 In a classroom demonstration, hydrogen gas and oxygen gas are mixed in a balloon. The mixture is stable under normal conditions, but if a spark is applied to it or some powdered metal is added, the mixture explodes. (a) Is the spark acting as a catalyst? Explain. (b) Is the metal acting as a catalyst? Explain.

16.79 A principle of green chemistry is that the energy requirements of industrial processes should have minimal environmental impact. How can the use of catalysts lead to "greener" technologies?

Comprehensive Problems

16.80 Experiments show that each of the following redox reactions is second order overall:

Reaction 1: $NO_2(g) + CO(g) \longrightarrow NO(g) + CO_2(g)$

Reaction 2: $NO(g) + O_3(g) \longrightarrow NO_2(g) + O_2(g)$

(a) When $[NO_2]$ in reaction 1 is doubled, the rate quadruples. Write the rate law for this reaction.

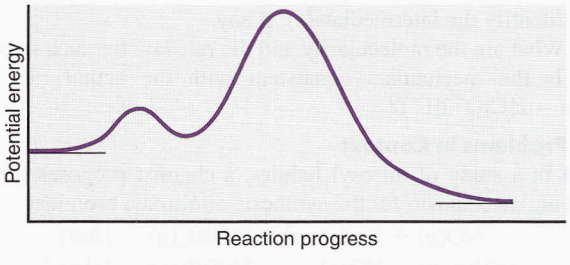
(b) When [NO] in reaction 2 is doubled, the rate doubles. Write the rate law for this reaction.

(c) In each reaction, the initial concentrations of the reactants are equal. For each reaction, what is the ratio of the initial rate to the rate when the reaction is 50% complete?

(d) In reaction 1, the initial $[NO_2]$ is twice the initial [CO]. What is the ratio of the initial rate to the rate at 50% completion?

(e) In reaction 2, the initial [NO] is twice the initial $[O_3]$. What is the ratio of the initial rate to the rate at 50% completion?

16.81 Consider the following reaction energy diagram:



(a) How many elementary steps are in the reaction mechanism?

(b) Which step is rate limiting?

(c) Is the overall reaction exothermic or endothermic?

16.82 Reactions between certain organic (alkyl) halides and water produce alcohols. Consider the overall reaction for *t*-butyl bromide (2-bromo-2-methylpropane):

$$(CH_3)_3CBr(aq) + H_2O(l) \longrightarrow (CH_3)_3COH(aq) + H^+(aq) + Br^-(aq)$$

The experimental rate law is rate $= k[(CH_3)_3CBr]$. The accepted mechanism for the reaction is

(1) $(CH_3)_3C{-}Br(aq) \longrightarrow (CH_3)_3C^+(aq) + Br^-(aq)$ [slow]

(2) $(CH_3)_3C^+(aq) + H_2O(l) \longrightarrow (CH_3)_3C{-}OH_2^+(aq)$ [fast]

(3) $(CH_3)_3C{-}OH_2^+(aq) \longrightarrow H^+(aq) + (CH_3)_3C{-}OH(aq)$ [fast]

(a) Why doesn't H_2O appear in the rate law?

(b) Write rate laws for the elementary steps.

(c) What reaction intermediates appear in the mechanism?

(d) Show that the mechanism is consistent with the experimental rate law.

16.83 The catalytic destruction of ozone occurs via a two-step mechanism, where X can be any of several species:

(1) $X + O_3 \longrightarrow XO + O_2$ [slow]

(2) $XO + O \longrightarrow X + O_2$ [fast]

(a) Write the overall reaction.

(b) Write the rate law for each step.

(c) X acts as _____, and XO acts as _____.

(d) High-flying aircraft release NO into the stratosphere, which catalyzes this process. When O_3 and NO concentrations are 5×10^{12} molecule/cm^3 and 1.0×10^9 molecule/cm^3, respectively, what is the rate of O_3 depletion (k for the rate-determining step is 6×10^{-15} cm^3/molecule·s)?

(e) Is the O_3 concentration in part (d) reasonable for this reaction, given that stratospheric O_3 never exceeds 10 mg/L?

16.84 Archeologists can determine the age of artifacts made of wood or bone by measuring the amount of the radioactive isotope ^{14}C present in the object. The amount of isotope decreases in a first-order process. If 15.5% of the original amount of ^{14}C is present in a wooden tool at the time of analysis, what is the age of the tool? The half-life of ^{14}C is 5730 yr.

16.85 A slightly bruised apple will rot extensively in about 4 days at room temperature (20°C). If it is kept in the refrigerator at 0°C, the same extent of rotting takes about 16 days. What is the activation energy for the rotting reaction?

16.86 Benzoyl peroxide, the substance most widely used against acne, has a half-life of 9.8×10^3 days when refrigerated. How long will it take to lose 5% of its potency (95% remaining)?

16.87 The rate law for the reaction

$$NO_2(g) + CO(g) \longrightarrow NO(g) + CO_2(g)$$

is rate $= k[NO_2]^2$; one possible mechanism is shown on p. 703.

(a) Draw a reaction energy diagram for that mechanism, given that $\Delta H^0_{overall} = -226$ kJ/mol.

(b) The following alternative mechanism has been proposed:

(1) $2NO_2(g) \longrightarrow N_2(g) + 2O_2(g)$ [slow]

(2) $2CO(g) + O_2(g) \longrightarrow 2CO_2(g)$ [fast]

(3) $N_2(g) + O_2(g) \longrightarrow 2NO(g)$ [fast]

Is the alternative mechanism consistent with the rate law? Is one mechanism more reasonable physically? Explain.

16.88 Consider the following general reaction and data:

$$2A + 2B + C \longrightarrow D + 3E$$

Exp't	Initial [A] (mol/L)	Initial [B] (mol/L)	Initial [C] (mol/L)	Initial Rate (mol/L·s)
1	0.024	0.085	0.032	6.0×10^{-6}
2	0.096	0.085	0.032	9.6×10^{-5}
3	0.024	0.034	0.080	1.5×10^{-5}
4	0.012	0.170	0.032	1.5×10^{-6}

(a) What is the reaction order with respect to each reactant?

(b) Calculate the rate constant.

(c) Write the rate law for this reaction.

(d) Express the rate in terms of changes in concentration with time for each of the components.

16.89 In acidic solution, the breakdown of sucrose into glucose and fructose has this rate law: rate $= k[H^+][\text{sucrose}]$. The initial rate of sucrose breakdown is measured in a solution that is 0.01 *M* H^+, 1.0 *M* sucrose, 0.1 *M* fructose, and 0.1 *M* glucose. How does the rate change if

(a) [Sucrose] is changed to 2.5 M?
(b) [Sucrose], [fructose], and [glucose] are all changed to 0.5 M?
(c) $[H^+]$ is changed to 0.0001 M?
(d) [Sucrose] and $[H^+]$ are both changed to 0.1 M?

16.90 Enzymes are remarkably efficient catalysts that can increase reaction rates by as many as 20 orders of magnitude.
(a) How does an enzyme affect the transition state of a reaction, and how does this effect increase the reaction rate?
(b) What characteristics of enzymes give them this tremendous effectiveness as catalysts?

16.91 Biacetyl, the flavoring that makes margarine taste "just like butter," is extremely stable at room temperature, but at 200°C it undergoes a first-order breakdown with a half-life of 9.0 min. An industrial flavor-enhancing process requires that a biacetyl-flavored food be heated briefly at 200°C. How long can the food be heated and retain 85% of its buttery flavor?

16.92 Biochemists consider the citric acid cycle to be the central reaction sequence in metabolism. One of the key steps is an oxidation catalyzed by the enzyme isocitrate dehydrogenase and the oxidizing agent NAD^+. Under certain conditions, the reaction in yeast obeys 11th-order kinetics:

$$\text{Rate} = k[\text{enzyme}][\text{isocitrate}]^4[\text{AMP}]^2[NAD^+]^m[Mg^{2+}]^2$$

What is the order with respect to NAD^+?

16.93 At body temperature (37°C), k of an enzyme-catalyzed reaction is 2.3×10^{14} times greater than k of the uncatalyzed reaction. Assuming that the frequency factor A is the same for both reactions, by how much does the enzyme lower the E_a?

16.94 Enzymes in human liver catalyze a large number of reactions that degrade ingested toxic chemicals. By what factor is the rate of a detoxification reaction changed if a liver enzyme lowers the activation energy by 5 kJ/mol at 37°C?

16.95 Experiment shows that the rate of formation of carbon tetrachloride from chloroform,

$$CHCl_3(g) + Cl_2(g) \longrightarrow CCl_4(g) + HCl(g)$$

is first order in $CHCl_3$, $\frac{1}{2}$ order in Cl_2, and $\frac{3}{2}$ order overall. Show that the following mechanism is consistent with the overall rate law:

(1) $Cl_2(g) \rightleftharpoons 2Cl(g)$ [fast]
(2) $Cl(g) + CHCl_3(g) \longrightarrow HCl(g) + CCl_3(g)$ [slow]
(3) $CCl_3(g) + Cl(g) \longrightarrow CCl_4(g)$ [fast]

16.96 A biochemist studying breakdown of the insecticide DDT finds that it decomposes by a first-order reaction with a half-life of 12 yr. How long does it take DDT in a soil sample to decompose from 275 ppbm to 10. ppbm (parts per billion by mass)?

16.97 Proteins in the body undergo continual breakdown and synthesis. Insulin is a polypeptide hormone that stimulates fat and muscle to take up glucose. Once released from the pancreas, it has a first-order half-life in the blood of 8.0 min. To maintain an adequate blood concentration of insulin, it must be replenished in a time interval equal to $1/k$. How long is this interval?

16.98 For the reaction $A(g) + B(g) \longrightarrow AB(g)$, the rate is 0.20 mol/L·s, when $[A]_0 = [B]_0 = 1.0$ mol/L. If the reaction is first order in B and second order in A, what is the rate when $[A]_0 = 2.0$ mol/L and $[B]_0 = 3.0$ mol/L?

16.99 The hydrolysis of sucrose occurs by this overall reaction:

$$\underset{\text{sucrose}}{C_{12}H_{22}O_{11}(s)} + H_2O(l) \longrightarrow \underset{\text{glucose}}{C_6H_{12}O_6(aq)} + \underset{\text{fructose}}{C_6H_{12}O_6(aq)}$$

A nutritional biochemist obtains the following kinetic data:

[Sucrose] (mol/L)	Time (h)
0.501	0.00
0.451	0.50
0.404	1.00
0.363	1.50
0.267	3.00

(a) Determine the rate constant and the half-life of the reaction.
(b) How long does it take to hydrolyze 75% of the sucrose?
(c) Other studies have shown that this reaction is actually second order overall but appears to follow first-order kinetics. (Such a reaction is called a *pseudo–first-order reaction*.) Suggest a reason for this apparent first-order behavior.

16.100 Is each of these statements true? If not, explain why.
(a) At a given T, all molecules have the same kinetic energy.
(b) Halving the P of a gaseous reaction doubles the rate.
(c) A higher activation energy gives a lower reaction rate.
(d) A temperature rise of 10°C doubles the rate of any reaction.
(e) If reactant molecules collide with greater energy than the activation energy, they change into product molecules.
(f) The activation energy of a reaction depends on temperature.
(g) The rate of a reaction increases as the reaction proceeds.
(h) Activation energy depends on collision frequency.
(i) A catalyst increases the rate by increasing collision frequency.
(j) Exothermic reactions are faster than endothermic reactions.
(k) Temperature has no effect on the frequency factor (A).
(l) The activation energy of a reaction is lowered by a catalyst.
(m) For most reactions, ΔH_{rxn} is lowered by a catalyst.
(n) The orientation probability factor (p) is near unity for reactions between single atoms.
(o) The initial rate of a reaction is its maximum rate.
(p) A bimolecular reaction is generally twice as fast as a unimolecular reaction.
(q) The molecularity of an elementary reaction is proportional to the molecular complexity of the reactant(s).

16.101 For the decomposition of gaseous dinitrogen pentaoxide, $2N_2O_5(g) \longrightarrow 4NO_2(g) + O_2(g)$, the rate constant is $k = 2.8\times10^{-3}\ s^{-1}$ at 60°C. The initial concentration of N_2O_5 is 1.58 mol/L. (a) What is $[N_2O_5]$ after 5.00 min? (b) What fraction of the N_2O_5 has decomposed after 5.00 min?

16.102 Even when a mechanism is consistent with the rate law, later experimentation may show it to be incorrect or only one of several alternatives. As an example, the reaction between hydrogen and iodine has the following rate law: rate $= k[H_2][I_2]$. The long-accepted mechanism proposed a single bimolecular step; that is, the overall reaction was thought to be elementary:

$$H_2(g) + I_2(g) \longrightarrow 2HI(g)$$

In the 1960s, however, spectroscopic evidence showed the presence of free I atoms during the reaction. Kineticists have since proposed a three-step mechanism:

(1) $I_2(g) \rightleftharpoons 2I(g)$ [fast]
(2) $H_2(g) + I(g) \rightleftharpoons H_2I(g)$ [fast]
(3) $H_2I(g) + I(g) \longrightarrow 2HI(g)$ [slow]

Show that this mechanism is consistent with the rate law.

16.103 Suggest an experimental method for measuring the change in concentration with time for each of the following reactions:

(a) $CH_3CH_2Br(l) + H_2O(l) \longrightarrow CH_3CH_2OH(l) + HBr(aq)$
(b) $2NO(g) + Cl_2(g) \longrightarrow 2NOCl(g)$

16.104 An atmospheric chemist fills a container with gaseous N_2O_5 to a pressure of 125 kPa, and the gas decomposes to NO_2 and O_2. What is the partial pressure of NO_2, P_{NO_2} (in kPa), when the total pressure is 178 kPa?

16.105 Many drugs decompose in blood by a first-order process.
(a) Two tablets of aspirin supply 0.60 g of the active compound. After 30 min, this compound reaches a maximum concentration of 2 mg/100 mL of blood. If the half-life for its breakdown is 90 min, what is its concentration (in mg/100 mL) 2.5 h after it reaches its maximum concentration?
(b) In 8.0 h, secobarbital sodium, a common sedative, reaches a blood level that is 18% of its maximum. What is $t_{1/2}$ of the decomposition of secobarbital sodium in blood?
(c) The blood level of the sedative phenobarbital sodium drops to 59% of its maximum after 20. h. What is $t_{1/2}$ for its breakdown in blood?
(d) For the decomposition of an antibiotic in a person with a normal temperature (98.6°F), $k = 3.1\times10^{-5}\ s^{-1}$; for a person with a fever at 101.9°F, $k = 3.9\times10^{-5}\ s^{-1}$. If the sick person must take another pill when $\frac{2}{3}$ of the first pill has decomposed, how many hours should she wait to take a second pill? A third pill?
(e) Calculate E_a for decomposition of the antibiotic in part (d).

16.106 Iodide ion reacts with chloroform to displace chloride ion in a common organic substitution reaction:

$$I^- + CH_3Cl \longrightarrow CH_3I + Cl^-$$

(a) Draw a wedge-bond structural formula of chloroform and indicate the most effective direction of I^- attack.
(b) The analogous reaction with 2-chlorobutane [Figure P16.106(b)] results in a major change in specific rotation as measured by polarimetry. Explain, showing a wedge-bond structural formula of the product.
(c) Under different conditions, 2-chlorobutane loses Cl^- in a rate-determining step to form a planar intermediate [Figure P16.106(c)]. This cationic species reacts with HI and then loses H^+ to form a product that exhibits no optical activity. Explain, showing a wedge-bond structural formula.

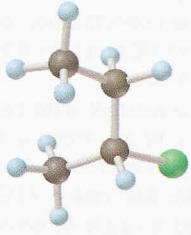


Figure P16.106(b)

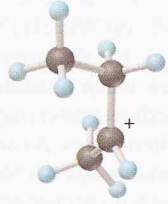

Figure P16.106(c)

16.107 In Houston (near sea level), water boils at 100.0°C. In Cripple Creek, Colorado (near 9500 ft), it boils at 90.0°C. If it takes 4.8 min to cook an egg in Cripple Creek and 4.5 min in Houston, what is E_a for this process?

16.108 Sulfonation of benzene has the following mechanism:

(1) $2H_2SO_4 \longrightarrow H_3O^+ + HSO_4^- + SO_3$ [fast]
(2) $SO_3 + C_6H_6 \longrightarrow H(C_6H_5^+)SO_3^-$ [slow]
(3) $H(C_6H_5^+)SO_3^- + HSO_4^- \longrightarrow C_6H_5SO_3^- + H_2SO_4$ [fast]
(4) $C_6H_5SO_3^- + H_3O^+ \longrightarrow C_6H_5SO_3H + H_2O$ [fast]

(a) Write an overall equation for the reaction.
(b) Write the overall rate law for the initial rate of the reaction.

16.109 Acetone is one of the most important solvents in organic chemistry, used to dissolve everything from fats and waxes to airplane glue and nail polish. At high temperatures, it decomposes in a first-order process to methane and ketene ($CH_2{=}C{=}O$). At 600°C, the rate constant is $8.7\times10^{-3}\ s^{-1}$.
(a) What is the half-life of the reaction?
(b) How much time is required for 40.% of a sample of acetone to decompose?
(c) How much time is required for 90.% of a sample of acetone to decompose?

16.110 In the lower troposphere, ozone is one of the components of photochemical smog. It is generated in air when nitrogen dioxide, formed by the oxidation of nitrogen monoxide from car exhaust, reacts by the following mechanism:

(1) $NO_2(g) \xrightarrow{k_1} NO(g) + O(g)$
(2) $O(g) + O_2(g) \xrightarrow{k_2} O_3(g)$

Assuming the rate of formation of atomic oxygen in step 1 equals the rate of its consumption in step 2, use the data below to calculate (a) the concentration of atomic oxygen [O]; (b) the rate of ozone formation.

$k_1 = 6.0\times10^{-3}\ s^{-1}$ $\quad [NO_2] = 4.0\times10^{-9}\ M$
$k_2 = 1.0\times10^{6}$ L/mol·s $\quad [O_2] = 1.0\times10^{-2}\ M$

16.111 Chlorine is commonly used to disinfect drinking water, and inactivation of pathogens by chlorine follows first-order kinetics. The following data show *E. coli* inactivation:

Contact time (min)	Percent (%) inactivation
0.00	0.0
0.50	68.3
1.00	90.0
1.50	96.8
2.00	99.0
2.50	99.7
3.00	99.9

(a) Determine the first-order inactivation constant, k. [*Hint*: % inactivation $= 100 \times (1 - [A]_t/[A]_0)$.]
(b) How much contact time is required for 95% inactivation?

16.112 The reaction and rate law for the gas-phase decomposition of dinitrogen pentaoxide are

$$2N_2O_5(g) \longrightarrow 4NO_2(g) + O_2(g) \qquad \text{rate} = k[N_2O_5]$$

Which of the following can be considered valid mechanisms for the reaction?

I One-step collision

II
$2N_2O_5(g) \longrightarrow 2NO_3(g) + 2NO_2(g)$ [slow]
$2NO_3(g) \longrightarrow 2NO_2(g) + 2O(g)$ [fast]
$2O(g) \longrightarrow O_2(g)$ [fast]

III
$N_2O_5(g) \rightleftharpoons NO_3(g) + NO_2(g)$ [fast]
$NO_2(g) + N_2O_5(g) \longrightarrow 3NO_2(g) + O(g)$ [slow]
$NO_3(g) + O(g) \longrightarrow NO_2(g) + O_2(g)$ [fast]

IV
$2N_2O_5(g) \rightleftharpoons 2NO_2(g) + N_2O_3(g) + 3O(g)$ [fast]
$N_2O_3(g) + O(g) \longrightarrow 2NO_2(g)$ [slow]
$2O(g) \longrightarrow O_2(g)$ [fast]

V
$2N_2O_5(g) \longrightarrow N_4O_{10}(g)$ [slow]
$N_4O_{10}(g) \longrightarrow 4NO_2(g) + O_2(g)$ [fast]

16.113 Nitrification is a biological process for removing NH_3 from wastewater as NH_4^+:

$$NH_4^+ + 2O_2 \longrightarrow NO_3^- + 2H^+ + H_2O$$

The first-order rate constant is given as

$$k_1 = 0.47e^{0.095(T - 15°C)}$$

where k_1 is in day^{-1} and T is in °C.

(a) If the initial concentration of NH_3 is 3.0 mol/m^3, how long will it take to reduce the concentration to 0.35 mol/m^3 in the spring (T = 20°C)? (b) In the winter (T = 10°C)? (c) Using your answer to part (a), what is the rate of O_2 consumption?

16.114 Carbon disulfide, a poisonous, flammable liquid, is an excellent solvent for phosphorus, sulfur, and some other nonmetals. A kinetic study of its gaseous decomposition reveals these data:

Experiment	Initial $[CS_2]$ (mol/L)	Initial Rate (mol/L·s)
1	0.100	2.7×10^{-7}
2	0.080	2.2×10^{-7}
3	0.055	1.5×10^{-7}
4	0.044	1.2×10^{-7}

(a) Write the rate law for the decomposition of CS_2.

(b) Calculate the average value of the rate constant.

16.115 Water exchanges between the human body and surroundings in a first-order process with an average $t_{1/2}$ of 11 days. (a) What is the rate constant in day^{-1}? (b) A person receives ^3H_2O, and the radioactive ^3H distributes uniformly throughout the body very rapidly. How long does it take for the radioactivity to be reduced by 90% ($t_{1/2}$ of ^3H is 12.3 yr)?

16.116 In a *clock reaction,* a dramatic color change occurs at a time determined by concentration and temperature. One of the most famous is the iodine clock reaction. The overall equation is

$$2I^-(aq) + S_2O_8^{2-}(aq) \longrightarrow I_2(aq) + 2SO_4^{2-}(aq)$$

As I_2 forms, it is immediately consumed by its reaction with a fixed amount of added $S_2O_3^{2-}$:

$$I_2(aq) + 2S_2O_3^{2-}(aq) \longrightarrow 2I^-(aq) + S_4O_6^{2-}(aq)$$

Once the $S_2O_3^{2-}$ is consumed, the excess I_2 forms a blue-black product with starch present in solution:

$$I_2 + \text{starch} \longrightarrow \text{starch}\cdot I_2 \text{ (blue-black)}$$

The rate of the reaction is also influenced by the total concentration of ions, so KCl and $(NH_4)_2SO_4$ are added to maintain a constant value. Use the data below to determine the following:

(a) The average rate for each trial

(b) The order with respect to each reactant

(c) The rate constant at 23°C

(d) The rate law for the overall reaction

	Exp't 1	Exp't 2	Exp't 3
0.200 *M* KI (mL)	10.0	20.0	20.0
0.100 *M* $Na_2S_2O_8$ (mL)	20.0	20.0	10.0
0.0050 *M* $Na_2S_2O_3$ (mL)	10.0	10.0	10.0
0.200 *M* KCl (mL)	10.0	0.0	0.0
0.100 *M* $(NH_4)_2SO_4$ (mL)	0.0	0.0	10.0
Time to color (s)	29.0	14.5	14.5

16.117 Two oxidations start with O_2 at high pressure and a large excess of the solid being oxidized. One reaction is first order in O_2, and the other is second order in O_2. Both rate constants have the same numerical value, 1.7×10^{-3}, and each reaction starts with $[O_2]$ = 2.045 *M*.

(a) How much time does it take each reaction to consume $\frac{1}{2}$ of the O_2? Which takes longer?

(b) How much time does it take each reaction to consume $\frac{3}{4}$ of the O_2? Which takes longer?

(c) From graphs of concentration vs. time for each reaction, find the time when the O_2 concentrations are equal.

16.118 The mathematics of the first-order rate law can be applied to any situation in which a quantity decreases by a constant fraction per unit of time (or any other variable).

(a) As light moves through a solution, its intensity decreases per unit distance traveled in the solution. Show that

$$\ln\left(\frac{\text{intensity of light leaving the solution}}{\text{intensity of light entering the solution}}\right) = -\text{fraction of light removed per unit of length} \times \text{distance traveled in solution}$$

(b) The value of your savings declines under conditions of constant inflation. Show that

ln (value remaining) = −fraction lost per unit of time × savings time interval

16.119 The growth of *Pseudomonas* bacteria is modeled as a first-order process with k = 0.035 min^{-1} at 37°C. The initial *Pseudomonas* population density is 1.0×10^3 cells/L. (a) What is the population density after 2 h? (b) What is the time required for the population to go from 1.0×10^3 to 2.0×10^3 cells/ L?

16.120 Consider the following organic reaction, in which one halogen replaces another in an alkyl halide:

$$CH_3CH_2Br + KI \longrightarrow CH_3CH_2I + KBr$$

In acetone, this particular reaction goes to completion because KI is soluble in acetone but KBr is not. In the mechanism, I^- approaches the carbon *opposite* to the Br (see Figure 16.19, with I^- instead of OH^-). After Br^- has been replaced by I^- and precipitates as KBr, other I^- ions react with the ethyl iodide by the same mechanism.

(a) If we designate the carbon bonded to the halogen as C-1, what is the shape around C-1 and the hybridization of C-1 in ethyl iodide?

(b) In the transition state, one of the two lobes of the unhybridized 2*p* orbital of C-1 overlaps a *p* orbital of I, while the other lobe overlaps a *p* orbital of Br. What is the shape around C-1 and the hybridization of C-1 in the transition state?

(c) The deuterated reactant, CH_3CHDBr (where D is ^2H), has two optical isomers because C-1 is chiral. If the reaction is run with one of the isomers, the ethyl iodide is *not* optically active. Explain.

16.121 Another radioisotope of iodine, ^{131}I, is also used to study thyroid function (see Follow-up Problem 16.5). A patient is given a sample that is 1.7×10^{-4} *M* ^{131}I. If the half-life is 8.04 days, what fraction of the radioactivity remains after 30. days?

16.122 The effect of substrate concentration on the first-order microbial growth rate follows the Monod equation:

$$\mu = \frac{\mu_{max}\, S}{K_s + S}$$

where μ is the first-order growth rate (s^{-1}), μ_{max} is the maximum growth rate (s^{-1}), S is the substrate concentration (kg/m^3), and K_s is the half-saturation coefficient (kg/m^3). For $\mu_{max} = 1.5\times10^{-4}\ s^{-1}$ and K_s = 0.03 kg/m^3:

(a) Prepare a plot of μ vs. S for S between 0.0 and 1.0 kg/m^3.

(b) The initial population density is 5.0×10^3 cells/m^3. What is the density after 1.0 h, if the initial S is 0.30 kg/m^3?

(c) What is it if the initial S is 0.70 kg/m^3?

Escalator equilibrium. Like the continual up-and-down of people on an escalator, the forward and reverse steps of a chemical reaction can maintain constant concentrations by moving constant numbers of entities in both directions. In this chapter, you'll see how a system attains equilibrium, how we determine the extent of the process, and how these systems adapt to external forces.

17.6 Reaction Conditions and the Equilibrium State: Le Châtelier's Principle
- Change in Concentration
- Change in Pressure (Volume)
- Change in Temperature
- Lack of Effect of a Catalyst

Our study of kinetics in the previous chapter addressed one of three central questions in reaction chemistry, that of reaction rate, which also concerns mechanism. Now we turn to the second question, previewed in Chapter 4: how much product forms under a given set of starting concentrations and conditions? The principles of kinetics and equilibrium apply to different aspects of a reaction:

- Kinetics applies to the *speed* of a reaction, the concentration of product that appears (or of reactant that disappears) per unit time.
- Equilibrium applies to the *extent* of a reaction, the concentration of product that has appeared after an unlimited time, or once no further change occurs.

Just as reactions vary greatly in their speed, they also vary in their extent. A fast reaction may go almost completely or barely at all toward products. Consider the dissociation of an acid in water. In 1 *M* HCl, virtually all the hydrogen chloride molecules are dissociated into ions. In contrast, in 1 *M* CH_3COOH, fewer than 1% of the acetic acid molecules are dissociated at any given time. Yet both reactions take less than a second to reach completion. Similarly, some slow reactions eventually yield a large amount of product, whereas others yield very little. After a few years at ordinary temperatures, a steel water-storage tank will rust, and it will do so completely given enough time; but no matter how long you wait, the water inside will not decompose to hydrogen and oxygen.

Knowing the extent of a given reaction is crucial. How much product—medicine, polymer, or fuel—can you obtain from a particular reaction mixture? How can you adjust conditions to obtain more? If a reaction is slow but has a good yield, will a catalyst speed it up enough to make it useful?

IN THIS CHAPTER . . . We consider equilibrium principles in systems of gases and pure liquids and solids; we'll discuss various solution equilibria in the next two chapters. Throughout these chapters, you'll learn how to solve the major kinds of equilibrium problems. We first examine the equilibrium state at the macroscopic and molecular levels. Then we focus on the relation between the reaction quotient, which changes as the reaction proceeds, and the equilibrium constant, which applies to the system at equilibrium. We express the equilibrium condition in terms of concentrations or pressures. Then we see how to determine whether a system is proceeding toward products or reactants as it approaches equilibrium. We examine how reaction conditions affect the equilibrium state and end with applications of equilibrium in metabolism and in industrial production.

Concepts & Skills to Review

before you study this chapter

- reversibility of reactions (Section 4.7)
- equilibrium vapor pressure (Section 12.2)
- equilibrium nature of a saturated solution (Section 13.4)
- dependence of rate on concentration (Sections 16.2 and 16.6)
- rate laws for elementary reactions (Section 16.7)
- function of a catalyst (Section 16.8)

17.1 THE EQUILIBRIUM STATE AND THE EQUILIBRIUM CONSTANT

Countless experiments with chemical systems have shown that, in a state of equilibrium, *the concentrations of reactants and products no longer change with time.* This apparent cessation of chemical activity occurs because *all reactions are reversible.* Let's examine a chemical system at the macroscopic and molecular levels to see how the equilibrium state arises. The system consists of two gases, colorless dinitrogen tetraoxide and brown nitrogen dioxide:

$$N_2O_4(g;\ \text{colorless}) \rightleftharpoons 2NO_2(g;\ \text{brown})$$

When we introduce some $N_2O_4(l)$ into a sealed flask kept at 200°C, a change occurs immediately. The liquid vaporizes (bp = 21°C) and the gas begins to turn pale brown. The color slowly darkens, but after a few moments, the color stops changing, as shown in Figure 17.1 on the next page.

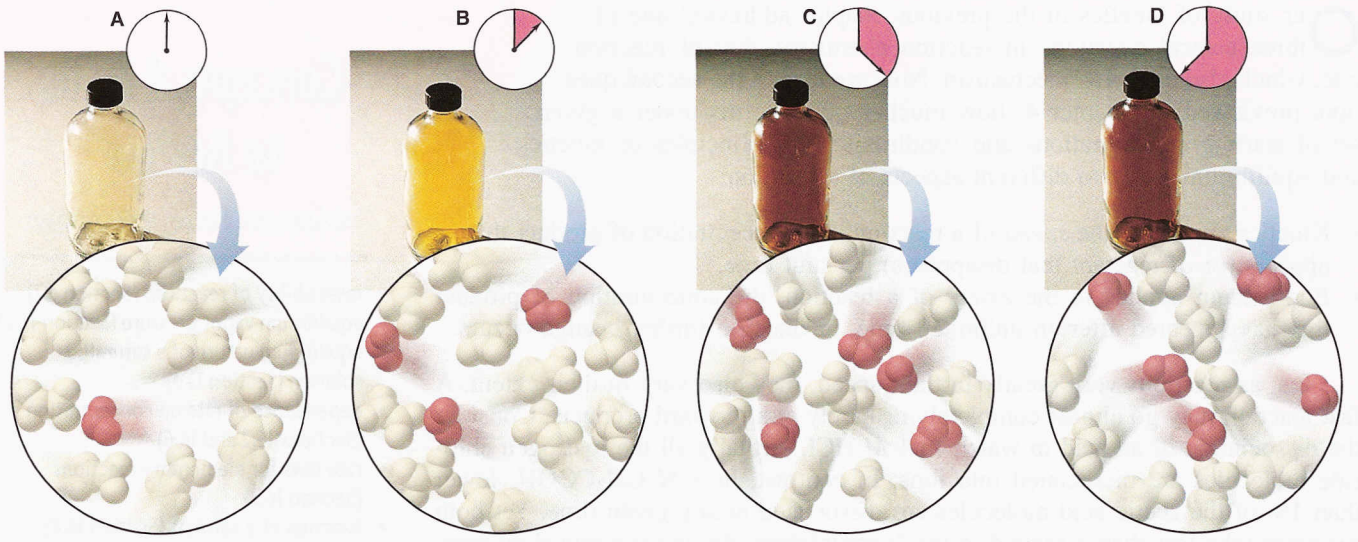

Figure 17.1 Reaching equilibrium on the macroscopic and molecular levels. A, When the experiment begins, the reaction mixture consists mostly of colorless N_2O_4. **B,** As N_2O_4 decomposes to reddish brown NO_2, the color of the mixture becomes pale brown. **C,** When equilibrium is reached, the concentrations of NO_2 and N_2O_4 are constant, and the color reaches its final intensity. **D,** Because the reaction continues in the forward and reverse directions at equal rates, the concentrations (and color) remain constant.

Now we repeat the process, and as we close in on the molecular level, a much more dynamic scene unfolds. The N_2O_4 molecules fly wildly throughout the flask, a few splitting into two NO_2 molecules. As time passes, more N_2O_4 molecules decompose and the concentration of NO_2 rises. As observers in the macroscopic world, we see the flask contents darken, because NO_2 is reddish brown. As the number of N_2O_4 molecules decreases, N_2O_4 decomposition slows. At the same time, increasing numbers of NO_2 molecules collide and combine, so re-formation of N_2O_4 speeds up. Eventually, N_2O_4 molecules decompose into NO_2 molecules as fast as the NO_2 molecules combine into N_2O_4. The system has reached equilibrium: *reactant and product concentrations stop changing because the forward and reverse rates have become equal:*

$$\text{At equilibrium: } \text{rate}_{\text{fwd}} = \text{rate}_{\text{rev}} \tag{17.1}$$

Thus, a system at equilibrium continues to be dynamic at the molecular level, but we observe *no further* ***net*** *change because changes in one direction are balanced by changes in the other.*

At a particular temperature, when the system reaches equilibrium, product and reactant concentrations are constant. Therefore, their ratio must be a constant. We'll use the N_2O_4-NO_2 system to derive this constant. At equilibrium, we have

$$\text{rate}_{\text{fwd}} = \text{rate}_{\text{rev}}$$

In this case, both forward and reverse reactions are elementary steps (Section 16.7), so we can write their rate laws directly from the balanced equation:

$$k_{\text{fwd}}[N_2O_4]_{\text{eq}} = k_{\text{rev}}[NO_2]^2_{\text{eq}}$$

where k_{fwd} and k_{rev} are the forward and reverse rate constants, respectively, and the subscript "eq" refers to concentrations at equilibrium. By rearranging, we set the ratio of the rate constants equal to the ratio of the concentration terms:

$$\frac{k_{\text{fwd}}}{k_{\text{rev}}} = \frac{[NO_2]^2_{\text{eq}}}{[N_2O_4]_{\text{eq}}}$$

The ratio of constants gives rise to a new overall constant called the **equilibrium constant (*K*):**

$$K = \frac{k_{fwd}}{k_{rev}} = \frac{[NO_2]^2_{eq}}{[N_2O_4]_{eq}} \qquad (17.2)$$

The equilibrium constant K is a number equal to a particular ratio of equilibrium concentrations of product and reactant at a particular temperature. We examine this idea closely in the next section and show that it holds as well for overall reactions made up of several elementary steps.

The magnitude of K is an indication of how far a reaction proceeds toward product at a given temperature. Remember, it is the opposing *rates* that are equal at equilibrium, not necessarily the concentrations. Indeed, different reactions, even at the same temperature, have a wide range of concentrations at equilibrium—from almost all reactant to almost all product—and, therefore, they have a wide range of equilibrium constants (Figure 17.2). Here are three examples of different magnitudes of *K*:

1. *Small K.* If a reaction yields very little product before reaching equilibrium, it has a small *K*, and we may even say there is "no reaction." For example, the oxidation of nitrogen barely proceeds at 1000 K:*

$$N_2(g) + O_2(g) \rightleftharpoons 2NO(g) \qquad K = 1\times10^{-30}$$

2. *Large K.* Conversely, if a reaction reaches equilibrium with very little reactant remaining, it has a large *K*, and we say it "goes to completion." The oxidation of carbon monoxide goes to completion at 1000 K:

$$2CO(g) + O_2(g) \rightleftharpoons 2CO_2(g) \qquad K = 2.2\times10^{22}$$

3. *Intermediate K.* When significant amounts of both reactant and product are present at equilibrium, *K* has an intermediate value, as when bromine monochloride breaks down to its elements at 1000 K:

$$2BrCl(g) \rightleftharpoons Br_2(g) + Cl_2(g) \qquad K = 5$$

*To distinguish the equilibrium constant from the Kelvin temperature unit, the equilibrium constant is written with an uppercase italic *K*, whereas the kelvin is an uppercase roman K. Also, since the kelvin is a unit, it always follows a number.

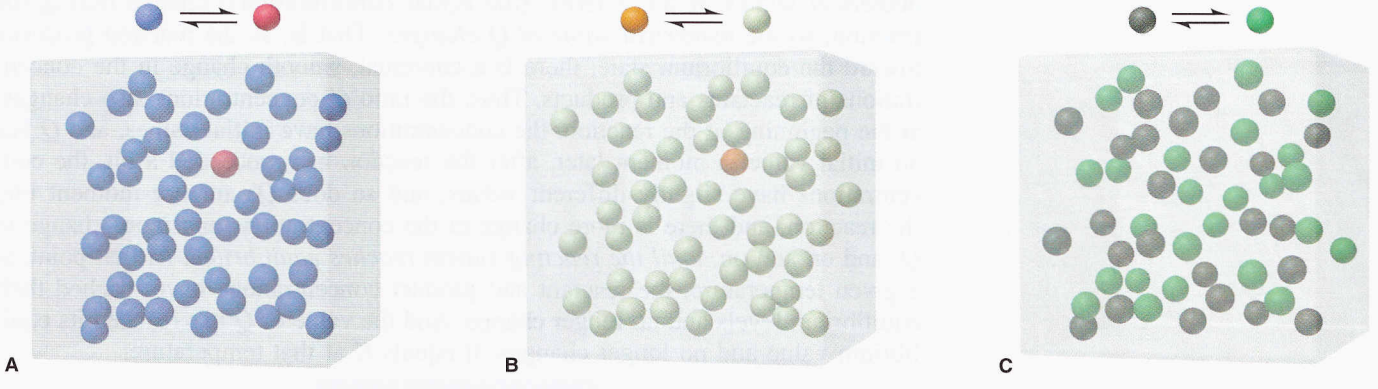

Figure 17.2 The range of equilibrium constants. A, A system that reaches equilibrium with very little product has a small *K*. For this reaction, $K = 1/49 = 0.020$. **B,** A system that reaches equilibrium with nearly all product has a large *K*. For this reaction, $K = 49/1 = 49$. **C,** A system that reaches equilibrium with significant concentrations of reactant and product has an intermediate *K*. For this reaction, $K = 25/25 = 1.0$.

SECTION SUMMARY

Kinetics and equilibrium are distinct aspects of a reaction system; that is, rate and yield are not necessarily related. When the forward and reverse reactions occur at the same rate, the system has reached dynamic equilibrium and concentrations no longer change. The equilibrium constant (K) is a number based on a particular ratio of product and reactant concentrations. K is small for reactions that reach equilibrium with a high concentration of reactant(s) and large for reactions that reach equilibrium with a low concentration of reactant(s).

17.2 THE REACTION QUOTIENT AND THE EQUILIBRIUM CONSTANT

Our derivation of the equilibrium constant in Section 17.1 was based on kinetics. But the fundamental observation of equilibrium studies was stated many years before the principles of kinetics were developed. In 1864, two Norwegian chemists, Cato Guldberg and Peter Waage, observed that *at a given temperature, a chemical system reaches a state in which a particular ratio of reactant and product concentrations has a constant value*. This is one way of stating the **law of chemical equilibrium,** or the **law of mass action.** No mention of rates appears.

In their discovery of the law of mass action, Guldberg and Waage studied many reactions in which reactant and product concentrations varied widely. They found that, *for a particular system and temperature, the same equilibrium state is attained regardless of how the reaction is run.* For example, in the N_2O_4-NO_2 system at 200°C, we can start with pure reactant (N_2O_4), pure product (NO_2), or any mixture of NO_2 and N_2O_4, and the ratio of concentrations will attain the same equilibrium value (within experimental error).

The particular ratio of concentration terms that we write for a given reaction is called the **reaction quotient (*Q*,** or **mass-action expression).** For the breakdown of N_2O_4 to form NO_2, the reaction quotient, which is based directly on the balanced equation, is

$$Q = \frac{[NO_2]^2}{[N_2O_4]}$$

Although the reactant and product concentration *terms* in Q remain the same, the numerical *values* of those terms (the actual concentrations) change during the reaction, so the *numerical value of Q changes*. That is, as the reaction proceeds toward the equilibrium state, there is a continual, smooth change in the concentrations of reactants and products. Thus, the ratio of concentrations also changes: at the beginning of the reaction, the concentrations have initial values, and Q has an initial value; a moment later, after the reaction has proceeded a bit, the concentrations have slightly different values, and so does Q; another moment into the reaction, and there is more change in the concentrations and more change in Q; and on and on, *until the reacting system reaches equilibrium*. At that point, at a given temperature, the reactant and product concentrations have reached their equilibrium levels and no longer change. And the value of Q has reached its equilibrium value and no longer changes. It equals K at that temperature:

$$\text{At equilibrium: } Q = K \qquad (17.3)$$

So, monitoring Q tells whether the system has reached equilibrium, how far away it is if it has not, and, as we discuss later, in which direction it is changing to reach equilibrium. Table 17.1 presents four experiments, each a different run of the N_2O_4-NO_2 reaction at 200°C. The two essential points to note are:

Table 17.1 Initial and Equilibrium Concentration Ratios for the N_2O_4-NO_2 System at 200°C (473 K)

	Initial		Ratio (Q)	Equilibrium		Ratio (K)
Exp't.	$[N_2O_4]$	$[NO_2]$	$[NO_2]^2/[N_2O_4]$	$[N_2O_4]_{eq}$	$[NO_2]_{eq}$	$[NO_2]_{eq}^2/[N_2O_4]_{eq}$
1	0.1000	0.0000	0.0000	0.00357	0.193	10.4
2	0.0000	0.1000	∞	9.24×10^{-4}	9.82×10^{-2}	10.4
3	0.0500	0.0500	0.0500	0.00204	0.146	10.4
4	0.0750	0.0250	0.00833	0.00275	0.170	10.5

- The ratio of *initial* concentrations varies widely but always gives the same ratio of *equilibrium* concentrations.
- The *individual* equilibrium concentrations are different in each case, but the *ratio* of these equilibrium concentrations is constant.

The curves in Figure 17.3 show experiment 1 in Table 17.1. Note that $[N_2O_4]$ and $[NO_2]$ change smoothly during the course of the reaction and, thus, so does the value of Q. Once the system reaches equilibrium, as indicated by the constant brown color, the concentrations no longer change and Q equals K. In other words, for any given chemical system, *K is a special value of Q that occurs when the reactant and product terms have their equilibrium values.*

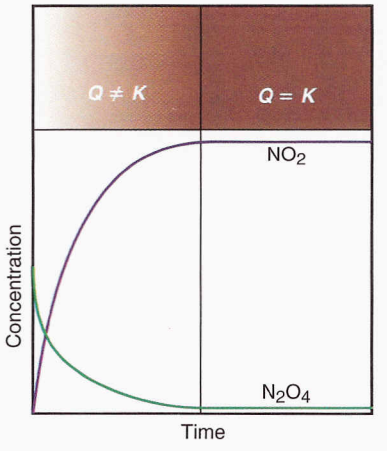

Figure 17.3 The change in Q during the N_2O_4-NO_2 reaction. The curved plots and the darkening brown screen above them show that $[N_2O_4]$ and $[NO_2]$, and therefore the value of Q, change with time. Before equilibrium is reached, the concentrations are changing continuously, so $Q \neq K$. Once equilibrium is reached (*vertical line*) and any time thereafter, $Q = K$.

Writing the Reaction Quotient

In Chapter 16, you saw that the rate law for an overall reaction cannot be written from the balanced equation, but must be determined from rate data. In contrast, the reaction quotient *can* be written directly from the balanced equation: *Q is a ratio made up of product concentration terms multiplied together and divided by reactant concentration terms multiplied together, with each term raised to the power of its stoichiometric coefficient in the balanced equation.*

The most common form of the reaction quotient shows reactant and product terms as molar concentrations, which are designated by square brackets, [ ]. In these cases, which you've seen so far, K is the *equilibrium constant based on concentrations*, designated from now on as K_c. Similarly, we designate the reaction quotient based on concentrations as Q_c. For the general balanced equation

$$aA + bB \rightleftharpoons cC + dD$$

where a, b, c, and d are the stoichiometric coefficients, the reaction quotient is

$$Q_c = \frac{[C]^c[D]^d}{[A]^a[B]^b} \qquad (17.4)$$

(Another form of the reaction quotient that we discuss later shows gaseous reactant and product terms as pressures.)

To construct the reaction quotient for any reaction, write the balanced equation first. For the formation of ammonia from its elements, for example, the balanced equation (with colored coefficients for easy reference) is

$$N_2(g) + 3H_2(g) \rightleftharpoons 2NH_3(g)$$

To construct the reaction quotient, we place the product term in the numerator and the reactant terms in the denominator, multiplied by each other, and raise each term to the power of its balancing coefficient (colored here as in the equation):

$$Q_c = \frac{[NH_3]^2}{[N_2][H_2]^3}$$

Let's practice this essential skill.

SAMPLE PROBLEM 17.1 Writing the Reaction Quotient from the Balanced Equation

Problem Write the reaction quotient, Q_c, for each of the following reactions:
(a) The decomposition of dinitrogen pentaoxide, $N_2O_5(g) \rightleftharpoons NO_2(g) + O_2(g)$
(b) The combustion of propane gas, $C_3H_8(g) + O_2(g) \rightleftharpoons CO_2(g) + H_2O(g)$
Plan We balance the equations and then construct the reaction quotient (Equation 17.4).

Solution **(a)** $2N_2O_5(g) \rightleftharpoons 4NO_2(g) + O_2(g) \quad Q_c = \dfrac{[NO_2]^4[O_2]}{[N_2O_5]^2}$

(b) $C_3H_8(g) + 5O_2(g) \rightleftharpoons 3CO_2(g) + 4H_2O(g) \quad Q_c = \dfrac{[CO_2]^3[H_2O]^4}{[C_3H_8][O_2]^5}$

Check Always be sure that the exponents in Q are the same as the balancing coefficients. A good check is to reverse the process: turn the numerator into products and the denominator into reactants, and change the exponents to coefficients.

FOLLOW-UP PROBLEM 17.1 Write a reaction quotient, Q_c, for each of the following reactions (unbalanced):
(a) The first step in nitric acid production, $NH_3(g) + O_2(g) \rightleftharpoons NO(g) + H_2O(g)$
(b) The disproportionation of nitric oxide, $NO(g) \rightleftharpoons N_2O(g) + NO_2(g)$

Variations in the Form of the Reaction Quotient

As you'll see in the upcoming discussion, the reaction quotient Q is a collection of terms based on the balanced equation *exactly as written* for a given reaction. Therefore, the value of Q, which varies during the reaction, and the value of K, the constant value of Q when the system has reached equilibrium, also depend on how the balanced equation is written.

A Word about Units for *Q* and *K* In this text (and most others), *the values of Q and K are shown as unitless numbers*. This is because each term in the reaction quotient represents the *ratio* of the measured quantity of the substance (molar concentration or pressure) to the thermodynamic standard-state quantity of the substance. Recall from Section 6.6 that these standard states are 1 M for a substance in solution, 1 atm for gases, and the pure substance for a liquid or solid. Thus, a concentration of 1.20 M becomes $\dfrac{1.20\ M}{1\ M} = 1.20$; similarly, a pressure of 0.53 atm becomes $\dfrac{0.53\ \text{atm}}{1\ \text{atm}} = 0.53$. (As you'll see shortly, the molar "concentration" of a pure liquid or solid, that is, the number of moles per liter of the substance, is a constant, and the term does not appear in Q at all.) With these quantity terms unitless, the ratio of terms we use to find the value of Q (or K) is also unitless.

Form of *Q* for an Overall Reaction Notice that we've been writing reaction quotients without knowing whether an equation represents an individual reaction step or an overall multistep reaction. We can do this because we obtain the same expression for the overall reaction as we do when we combine the expressions for the individual steps. That is, *if an overall reaction is the **sum** of two or more reactions, the overall reaction quotient (or equilibrium constant) is the **product** of the reaction quotients (or equilibrium constants) for the steps:*

$$Q_{\text{overall}} = Q_1 \times Q_2 \times Q_3 \times \cdots$$

and

$$K_{\text{overall}} = K_1 \times K_2 \times K_3 \times \cdots \qquad (17.5)$$

Sample Problem 17.2 demonstrates this point.

SAMPLE PROBLEM 17.2 Writing the Reaction Quotient for an Overall Reaction

Problem Understanding reactions involving normal components of air is essential for solving problems dealing with atmospheric pollution. Here is a reaction sequence involving N_2 and O_2, the most abundant gases in air. Nitrogen dioxide is a toxic pollutant that contributes to photochemical smog (see photo).

(1) $N_2(g) + O_2(g) \rightleftharpoons 2NO(g)$ $\quad K_{c1} = 4.3\times10^{-25}$

(2) $2NO(g) + O_2(g) \rightleftharpoons 2NO_2(g)$ $\quad K_{c2} = 6.4\times10^{9}$

(a) Show that the overall Q_c for this reaction sequence is the same as the product of the Q_c's for the individual reactions.

(b) Given that the K_c's occur at the same temperature, find K_c for the overall reaction.

Plan In **(a)**, we first write the overall reaction by adding the individual reactions and then write the overall Q_c. Next, we write the Q_c for each reaction. Because we *add* the individual steps, we *multiply* their Q_c's and cancel common terms to obtain the overall Q_c. In **(b)**, we are given the individual K_c values (4.3×10^{-25} and 6.4×10^{9}), so we multiply them to find $K_{c(overall)}$.

Solution **(a)** Writing the overall reaction and its reaction quotient:

$$\begin{array}{ll} (1) & N_2(g) + O_2(g) \rightleftharpoons \cancel{2NO(g)} \\ (2) & \cancel{2NO(g)} + O_2(g) \rightleftharpoons 2NO_2(g) \\ \hline \text{Overall:} & N_2(g) + 2O_2(g) \rightleftharpoons 2NO_2(g) \end{array}$$

$$Q_{c(overall)} = \frac{[NO_2]^2}{[N_2][O_2]^2}$$

Writing the reaction quotients for the individual steps:

For step 1, $$Q_{c1} = \frac{[NO]^2}{[N_2][O_2]}$$

For step 2, $$Q_{c2} = \frac{[NO_2]^2}{[NO]^2[O_2]}$$

Multiplying the individual reaction quotients and canceling:

$$Q_{c1} \times Q_{c2} = \frac{\cancel{[NO]^2}}{[N_2][O_2]} \times \frac{[NO_2]^2}{\cancel{[NO]^2}[O_2]} = \frac{[NO_2]^2}{[N_2][O_2]^2} = Q_{c(overall)}$$

(b) Calculating the overall K_c:

$$K_{c(overall)} = K_{c1} \times K_{c2} = (4.3\times10^{-25})(6.4\times10^{9}) = 2.8\times10^{-15}$$

Check Round off and check the calculation in part (b):

$$K_c \approx (4\times10^{-25})(6\times10^{9}) = 24\times10^{-16} = 2.4\times10^{-15}$$

Smog over Los Angeles.

FOLLOW-UP PROBLEM 17.2

The following sequence of individual steps has been proposed for the overall reaction between H_2 and Br_2 to form HBr:

(1) $Br_2(g) \rightleftharpoons 2Br(g)$

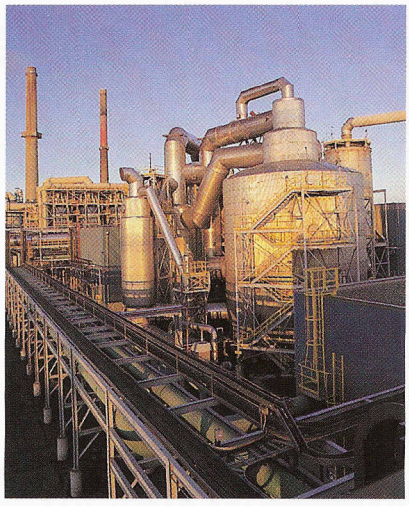
(2) $Br(g) + H_2(g) \rightleftharpoons HBr(g) + H(g)$

(3) $H(g) + Br(g) \rightleftharpoons HBr(g)$

Write the overall balanced equation and show that the overall Q_c is the product of the Q_c's for the individual steps.

Form of *Q* for a Forward and Reverse Reaction The form of the reaction quotient depends on the *direction* in which the balanced equation is written. Consider, for example, the oxidation of sulfur dioxide to sulfur trioxide. This reaction is a key step in acid rain formation and sulfuric acid production (see photo). The balanced equation is

$$2SO_2(g) + O_2(g) \rightleftharpoons 2SO_3(g)$$



A sulfuric acid manufacturing plant.

The reaction quotient for this equation *as written* is

$$Q_{c(fwd)} = \frac{[SO_3]^2}{[SO_2]^2[O_2]}$$

If we had written the reverse reaction, the decomposition of sulfur trioxide,

$$2SO_3(g) \rightleftharpoons 2SO_2(g) + O_2(g)$$

the reaction quotient would be the *reciprocal* of $Q_{c(fwd)}$:

$$Q_{c(rev)} = \frac{[SO_2]^2[O_2]}{[SO_3]^2} = \frac{1}{Q_{c(fwd)}}$$

Thus, *a reaction quotient (or equilibrium constant) for a forward reaction is the* ***reciprocal*** *of the reaction quotient (or equilibrium constant) for the reverse reaction:*

$$Q_{c(fwd)} = \frac{1}{Q_{c(rev)}} \quad \text{and} \quad K_{c(fwd)} = \frac{1}{K_{c(rev)}} \tag{17.6}$$

The K_c values for the forward and reverse reactions at 1000 K are

$$K_{c(fwd)} = 261 \quad \text{and} \quad K_{c(rev)} = \frac{1}{K_{c(fwd)}} = \frac{1}{261} = 3.83\times10^{-3}$$

These values make sense: if the forward reaction goes far to the right (high K_c), the reverse reaction does not (low K_c).

Form of *Q* for a Reaction with Coefficients Multiplied by a Common Factor

Multiplying all the coefficients of the equation by some factor also changes the form of Q. For example, multiplying all the coefficients in the previous equation for the formation of SO_3 by $\frac{1}{2}$ gives

$$SO_2(g) + \tfrac{1}{2}O_2(g) \rightleftharpoons SO_3(g)$$

For this equation, the reaction quotient is

$$Q'_{c(fwd)} = \frac{[SO_3]}{[SO_2][O_2]^{1/2}}$$

Notice that Q_c for the halved equation equals Q_c for the original equation raised to the $\frac{1}{2}$ power:

$$Q'_{c(fwd)} = Q_{c(fwd)}^{1/2} = \left(\frac{[SO_3]^2}{[SO_2]^2[O_2]}\right)^{1/2} = \frac{[SO_3]}{[SO_2][O_2]^{1/2}}$$

Once again, the same property holds for the equilibrium constants. Relating the halved reaction to the original, we have

$$K'_{c(fwd)} = K_{c(fwd)}^{1/2} = (261)^{1/2} = 16.2$$

Similarly, if you double coefficients, the reaction quotient is the original expression squared; if you triple coefficients, it is the original expression cubed; and so on. It may seem that we have changed the extent of the reaction, as indicated by a change in K, merely by changing the balancing coefficients of the equation, but this clearly cannot be true. *A particular K has meaning only in relation to a particular balanced equation.* In this case, $K_{c(fwd)}$ and $K'_{c(fwd)}$ relate to different equations and thus cannot be compared directly.

In general, *if all the coefficients of the balanced equation are multiplied by some factor, that factor becomes the exponent for relating the reaction quotients and the equilibrium constants.* For a multiplying factor n, which we can write as

$$n(aA + bB \rightleftharpoons cC + dD)$$

the reaction quotient and equilibrium constant are

$$Q' = Q^n = \left(\frac{[C]^c[D]^d}{[A]^a[B]^b}\right)^n \quad \text{and} \quad K' = K^n \tag{17.7}$$

SAMPLE PROBLEM 17.3 Finding the Equilibrium Constant for an Equation Multiplied by a Common Factor

Problem For the ammonia-formation reaction,

$$N_2(g) + 3H_2(g) \rightleftharpoons 2NH_3(g)$$

the equilibrium constant, K_c, is 2.4×10^{-3} at 1000 K. If we change the coefficients of this equation, which we'll call the reference (ref) equation, what are the values of K_c for the following balanced equations?

(a) $\frac{1}{3}N_2(g) + H_2(g) \rightleftharpoons \frac{2}{3}NH_3(g)$ **(b)** $NH_3(g) \rightleftharpoons \frac{1}{2}N_2(g) + \frac{3}{2}H_2(g)$

Plan We compare each equation with the reference equation to see how the direction and coefficients have changed. In **(a),** the equation is the reference equation multiplied by $\frac{1}{3}$, so K_c equals $K_{c(ref)}$ (2.4×10^{-3}) raised to the $\frac{1}{3}$ power. In **(b),** the equation is one-half the *reverse* of the reference equation, so K_c is the reciprocal of $K_{c(ref)}$ raised to the $\frac{1}{2}$ power.

Solution The reaction quotient for the reference equation is $Q_{c(ref)} = \dfrac{[NH_3]^2}{[N_2][H_2]^3}$.

(a)
$$Q_c = Q_{c(ref)}^{1/3} = \left(\frac{[NH_3]^2}{[N_2][H_2]^3}\right)^{1/3} = \frac{[NH_3]^{2/3}}{[N_2]^{1/3}[H_2]}$$

Thus,
$$K_c = K_{c(ref)}^{1/3} = (2.4\times10^{-3})^{1/3} = 0.13$$

(b)
$$Q_c = \left(\frac{1}{Q_{c(ref)}}\right)^{1/2} = \left(\frac{1}{\dfrac{[NH_3]^2}{[N_2][H_2]^3}}\right)^{1/2} = \frac{[N_2]^{1/2}[H_2]^{3/2}}{[NH_3]}$$

Thus,
$$K_c = \left(\frac{1}{K_{c(ref)}}\right)^{1/2} = \left(\frac{1}{2.4\times10^{-3}}\right)^{1/2} = 20.$$

Check A good check is to work the math backward. For **(a),** $(0.13)^3 = 2.2\times10^{-3}$, within rounding of 2.4×10^{-3}. The reaction goes in the same direction, so at equilibrium, there should be mostly reactants, as $K_c < 1$ indicates. For **(b),** $1/(20.)^2 = 2.5\times10^{-3}$, again within rounding. At equilibrium, the reverse reaction should yield mostly products, as $K_c > 1$ indicates.

FOLLOW-UP PROBLEM 17.3 At 1200 K, the reaction of hydrogen and chlorine to form hydrogen chloride is

$$H_2(g) + Cl_2(g) \rightleftharpoons 2HCl(g) \qquad K_c = 7.6\times10^8$$

Calculate K_c for the following reactions:

(a) $\frac{1}{2}H_2(g) + \frac{1}{2}Cl_2(g) \rightleftharpoons HCl(g)$ **(b)** $\frac{4}{3}HCl(g) \rightleftharpoons \frac{2}{3}H_2(g) + \frac{2}{3}Cl_2(g)$

Form of *Q* for a Reaction Involving Pure Liquids and Solids Until now, we've looked at *homogeneous* equilibria, systems in which all the components of the reaction are in the same phase, such as a system of reacting gases. When the components are in different phases, the system reaches *heterogeneous* equilibrium.

Consider the decomposition of limestone to lime and carbon dioxide, in which a gas and two solids make up the reaction components:

$$CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g)$$

Based on the rules for writing the reaction quotient, we have

$$Q_c = \frac{[CaO][CO_2]}{[CaCO_3]}$$

A pure solid, however, such as $CaCO_3$ or CaO, always has the same *concentration* at a given temperature, that is, the same number of moles per liter of the solid, just as it has the same density (g/cm^3) at a given temperature. Moreover, a solid's volume changes very little with temperature, so its concentration also changes very little. For these reasons, the concentration of a pure solid is constant, and the same argument applies to the concentration of a pure liquid.

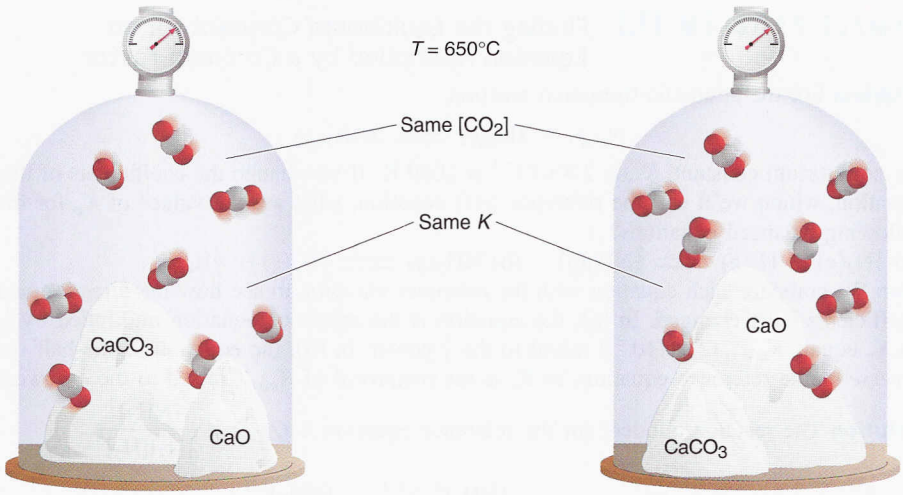


Figure 17.4 The reaction quotient for a heterogeneous system. Even though the two containers have different amounts of the two solids CaO and $CaCO_3$, as long as both solids are present, at a given temperature, the containers have the same $[CO_2]$ at equilibrium.

Because we are concerned only with concentrations that *change* as they approach equilibrium, *we eliminate the terms for pure liquids and solids from the reaction quotient*. We do this by incorporating their constant concentrations into a rearranged reaction quotient, Q'_c. We multiply both sides of the equation by $[CaCO_3]$ and divide both sides by [CaO]. Thus, the only substance whose concentration can change is the gas CO_2:

$$Q'_c = Q_c \frac{[CaCO_3]}{[CaO]} = [CO_2]$$

No matter how much CaO and $CaCO_3$ are in the reaction vessel, *as long as some of each is present*, the reaction quotient for the reaction equals the CO_2 concentration (Figure 17.4).

Table 17.2 summarizes the ways of writing Q and calculating K.

Table 17.2 Ways of Expressing Q and Calculating K

Form of Chemical Equation	Form of Q	Value of K
Reference reaction: A $\rightleftharpoons$ B	$Q_{(ref)} = \frac{[B]}{[A]}$	$K_{(ref)} = \frac{[B]_{eq}}{[A]_{eq}}$
Reverse reaction: B $\rightleftharpoons$ A	$Q = \frac{1}{Q_{(ref)}} = \frac{[A]}{[B]}$	$K = \frac{1}{K_{(ref)}}$
Reaction as sum of two steps: (1) A $\rightleftharpoons$ C	$Q_1 = \frac{[C]}{[A]}; Q_2 = \frac{[B]}{[C]}$	
(2) C $\rightleftharpoons$ B	$Q_{overall} = Q_1 \times Q_2 = Q_{(ref)} = \frac{\cancel{[C]}}{[A]} \times \frac{[B]}{\cancel{[C]}} = \frac{[B]}{[A]}$	$K_{overall} = K_1 \times K_2 = K_{(ref)}$
Coefficients multiplied by n	$Q = Q^n_{(ref)}$	$K = K^n_{(ref)}$
Reaction with pure solid or liquid component, such as A(s)	$Q = Q_{(ref)}[A] = [B]$	$K = K_{(ref)}[A] = [B]$

SECTION SUMMARY

The reaction quotient, *Q*, is a particular ratio of product to reactant terms. Substituting experimental values into this expression gives the value of *Q*, which changes as the reaction proceeds. When the system reaches equilibrium at a particular temperature, $Q = K$. If a reaction is the sum of two or more steps, the overall *Q* (or *K*) is the product of the individual *Q*'s (or *K*'s). The *form* of *Q* is based directly on the balanced equation for the reaction exactly as written, so it changes if the equation is reversed or multiplied by some factor, and *K* changes accordingly. Pure liquids or solids do not appear as terms in the expression for *Q* because their concentrations are constant.

17.3 EXPRESSING EQUILIBRIA WITH PRESSURE TERMS: RELATION BETWEEN K_c AND K_p

It is easier to measure the pressure of a gas than its concentration and, as long as the gas behaves ideally under the conditions of the experiment, the ideal gas law (Section 5.3) allows us to relate these variables to each other:

$$PV = nRT, \quad \text{so} \quad P = \frac{n}{V}RT \quad \text{or} \quad \frac{P}{RT} = \frac{n}{V}$$

where *P* is the pressure of a gas and n/V is its molar concentration (M). Thus, with *R* a constant and *T* kept constant, *pressure is directly proportional to molar concentration*. When the substances involved in the reaction are gases, we can express the reaction quotient and calculate its value in terms of partial pressures instead of concentrations. For example, in the reaction between gaseous NO and O_2,

$$2NO(g) + O_2(g) \rightleftharpoons 2NO_2(g)$$

the reaction quotient based on partial pressures, Q_p, is

$$Q_p = \frac{P_{NO_2}^2}{P_{NO}^2 \times P_{O_2}}$$

(In later chapters, you'll see cases where some reaction components are expressed as concentrations and others as partial pressures.) The equilibrium constant obtained when all components are present at their equilibrium partial pressures is designated K_p, the *equilibrium constant based on pressures*. In many cases, K_p has a value different from K_c, but the two constants are related; thus, if you know one, you can calculate the other by noting the *change in amount (mol) of gas*, Δn_{gas}, from the balanced equation. Let's see this relationship by converting the terms in Q_c for the reaction of NO and O_2 to those in Q_p:

$$2NO(g) + O_2(g) \rightleftharpoons 2NO_2(g)$$

As the balanced equation shows,

$$3 \text{ mol (2 mol + 1 mol) gaseous reactants} \rightleftharpoons 2 \text{ mol gaseous products}$$

With Δ meaning final minus initial (products minus reactants), we have

$$\Delta n_{gas} = \text{moles of gaseous product} - \text{moles of gaseous reactant} = 2 - 3 = -1$$

Keep this value of Δn_{gas} in mind because it appears in the algebraic conversion that follows. The reaction quotient based on concentrations is

$$Q_c = \frac{[NO_2]^2}{[NO]^2[O_2]}$$

Using the ideal gas law as $n/V = P/RT$, we first express concentrations as n/V and convert them to partial pressures, *P*; then we collect the *RT* terms and cancel:

$$Q_c = \frac{\frac{n_{NO_2}^2}{V^2}}{\frac{n_{NO}^2}{V^2} \times \frac{n_{O_2}}{V}} = \frac{\frac{P_{NO_2}^2}{(RT)^2}}{\frac{P_{NO}^2}{(RT)^2} \times \frac{P_{O_2}}{RT}} = \frac{P_{NO_2}^2}{P_{NO}^2 \times P_{O_2}} \times \frac{\frac{1}{(RT)^2}}{\frac{1}{(RT)^2} \times \frac{1}{RT}} = \frac{P_{NO_2}^2}{P_{NO}^2 \times P_{O_2}} \times RT$$

The far right side of the previous expression is Q_p multiplied by RT: $Q_c = Q_p(RT)$. Also, at equilibrium, $K_c = K_p(RT)$; thus, $K_p = \dfrac{K_c}{RT}$, or $K_c(RT)^{-1}$.

Notice that *the exponent of the RT term equals the change in the amount (mol) of gas (Δn_{gas}) from the balanced equation, −1*. Thus, in general, we have

$$K_p = K_c(RT)^{\Delta n_{gas}} \qquad (17.8)$$

The units for the partial pressure terms in K_p are generally atmospheres, pascals, or torr, raised to some power, and the units of R must be consistent with those units. As Equation 17.8 shows, for those reactions in which the amount (mol) of gas does not change, we have $\Delta n_{gas} = 0$, so the RT term drops out and $K_p = K_c$.

SAMPLE PROBLEM 17.4 Converting Between K_c and K_p

Problem A chemical engineer injects limestone ($CaCO_3$) into the hot flue gas of a coal-burning power plant to form lime (CaO), which scrubs SO_2 from the gas and forms gypsum ($CaSO_4 \cdot 2H_2O$). Find K_c for the following reaction, if CO_2 pressure is in atmospheres:

$$CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g) \qquad K_p = 2.1\times10^{-4} \text{ (at 1000. K)}$$

Plan We know K_p (2.1×10^{-4}), so to convert between K_p and K_c, we must first determine Δn_{gas} from the balanced equation. Then we rearrange Equation 17.8. With gas pressure in atmospheres, R is 0.0821 atm·L/mol·K.

Solution Determining Δn_{gas}: There is 1 mol of gaseous product and no gaseous reactant, so $\Delta n_{gas} = 1 - 0 = 1$.

Rearranging Equation 17.8 and calculating K_c:

$$K_p = K_c(RT)^1 \qquad \text{so} \qquad K_c = K_p(RT)^{-1}$$

$$K_c = (2.1\times10^{-4})(0.0821 \times 1000.)^{-1} = 2.6\times10^{-6}$$

Check Work backward to see whether you obtain the given K_p:

$$K_p = (2.6\times10^{-6})(0.0821 \times 1000.) = 2.1\times10^{-4}$$

FOLLOW-UP PROBLEM 17.4 Calculate K_p for the following reaction:

$$PCl_3(g) + Cl_2(g) \rightleftharpoons PCl_5(g) \qquad K_c = 1.67 \text{ (at 500. K)}$$

SECTION SUMMARY

The reaction quotient and the equilibrium constant can be expressed in terms of concentrations (Q_c and K_c); for gases, they are expressed in terms of partial pressures (Q_p and K_p). The values of K_p and K_c are related by using the ideal gas law: $K_p = K_c(RT)^{\Delta n_{gas}}$.

17.4 REACTION DIRECTION: COMPARING *Q* AND *K*

Suppose you start a reaction with a mixture of reactants and products and you know the equilibrium constant at the temperature of the reaction. How do you know if the reaction has reached equilibrium? And, if it hasn't, how do you know in which direction it is progressing to reach equilibrium? The value of Q can change; thus, at any particular time during the reaction, Q can be smaller than K, larger than K, or, when the system reaches equilibrium, equal to K. By comparing the value of Q at a particular time with the known K, you can tell whether the reaction has attained equilibrium or, if not, in which direction it is progressing. With product terms in the numerator of Q and reactant terms in the denominator, *more product makes the ratio of terms larger, and more reactant makes the ratio smaller.*

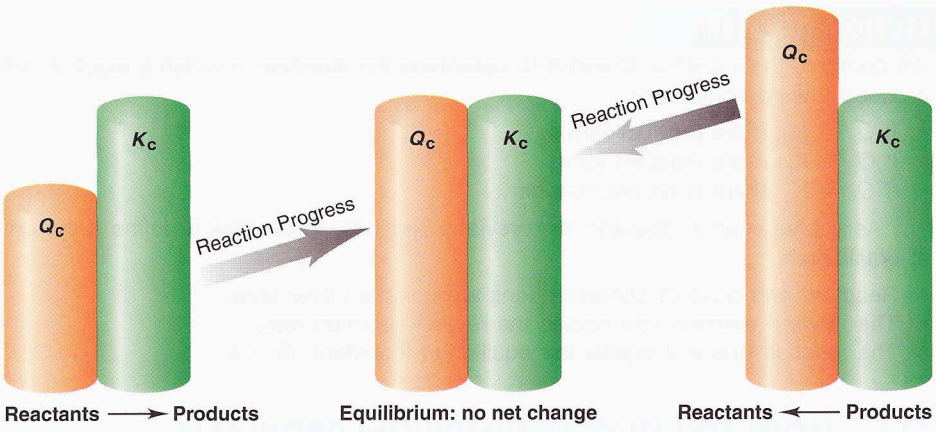

Figure 17.5 Reaction direction and the relative sizes of *Q* and *K*. When Q_c is smaller than K_c, the equilibrium of the reaction system shifts to the right, that is, toward products. When Q_c is larger than K_c, the equilibrium of the reaction system shifts to the left. Both shifts continue until $Q_c = K_c$. Note that the size of K_c remains the same throughout.

The three possible relative sizes of Q and K are shown in Figure 17.5.

- $Q < K$. If the value of Q is smaller than K, the denominator (reactants) is large relative to the numerator (products). For Q to become equal to K, the denominator must decrease and the numerator increase. In other words, the reaction will progress to the right, toward products, until equilibrium is reached:

$$\text{If } Q < K, \text{ reactants} \longrightarrow \text{products}$$

- $Q > K$. If Q is larger than K, the numerator (products) will decrease and the denominator (reactants) increase until equilibrium is reached. Therefore, the reaction will progress to the left, toward reactants:

$$\text{If } Q > K, \text{ reactants} \longleftarrow \text{products}$$

- $Q = K$. This situation exists only when the reactant and product concentrations (or pressures) have attained their equilibrium values. Thus, despite the dynamic processes occurring at the molecular level, no further net change occurs:

$$\text{If } Q = K, \text{ reactants} \rightleftharpoons \text{products}$$

SAMPLE PROBLEM 17.5 Comparing Q and K to Determine Reaction Direction

Problem For the reaction $N_2O_4(g) \rightleftharpoons 2NO_2(g)$, $K_c = 0.21$ at the lower temperature of 100°C. At a point during the reaction, $[N_2O_4] = 0.12\ M$ and $[NO_2] = 0.55\ M$. Is the reaction at equilibrium? If not, in which direction is it progressing?

Plan We write the expression for Q_c, find its value by substituting the given concentrations, and then compare its value with the given K_c.

Solution Writing the reaction quotient and solving for Q_c:

$$Q_c = \frac{[NO_2]^2}{[N_2O_4]} = \frac{0.55^2}{0.12} = 2.5$$

With $Q_c > K_c$, the reaction is not at equilibrium and will proceed to the left until $Q_c = K_c$.

Check With $[NO_2] > [N_2O_4]$, we expect to obtain a value for Q_c that is greater than 0.21. If $Q_c > K_c$, the numerator will decrease and the denominator will increase until $Q_c = K_c$; that is, this reaction will proceed toward reactants.

FOLLOW-UP PROBLEM 17.5 Chloromethane forms by the reaction

$$CH_4(g) + Cl_2(g) \rightleftharpoons CH_3Cl(g) + HCl(g)$$

At 1500 K, $K_p = 1.6\times10^4$. In the reaction mixture, $P_{CH_4} = 0.13$ atm, $P_{Cl_2} = 0.035$ atm, $P_{CH_3Cl} = 0.24$ atm, and $P_{HCl} = 0.47$ atm. Is CH_3Cl or CH_4 forming?

SECTION SUMMARY

We compare the values of Q and K to determine the direction in which a reaction will proceed toward equilibrium.

- If $Q_c < K_c$, more product forms.
- If $Q_c > K_c$, more reactant forms.
- If $Q_c = K_c$, there is no net change.

As you've seen in this and the previous sections, three criteria define a system at equilibrium:

- Reactant and product concentrations are constant over time.
- The forward reaction rate equals the reverse reaction rate.
- The reaction quotient equals the equilibrium constant: $Q = K$.

17.5 HOW TO SOLVE EQUILIBRIUM PROBLEMS

Many kinds of equilibrium problems arise in the real world, as well as on chemistry exams, but we can group most of them into two types:

1. In one type, we are given equilibrium quantities (concentrations or partial pressures) and solve for K.
2. In the other type, we are given K and initial quantities and solve for the equilibrium quantities.

Using Quantities to Determine the Equilibrium Constant

There are two common variations on the type of equilibrium problem in which we solve for K: one involves a straightforward substitution of quantities, and the other requires first finding some of the quantities.

Substituting Given Equilibrium Quantities into *Q* to Find *K* In the straightforward case, we are given the equilibrium quantities and we must calculate K.

Suppose, for example, that equal amounts of gaseous hydrogen and iodine are injected into a 1.50-L reaction flask at a fixed temperature. In time, the following equilibrium is attained:

$$H_2(g) + I_2(g) \rightleftharpoons 2HI(g)$$

At equilibrium, analysis shows that the flask contains 1.80 mol of H_2, 1.80 mol of I_2, and 0.520 mol of HI. We calculate K_c by finding the concentrations and substituting them into the reaction quotient. From the balanced equation, we write the reaction quotient:

$$Q_c = \frac{[HI]^2}{[H_2][I_2]}$$

We first have to convert the amounts (mol) to concentrations (mol/L), using the flask volume of 1.50 L:

$$[H_2] = \frac{1.80 \text{ mol}}{1.50 \text{ L}} = 1.20\ M$$

Similarly, $[I_2] = 1.20\ M$, and $[HI] = 0.347\ M$. Substituting these values into the expression for Q_c gives K_c:

$$K_c = \frac{(0.347)^2}{(1.20)(1.20)} = 8.36\times10^{-2}$$

Using a Reaction Table to Determine Equilibrium Quantities and Find *K* When some quantities are not given, we determine them first from the reaction stoichiometry and then find K. In the following example, pay close attention to a valuable tool being introduced: *the reaction table*.

In a study of carbon oxidation, an evacuated vessel containing a small amount of powdered graphite is heated to 1080 K, and then CO_2 is added to a pressure of 0.458 atm. Once the CO_2 is added, the system starts to produce CO. After equi-

librium has been reached, the total pressure inside the vessel is 0.757 atm. Calculate K_p.

As always, we start to solve the problem by writing the balanced equation and the reaction quotient:

$$CO_2(g) + C(\text{graphite}) \rightleftharpoons 2CO(g)$$

The data are given in atmospheres and we must find K_p, so we write Q in terms of partial pressures (note the absence of a term for the solid, C):

$$Q_p = \frac{P_{CO}^2}{P_{CO_2}}$$

We are given the initial P_{CO_2} and P_{total} at equilibrium. To find K_p, we must find the equilibrium pressures of CO_2 and CO, which requires solving a stoichiometry problem, and then substitute them into the expression for Q_p.

Let's stop for a moment before we begin the calculations to think through what happened in the vessel. An unknown portion of the CO_2 reacted with graphite to form an unknown amount of CO. We already know the *relative* amounts of CO_2 and CO from the balanced equation: for each mole of CO_2 that reacts, 2 mol of CO forms, which means that when x atm of CO_2 reacts, $2x$ atm of CO forms:

$$x \text{ atm } CO_2 \longrightarrow 2x \text{ atm CO}$$

From the data given, we can predict something about the size of K_p. If it were very large, almost all the CO_2 would be converted to CO, so the final (total) pressure would be twice the initial pressure [2(0.458 atm) $\approx$ 0.9 atm]. On the other hand, if K_p were very small, almost no CO would form, so the final pressure would be close to the initial pressure, 0.458 atm. However, the final pressure (0.757 atm) is between these extremes, so K_p must have an intermediate value. The pressure of CO_2 at equilibrium, $P_{CO_2(eq)}$, is the initial pressure, $P_{CO_2(init)}$, *minus* the change in CO_2 pressure, x, that is, the CO_2 that reacts:

$$P_{CO_2(init)} - x = P_{CO_2(eq)}$$

Similarly, the pressure of CO at equilibrium, $P_{CO(eq)}$, is the initial pressure, $P_{CO(init)}$, *plus* the change in CO pressure, which is the CO that forms, $2x$. Because $P_{CO(init)}$ is zero at the beginning of the reaction, we have

$$P_{CO(init)} + 2x = 0 + 2x = 2x = P_{CO(eq)}$$

A useful way to summarize this information is with a *reaction table* that shows the balanced equation and what we know about

- the *initial* quantities (concentrations or pressures) of reactants and products
- the *changes* in these quantities during the reaction
- the *equilibrium* quantities

Pressure (atm)	$CO_2(g)$	+	C(graphite)	$\rightleftharpoons$	$2CO(g)$
Initial	0.458		—		0
Change	$-x$		—		$+2x$
Equilibrium	$0.458 - x$		—		$2x$

Note that we *add the initial value to the change to obtain the equilibrium value* in each column. Note also that we include data *only for those substances whose concentrations change;* thus, in this case, the C(graphite) column is blank. We use reaction tables in many of the equilibrium problems here and in later chapters.

To solve for K_p, we substitute equilibrium values into the reaction quotient, so we have to find x. To do this, we use the other piece of data given, P_{total}. According to Dalton's law of partial pressures and using the quantities from the bottom (equilibrium) row of the reaction table,

$$P_{total} = 0.757 \text{ atm} = P_{CO_2(eq)} + P_{CO(eq)} = (0.458 \text{ atm} - x) + 2x$$

Thus,

$$0.757 \text{ atm} = 0.458 \text{ atm} + x \quad \text{and} \quad x = 0.299 \text{ atm}$$

With x known, we determine the equilibrium partial pressures:

$$P_{CO_2(eq)} = 0.458 \text{ atm} - x = 0.458 \text{ atm} - 0.299 \text{ atm} = 0.159 \text{ atm}$$
$$P_{CO(eq)} = 2x = 2(0.299 \text{ atm}) = 0.598 \text{ atm}$$

Now, we substitute these values into the expression for Q_p to find K_p:

$$Q_p = \frac{P^2_{CO(eq)}}{P_{CO_2(eq)}} = \frac{0.598^2}{0.159} = 2.25 = K_p$$

As we predicted, K_p is neither very large nor very small.

(From now on, the subscripts "init" and "eq" are used only when it is not clear whether a concentration or pressure is an initial or equilibrium value.)

SAMPLE PROBLEM 17.6 Calculating K_c from Concentration Data

Problem In order to study hydrogen halide decomposition, a researcher fills an evacuated 2.00-L flask with 0.200 mol of HI gas and allows the reaction to proceed at 453°C:

$$2HI(g) \rightleftharpoons H_2(g) + I_2(g)$$

At equilibrium, [HI] = 0.078 M. Calculate K_c.

Plan To calculate K_c, we need the equilibrium concentrations. We can find the initial [HI] from the amount (0.200 mol) and the flask volume (2.00 L), and we are given [HI] at equilibrium (0.078 M). From the balanced equation, when $2x$ mol of HI reacts, x mol of H_2 and x mol of I_2 form. We set up a reaction table, use the known [HI] at equilibrium to solve for x (the change in [H_2] or [I_2]), and substitute the concentrations into Q_c.

Solution Calculating initial [HI]:

$$[HI] = \frac{0.200 \text{ mol}}{2.00 \text{ L}} = 0.100 \, M$$

Setting up the reaction table, with x = [H_2] or [I_2] that forms and $2x$ = [HI] that reacts:

Concentration (M)	$2HI(g)$	$\rightleftharpoons$	$H_2(g)$	+	$I_2(g)$
Initial	0.100		0		0
Change	$-2x$		$+x$		$+x$
Equilibrium	$0.100 - 2x$		x		x

Solving for x, using the known [HI] at equilibrium:

$$[HI] = 0.100 \, M - 2x = 0.078 \, M$$
$$x = 0.011 \, M$$

Therefore, the equilibrium concentrations are

$$[H_2] = [I_2] = 0.011 \, M \quad \text{and} \quad [HI] = 0.078 \, M$$

Substituting into the reaction quotient:

$$Q_c = \frac{[H_2][I_2]}{[HI]^2}$$

Thus,

$$K_c = \frac{(0.011)(0.011)}{0.078^2} = 0.020$$

Check Rounding gives $\sim 0.01^2/0.08^2 = 0.02$. Because the initial [HI] of 0.100 M fell slightly at equilibrium to 0.078 M, relatively little product formed; so we expect $K_c < 1$.

FOLLOW-UP PROBLEM 17.6 The atmospheric oxidation of nitrogen monoxide, $2NO(g) + O_2(g) \rightleftharpoons 2NO_2(g)$, was studied at 184°C with initial pressures of 1.000 atm of NO and 1.000 atm of O_2. At equilibrium, $P_{O_2} = 0.506$ atm. Calculate K_p.

Using the Equilibrium Constant to Determine Quantities

Like the type of problem that involves finding K, the type that involves finding equilibrium concentrations (or pressures) has several variations. Sample Problem 17.7 is one variation, in which we know K and some of the equilibrium concentrations and must find another equilibrium concentration.

SAMPLE PROBLEM 17.7 Determining Equilibrium Concentrations from K_c

Problem In a study of the conversion of methane to other fuels, a chemical engineer mixes gaseous CH_4 and H_2O in a 0.32-L flask at 1200 K. At equilibrium, the flask contains 0.26 mol of CO, 0.091 mol of H_2, and 0.041 mol of CH_4. What is $[H_2O]$ at equilibrium? $K_c = 0.26$ for the equation

$$CH_4(g) + H_2O(g) \rightleftharpoons CO(g) + 3H_2(g)$$

Plan First, we use the balanced equation to write the reaction quotient. We can calculate the equilibrium concentrations from the given numbers of moles and the flask volume (0.32 L). Substituting these into Q_c and setting it equal to the given K_c (0.26), we solve for the unknown equilibrium concentration, $[H_2O]$.

Solution Writing the reaction quotient:

$$CH_4(g) + H_2O(g) \rightleftharpoons CO(g) + 3H_2(g) \qquad Q_c = \frac{[CO][H_2]^3}{[CH_4][H_2O]}$$

Determining the equilibrium concentrations:

$$[CH_4] = \frac{0.041 \text{ mol}}{0.32 \text{ L}} = 0.13\ M$$

Similarly, $[CO] = 0.81\ M$ and $[H_2] = 0.28\ M$.

Calculating $[H_2O]$ at equilibrium: Since $Q_c = K_c$, rearranging gives

$$[H_2O] = \frac{[CO][H_2]^3}{[CH_4]K_c} = \frac{(0.81)(0.28)^3}{(0.13)(0.26)} = 0.53\ M$$

Check Always check by substituting the concentrations into Q_c to confirm K_c:

$$Q_c = \frac{[CO][H_2]^3}{[CH_4][H_2O]} = \frac{(0.81)(0.28)^3}{(0.13)(0.53)} = 0.26 = K_c$$

FOLLOW-UP PROBLEM 17.7 Nitric oxide, oxygen, and nitrogen react by the following equation: $2NO(g) \rightleftharpoons N_2(g) + O_2(g)$; $K_c = 2.3\times10^{30}$ at 298 K. In the atmosphere, $P_{O_2} = 0.209$ atm and $P_{N_2} = 0.781$ atm. What is the equilibrium partial pressure of NO in the air we breathe? [*Hint*: You need K_p to find the partial pressure.]

In a somewhat more involved variation, we know K and *initial* quantities and must find *equilibrium* quantities, for which we use a reaction table. In Sample Problem 17.8, the amounts were chosen to simplify the math, allowing us to focus more easily on the overall approach.

SAMPLE PROBLEM 17.8 Determining Equilibrium Concentrations from Initial Concentrations and K_c

Problem Fuel engineers use the extent of the change from CO and H_2O to CO_2 and H_2 to regulate the proportions of synthetic fuel mixtures. If 0.250 mol of CO and 0.250 mol of H_2O are placed in a 125-mL flask at 900 K, what is the composition of the equilibrium mixture? At this temperature, K_c is 1.56 for the equation

$$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$$

Plan We have to find the "composition" of the equilibrium mixture, in other words, the equilibrium concentrations. As always, we use the balanced equation to write the reaction

quotient. We find the initial [CO] and [H_2O] from the given amounts (0.250 mol of each) and volume (0.125 L), use the balanced equation to define x and set up a reaction table, substitute into Q_c, and solve for x, from which we calculate the concentrations.

Solution Writing the reaction quotient:

$$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g) \qquad Q_c = \frac{[CO_2][H_2]}{[CO][H_2O]}$$

Calculating initial reactant concentrations:

$$[CO] = [H_2O] = \frac{0.250 \text{ mol}}{0.125 \text{ L}} = 2.00\ M$$

Setting up the reaction table, with x = [CO] and [H_2O] that react:

Concentration (M)	$CO(g)$	+	$H_2O(g)$	$\rightleftharpoons$	$CO_2(g)$	+	$H_2(g)$
Initial	2.00		2.00		0		0
Change	$-x$		$-x$		$+x$		$+x$
Equilibrium	$2.00 - x$		$2.00 - x$		x		x

Substituting into the reaction quotient and solving for x:

$$Q_c = \frac{[CO_2][H_2]}{[CO][H_2O]} = \frac{(x)(x)}{(2.00 - x)(2.00 - x)} = \frac{x^2}{(2.00 - x)^2}$$

At equilibrium, we have

$$Q_c = K_c = 1.56 = \frac{x^2}{(2.00 - x)^2}$$

We can apply the following math shortcut in this case *but not in general:* Because the right side of the equation is a perfect square, we take the square root of both sides:

$$\sqrt{1.56} = \frac{x}{2.00 - x} = \pm 1.25$$

A positive number (1.56) has a positive *and* a negative square root, but *only the positive root has any chemical meaning,* so we ignore the negative root:*

$$1.25 = \frac{x}{2.00 - x} \qquad \text{or} \qquad 2.50 - 1.25x = x$$

So $2.50 = 2.25x$; therefore, $x = 1.11\ M$

Calculating equilibrium concentrations:

$$[CO] = [H_2O] = 2.00\ M - x = 2.00\ M - 1.11\ M = 0.89\ M$$
$$[CO_2] = [H_2] = x = 1.11\ M$$

Check From the intermediate size of K_c, it makes sense that the changes in concentration are moderate. It's a good idea to check that the sign of x in the reaction table makes sense—only reactants were initially present, so the change had to proceed to the right: x is the change in concentration, so it has a negative sign for reactants and a positive sign for products. Also check that the equilibrium concentrations give the known K_c: $\frac{(1.11)(1.11)}{(0.89)(0.89)} = 1.56$.

FOLLOW-UP PROBLEM 17.8 The decomposition of HI at low temperature was studied by injecting 2.50 mol of HI into a 10.32-L vessel at 25°C. What is [H_2] at equilibrium for the reaction $2HI(g) \rightleftharpoons H_2(g) + I_2(g)$; $K_c = 1.26 \times 10^{-3}$?

---

*The negative root gives $-1.25 = \frac{x}{2.00 - x}$, or $-2.50 + 1.25x = x$.

So $-2.50 = -0.25x$, and $x = 10.\ M$

This value has no chemical meaning because we started with 2.00 M of each reactant, so it is impossible for 10. M to react. Moreover, the square root of an equilibrium constant is another equilibrium constant, which cannot have a negative value.

Using the Quadratic Formula to Solve for the Unknown The shortcut that we used to simplify the math in Sample Problem 17.8 is a special case that occurs when both numerator and denominator of the reaction quotient are perfect squares. It worked out that way because we started with equal concentrations of the two reactants, but that is not ordinarily the case.

Suppose, for example, we instead start the reaction in the sample problem with 2.00 M CO and 1.00 M H_2O. The reaction table is

Concentration (M)	$CO(g)$	+	$H_2O(g)$	$\rightleftharpoons$	$CO_2(g)$	+	$H_2(g)$
Initial	2.00		1.00		0		0
Change	$-x$		$-x$		$+x$		$+x$
Equilibrium	$2.00 - x$		$1.00 - x$		x		x

Substituting these values into Q_c, we obtain

$$Q_c = \frac{[CO_2][H_2]}{[CO][H_2O]} = \frac{(x)(x)}{(2.00 - x)(1.00 - x)} = \frac{x^2}{x^2 - 3.00x + 2.00}$$

At equilibrium, we have

$$1.56 = \frac{x^2}{x^2 - 3.00x + 2.00}$$

To solve for x in this case, we rearrange the previous expression into the form of a *quadratic equation:*

$$a\ x^2 + b\ x + c = 0$$

$$0.56x^2 - 4.68x + 3.12 = 0$$

where $a = 0.56$, $b = -4.68$, and $c = 3.12$. Then we can find x with the quadratic formula (Appendix A):

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

The $\pm$ sign means that we obtain two possible values for x:

$$x = \frac{4.68 \pm \sqrt{(-4.68)^2 - 4(0.56)(3.12)}}{2(0.56)}$$

$$x = 7.6\ M \quad \text{and} \quad x = 0.73\ M$$

Note that only one of the values for x makes sense chemically. The larger value gives negative concentrations at equilibrium (for example, $2.00\ M - 7.6\ M = -5.6\ M$), which have no meaning. Therefore, $x = 0.73\ M$, and we have

$$[CO] = 2.00\ M - x = 2.00\ M - 0.73\ M = 1.27\ M$$

$$[H_2O] = 1.00\ M - x = 0.27\ M$$

$$[CO_2] = [H_2] = x = 0.73\ M$$

Checking to see if these values give the known K_c, we have

$$K_c = \frac{(0.73)(0.73)}{(1.27)(0.27)} = 1.6 \text{ (within rounding of 1.56)}$$

Simplifying Assumptions for Finding an Unknown Quantity In many cases, we can use chemical "common sense" to make an assumption that avoids the use of the quadratic formula to find x. In general, *if a reaction has a relatively small K and a relatively large initial reactant concentration, the concentration change (x) can often be neglected* without introducing significant error. This assumption does not mean that $x = 0$, because then there would be no reaction. It means that if a reaction proceeds very little (small K) and if there is a high initial reactant concentration, only a very small amount will be used up; therefore, at equilibrium, the reactant concentration will have hardly changed:

$$[\text{reactant}]_{\text{init}} - x = [\text{reactant}]_{\text{eq}} \approx [\text{reactant}]_{\text{init}}$$

You can imagine a similar situation in everyday life. On a bathroom scale, you weigh 158 lb. Take off your wristwatch, and you still weigh 158 lb. Within the precision of the measurement, the weight of the wristwatch is so small compared with your body weight that it can be neglected:

Initial body weight − weight of watch = final body weight ≈ initial body weight

Similarly, if the initial concentration of A is, for example, 0.500 *M* and, because of a small K_c, the concentration of A that reacts is 0.002 *M*, we can assume that

$$0.500\ M - 0.002\ M = 0.498\ M \approx 0.500\ M$$

that is,

$$[A]_{init} - [A]_{reacting} = [A]_{eq} \approx [A]_{init} \qquad (17.9)$$

For the assumption that x is negligible to be justified, you must check that the error introduced is not significant. But how much is "significant"? One common, though somewhat arbitrary, criterion is the 5% rule: *if the assumption results in a change (error) in a concentration that is less than 5%, the error is not significant, and the assumption is justified.* Let's go through a sample problem and make this assumption to see how it simplifies the math, and then we'll see if the assumption is justified in the case of two different initial concentrations. We make this assumption often in Chapters 18 and 19.

SAMPLE PROBLEM 17.9 Calculating Equilibrium Concentrations with Simplifying Assumptions

Problem Phosgene is a potent chemical warfare agent that is now outlawed by international agreement. It decomposes by the reaction

$$COCl_2(g) \rightleftharpoons CO(g) + Cl_2(g) \qquad K_c = 8.3\times10^{-4}\ (\text{at } 360°C)$$

Calculate [CO], [Cl_2], and [$COCl_2$] when each of the following amounts of phosgene decomposes and reaches equilibrium in a 10.0-L flask:

(a) 5.00 mol of $COCl_2$ **(b)** 0.100 mol of $COCl_2$

Plan We know from the balanced equation that when x mol of $COCl_2$ decomposes, x mol of CO and x mol of Cl_2 form. We convert amount (5.00 mol or 0.100 mol) to concentration, define x and set up the reaction table, and substitute the values into Q_c. Before using the quadratic formula, we simplify the calculation by assuming that x is negligibly small. After solving for x, we check the assumption and find the concentrations. If the assumption is not justified, we must use the quadratic formula to find x.

Solution **(a)** For 5.00 mol of $COCl_2$. Writing the reaction quotient:

$$Q_c = \frac{[CO][Cl_2]}{[COCl_2]}$$

Calculating initial [$COCl_2$]:

$$[COCl_2]_{init} = \frac{5.00\ \text{mol}}{10.0\ \text{L}} = 0.500\ M$$

Setting up the reaction table, with $x = [COCl_2]_{reacting}$:

Concentration (*M*)	$COCl_2(g)$	$\rightleftharpoons$	$CO(g)$	+	$Cl_2(g)$
Initial	0.500		0		0
Change	$-x$		$+x$		$+x$
Equilibrium	$0.500 - x$		x		x

If we use the equilibrium values in Q_c, we obtain

$$Q_c = \frac{[CO][Cl_2]}{[COCl_2]} = \frac{x^2}{0.500 - x} = K_c = 8.3\times10^{-4}$$

Because K_c is small, the reaction does not proceed very far to the right, so let's assume that x (the [$COCl_2$] that reacts) is so much smaller than the initial concentration, 0.500 *M*, that the equilibrium concentration is nearly the same. Therefore,

$$0.500\ M - x \approx 0.500\ M$$

Using this assumption, we substitute and solve for x:

$$K_c = 8.3\times10^{-4} \approx \frac{x^2}{0.500}$$

$$x^2 \approx (8.3\times10^{-4})(0.500) \quad \text{so} \quad x \approx 2.0\times10^{-2}$$

Checking the assumption by finding the percent error:

$$\frac{2.0\times10^{-2}}{0.500} \times 100 = 4\% \qquad \text{(less than 5\%, so the assumption is justified)}$$

Solving for the equilibrium concentrations:

$$[CO] = [Cl_2] = x = 2.0\times10^{-2}\ M$$

$$[COCl_2] = 0.500\ M - x = 0.480\ M$$

(b) For 0.100 mol of $COCl_2$. The calculation in this case is the same as the calculation in part (a), except that $[COCl_2]_{init} = 0.100\ \text{mol}/10.0\ \text{L} = 0.0100\ M$. Thus, at equilibrium, we have

$$Q_c = \frac{[CO][Cl_2]}{[COCl_2]} = \frac{x^2}{0.0100 - x}$$

$$= K_c = 8.3\times10^{-4}$$

Making the assumption that $0.0100\ M - x \approx 0.0100\ M$ and solving for x:

$$K_c = 8.3\times10^{-4} \approx \frac{x^2}{0.0100}$$

$$x \approx 2.9\times10^{-3}$$

Checking the assumption:

$$\frac{2.9\times10^{-3}}{0.0100} \times 100 = 29\% \qquad \text{(more than 5\%, so the assumption is } \textit{not} \text{ justified)}$$

We must solve the quadratic equation, $x^2 + (8.3\times10^{-4})x - (8.3\times10^{-6}) = 0$, for which the only meaningful value of x is 2.5×10^{-3} (see Appendix A).
Solving for the equilibrium concentrations:

$$[CO] = [Cl_2] = 2.5\times10^{-3}\ M$$

$$[COCl_2] = 1.00\times10^{-2}\ M - x = 7.5\times10^{-3}\ M$$

Check Once again, the best check is to use the calculated values to be sure you obtain the given K_c.
Comment Note that the assumption was justified at the high initial concentration, but *not* at the low initial concentration.

FOLLOW-UP PROBLEM 17.9 In a study of the effect of temperature on halogen decomposition, 0.50 mol of I_2 was heated in a 2.5-L vessel, and the following reaction occurred: $I_2(g) \rightleftharpoons 2I(g)$.
(a) Calculate $[I_2]$ and [I] at equilibrium at 600 K; $K_c = 2.94\times10^{-10}$.
(b) Calculate $[I_2]$ and [I] at equilibrium at 2000 K; $K_c = 0.209$.

Mixtures of Reactants and Products: Determining Reaction Direction

In the problems we've worked so far, the direction of the reaction was obvious: with only reactants present at the start, the reaction *had* to go toward products. Thus, in the reaction tables, we knew that the unknown change in reactant concentration had a negative sign ($-x$) and the change in product concentration had a positive sign ($+x$). Suppose, however, we start with a *mixture* of reactants and products. Whenever the reaction direction is not obvious, we first *compare the value of Q with K to find the direction* in which the reaction proceeds to reach equilibrium. This tells us the sign of x, the unknown change in concentration. (In order to focus on this idea, the next sample problem eliminates the need for the quadratic formula.)

SAMPLE PROBLEM 17.10 Predicting Reaction Direction and Calculating Equilibrium Concentrations

Problem The research and development unit of a chemical company is studying the reaction of CH_4 and H_2S, two components of natural gas:

$$CH_4(g) + 2H_2S(g) \rightleftharpoons CS_2(g) + 4H_2(g)$$

In one experiment, 1.00 mol of CH_4, 1.00 mol of CS_2, 2.00 mol of H_2S, and 2.00 mol of H_2 are mixed in a 250-mL vessel at 960°C. At this temperature, $K_c = 0.036$.
(a) In which direction will the reaction proceed to reach equilibrium?
(b) If $[CH_4] = 5.56\ M$ at equilibrium, what are the equilibrium concentrations of the other substances?

Plan **(a)** To find the direction, we convert the given initial amounts and volume (0.250 L) to concentrations, calculate Q_c, and compare it with K_c. **(b)** Based on the results from (a), we determine the sign of each concentration change for the reaction table and then use the known $[CH_4]$ at equilibrium (5.56 M) to determine x and the other equilibrium concentrations.

Solution **(a)** Calculating the initial concentrations:

$$[CH_4] = \frac{1.00\ \text{mol}}{0.250\ \text{L}} = 4.00\ M$$

Similarly, $[H_2S] = 8.00\ M$, $[CS_2] = 4.00\ M$, and $[H_2] = 8.00\ M$.
Calculating the value of Q_c:

$$Q_c = \frac{[CS_2][H_2]^4}{[CH_4][H_2S]^2} = \frac{(4.00)(8.00)^4}{(4.00)(8.00)^2} = 64.0$$

Comparing Q_c and K_c: $Q_c > K_c$ (64.0 > 0.036), so the reaction goes to the left. Therefore, concentrations of reactants increase and those of products decrease.
(b) Setting up a reaction table, with $x = [CS_2]$ that reacts, which equals $[CH_4]$ that forms:

Concentration (M)	$CH_4(g)$	+	$2H_2S(g)$	$\rightleftharpoons$	$CS_2(g)$	+	$4H_2(g)$
Initial	4.00		8.00		4.00		8.00
Change	$+x$		$+2x$		$-x$		$-4x$
Equilibrium	$4.00 + x$		$8.00 + 2x$		$4.00 - x$		$8.00 - 4x$

Solving for x: At equilibrium,

$$[CH_4] = 5.56\ M = 4.00\ M + x$$

So,

$$x = 1.56\ M$$

Thus,

$$[H_2S] = 8.00\ M + 2x = 8.00\ M + 2(1.56\ M) = 11.12\ M$$

$$[CS_2] = 4.00\ M - x = 2.44\ M$$

$$[H_2] = 8.00\ M - 4x = 1.76\ M$$

Check The comparison of Q_c and K_c showed the reaction proceeding to the left. The given data from part (b) confirm this because $[CH_4]$ increases from 4.00 M to 5.56 M during the reaction. Check that the concentrations give the known K_c:

$$\frac{(2.44)(1.76)^4}{(5.56)(11.12)^2} = 0.0341, \text{ which is close to } 0.036$$

FOLLOW-UP PROBLEM 17.10 An inorganic chemist studying the reactions of phosphorus halides mixes 0.1050 mol of PCl_5 with 0.0450 mol of Cl_2 and 0.0450 mol of PCl_3 in a 0.5000-L flask at 250°C: $PCl_5(g) \rightleftharpoons PCl_3(g) + Cl_2(g)$; $K_c = 4.2\times10^{-2}$.
(a) In which direction will the reaction proceed?
(b) If $[PCl_5] = 0.2065\ M$ at equilibrium, what are the equilibrium concentrations of the other components?

By this time, you've seen quite a few variations on the type of equilibrium problem in which you know K and some initial quantities and must find the equilibrium quantities. Figure 17.6 presents a useful summary of the steps involved in solving these types of equilibrium problems. A good way to organize the steps is to group them into three overall parts.

SECTION SUMMARY

In most equilibrium problems, we use quantities (concentrations or pressures) of reactants and products to find K, or we use K to find quantities. We use a reaction table to summarize the initial quantities, how they change, and the equilibrium quantities. When K is small and the initial quantity of reactant is large, we assume the unknown change in the quantity (x) is so much smaller than the initial quantity that it can be neglected. If this assumption is not justified (that is, if the error is greater than 5%), we use the quadratic formula to find x. To determine reaction direction, we compare the values of Q and K.

17.6 REACTION CONDITIONS AND THE EQUILIBRIUM STATE: LE CHÂTELIER'S PRINCIPLE

The most remarkable feature of a system at equilibrium is its ability to return to equilibrium after a change in conditions moves it away from that state. This drive to reattain equilibrium is stated in **Le Châtelier's principle:** when a chemical system at equilibrium is disturbed, it reattains equilibrium by undergoing a net reaction that reduces the effect of the disturbance.

Two phrases in this statement need further explanation. First, what does it mean to "disturb" a system? At equilibrium, Q equals K. When a change in conditions forces the system temporarily out of equilibrium ($Q \neq K$), we say that the system has been stressed, or disturbed. Three common disturbances are a change in concentration of a component (that appears in Q), a change in pressure (caused by a change in volume), or a change in temperature. We'll discuss each of these changes below.

The other phrase, "net reaction," is often referred to as a shift in the *equilibrium position* of the system to the right or left. The equilibrium position is just the specific equilibrium concentrations (or pressures). A shift in the equilibrium position to the right means that there is a net reaction to the right (reactant to product) until equilibrium is reattained; a shift to the left means that there is a net reaction to the left (product to reactant). Thus, when a disturbance occurs, we say that the equilibrium position shifts, which means that *concentrations (or pressures) change in a way that reduces the disturbance, and the system attains a new equilibrium position* ($Q = K$ again).

Le Châtelier's principle allows us to predict the direction of the shift in equilibrium position. Most importantly, it helps research and industrial chemists create conditions that maximize yields. For the remainder of this section, we examine each of the three kinds of disturbances—concentration, pressure (volume), and temperature—to see how a system at equilibrium responds; then, we'll note whether a catalyst has any effect.

In the following discussions, we focus on the reversible gaseous reaction between phosphorus trichloride and chlorine to produce phosphorus pentachloride:

$$PCl_3(g) + Cl_2(g) \rightleftharpoons PCl_5(g)$$

SOLVING EQUILIBRIUM PROBLEMS

PRELIMINARY SETTING UP

1. Write the balanced equation
2. Write the reaction quotient, Q
3. Convert all amounts into the correct units (M or atm)

WORKING ON THE REACTION TABLE

4. When reaction direction is not known, compare Q with K
5. Construct a reaction table

✓Check the sign of x, the change in the quantity

SOLVING FOR x AND EQUILIBRIUM QUANTITIES

6. Substitute the quantities into Q
7. To simplify the math, assume that x is negligible ($[A]_{init} - x = [A]_{eq} \approx [A]_{init}$)
8. Solve for x

✓Check that assumption is justified (< 5% error). If not, solve quadratic equation for x.

9. Find the equilibrium quantities

✓Check to see that calculated values give the known K

Figure 17.6 Steps in solving equilibrium problems. These nine steps, grouped into three tasks, provide a useful approach to calculating equilibrium quantities, given initial quantities and K.

The Universality of Le Châtelier's Principle Although Le Châtelier limited the scope of his principle to physical and chemical systems, its application is much wider. Ecologists and economists, for example, often see it at work. On the African savannah, the numbers of herbivores (antelope, wildebeest, zebra) and carnivores (lion, cheetah) are in delicate balance. Any disturbance (drought, disease) causes shifts in the relative numbers until they attain a new balance. The economic principle of supply-and-demand is another example of this equilibrium principle. A given demand-supply balance for a product establishes a given price. If either demand or supply is disturbed, the disturbance causes a shift in the other and, therefore, in the prevailing price until a new balance is attained.

Animation: Le Châtelier's Principle
Online Learning Center

However, the basis of Le Châtelier's principle holds for any system at equilibrium, whether in the natural or social sciences.

The Effect of a Change in Concentration

When a system at equilibrium is disturbed by a change in concentration of one of the components, the system reacts in the direction that reduces the change:

- If the concentration increases, the system reacts to consume some of it.
- If the concentration decreases, the system reacts to produce some of it.

Of course, the component must be one that appears in Q; thus, pure liquids and solids, which do not appear in Q because their concentrations are constant, are not involved.

At 523 K, the PCl_3-Cl_2-PCl_5 system reaches equilibrium when

$$Q_c = \frac{[PCl_5]}{[PCl_3][Cl_2]} = 24.0 = K_c$$

What happens if we now inject some Cl_2 gas, one of the reactants? The system will always act to reduce the disturbance, so it will reduce the increase in reactant by proceeding toward the product side, thereby consuming some additional Cl_2. In terms of the reaction quotient, when we add Cl_2, the $[Cl_2]$ term increases, so the value of Q_c immediately falls as the denominator becomes larger; thus, the system is no longer at equilibrium. As some of the added Cl_2 reacts with some of the PCl_3 present and produces more PCl_5, the denominator becomes smaller once again and the numerator larger, until eventually Q_c again equals K_c. The concentrations of the components have changed, however: the concentrations of Cl_2 and PCl_5 are higher than in the original equilibrium position, and the concentration of PCl_3 is lower. Nevertheless, the ratio of values gives the same K_c. We describe this change by saying that *the equilibrium position shifts to the right when a component on the left is added:*

$$PCl_3 + Cl_2(\text{added}) \longrightarrow PCl_5$$

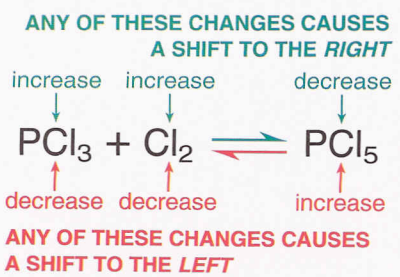
What happens if, instead of adding Cl_2, we remove some PCl_3, the other reactant? In this case, the system reduces the disturbance (the decrease in reactant), by proceeding toward the reactant side, thereby consuming some PCl_5. Once again, thinking in terms of Q_c, when we remove PCl_3, the $[PCl_3]$ term decreases, the denominator becomes smaller, and the value of Q_c rises above K_c. As some PCl_5 decomposes to PCl_3 and Cl_2, the numerator decreases and the denominator increases until Q_c equals K_c again. Here, too, the concentrations are different from those of the original equilibrium position, but K_c is not. We say that *the equilibrium position shifts to the left when a component on the left is removed:*

$$PCl_3(\text{removed}) + Cl_2 \longleftarrow PCl_5$$

The same points we just made for adding or removing a reactant also hold for adding or removing a product. If we add PCl_5, its concentration rises and the equilibrium position shifts to the left, just as it did when we removed some PCl_3; if we remove some PCl_5, the equilibrium position shifts to the right, just as it did when we added some Cl_2. In other words, no matter how the disturbance in concentration comes about, the system responds to make Q_c and K_c equal again. To summarize the effects of concentration changes (see margin):

- The equilibrium position shifts to the *right* if a reactant is added or a product is removed: [reactant] increases or [product] decreases.
- The equilibrium position shifts to the *left* if a reactant is removed or a product is added: [reactant] decreases or [product] increases.

In general, whenever the concentration of a component changes, *the equilibrium system reacts to consume some of the added substance or produce some of the removed substance.* In this way, the system "reduces the effect of the disturbance."



The effect is not completely eliminated, however, as we will see next from a quantitative comparison of original and new equilibrium positions.

Consider the case in which we added Cl_2 to the system at equilibrium. Suppose the original equilibrium position was established with the following concentrations: $[PCl_3] = 0.200\ M$, $[Cl_2] = 0.125\ M$, and $[PCl_5] = 0.600\ M$. Thus,

$$Q_c = \frac{[PCl_5]}{[PCl_3][Cl_2]} = \frac{0.600}{(0.200)(0.125)} = 24.0 = K_c$$

Now we add enough Cl_2 to increase its concentration by 0.075 M. Before any reaction occurs, this addition creates a new set of initial concentrations. Then the system reacts and comes to a new equilibrium position. From Le Châtelier's principle, we predict that adding more reactant will produce more product, that is, shift the equilibrium position to the right. Experiment shows that the new $[PCl_5]$ at equilibrium is 0.637 M.

Table 17.3 shows a reaction table of the entire process: the original equilibrium position, the disturbance, the (new) initial concentrations, the size and direction of the change needed to reattain equilibrium, and the new equilibrium position. Figure 17.7 depicts the process.

Table 17.3 The Effect of Added Cl_2 on the PCl_3-Cl_2-PCl_5 System

Concentration (M)	$PCl_3(g)$	+	$Cl_2(g)$	⇌	$PCl_5(g)$
Original equilibrium	0.200		0.125		0.600
Disturbance			+0.075		
New initial	0.200		0.200		0.600
Change	$-x$		$-x$		$+x$
New equilibrium	$0.200 - x$		$0.200 - x$		$0.600 + x$ (0.637)*

*Experimentally determined value.

From Table 17.3,

$$[PCl_5] = 0.600\ M + x = 0.637\ M, \quad \text{so } x = 0.037\ M$$

Also, $$[PCl_3] = [Cl_2] = 0.200\ M - x = 0.163\ M$$

Therefore, at equilibrium,

$$K_{c(original)} = \frac{0.600}{(0.200)(0.125)} = 24.0$$

$$K_{c(new)} = \frac{0.637}{(0.163)(0.163)} = 24.0$$

There are several key points to notice about the new equilibrium concentrations that exist after Cl_2 is added:

- As we predicted, $[PCl_5]$ (0.637 M) is higher than its original concentration (0.600 M).
- $[Cl_2]$ (0.163 M) is higher than its original equilibrium concentration (0.125 M), but lower than its initial concentration just after the addition (0.200 M); thus, the disturbance (addition of Cl_2) is *reduced but not eliminated.*
- $[PCl_3]$ (0.163 M), the other left-side component, is lower than its original concentration (0.200 M) because some reacted with the added Cl_2.
- Most importantly, although the position of equilibrium shifted to the right, K_c *remains the same.*

Be sure to note that the system adjusts by changing concentrations, but the value of Q_c *at equilibrium* is the same as in the original system. In other words, *at a given temperature,* K_c *does* **not** *change with a change in concentration.*

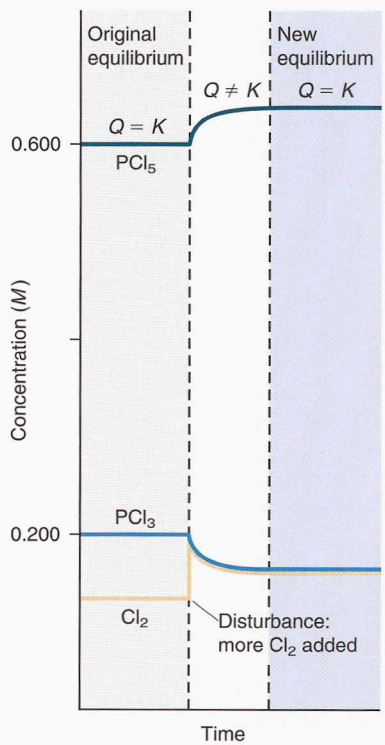


Figure 17.7 The effect of added Cl_2 on the PCl_3-Cl_2-PCl_5 system. In the original equilibrium (*gray region*), all concentrations are constant. When Cl_2 (*yellow curve*) is added, its concentration jumps and then starts to fall as Cl_2 reacts with some PCl_3 to form more PCl_5. After a period of time, equilibrium is re-established at new concentrations (*blue region*) but with the same K.

SAMPLE PROBLEM 17.11 Predicting the Effect of a Change in Concentration on the Equilibrium Position

Problem To improve air quality and obtain a useful product, chemists often remove sulfur from coal and natural gas by treating the fuel contaminant hydrogen sulfide with O_2:

$$2H_2S(g) + O_2(g) \rightleftharpoons 2S(s) + 2H_2O(g)$$

What happens to

(a) $[H_2O]$ if O_2 is added? **(b)** $[H_2S]$ if O_2 is added?
(c) $[O_2]$ if H_2S is removed? **(d)** $[H_2S]$ if sulfur is added?

Plan We write the reaction quotient to see how Q_c is affected by each disturbance, relative to K_c. This effect tells us the direction in which the reaction proceeds for the system to reattain equilibrium and how each concentration changes.

Solution Writing the reaction quotient: $Q_c = \dfrac{[H_2O]^2}{[H_2S]^2[O_2]}$

(a) When O_2 is added, the denominator of Q_c increases, so $Q_c < K_c$. The reaction proceeds to the right until $Q_c = K_c$ again, so $[H_2O]$ increases.

(b) As in part (a), when O_2 is added, $Q_c < K_c$. Some H_2S reacts with the added O_2 as the reaction proceeds to the right, so $[H_2S]$ decreases.

(c) When H_2S is removed, the denominator of Q_c decreases, so $Q_c > K_c$. As the reaction proceeds to the left to re-form H_2S, more O_2 is produced as well, so $[O_2]$ increases.

(d) The concentration of solid S is unchanged as long as some is present, so it does not appear in the reaction quotient. Adding more S has no effect, so $[H_2S]$ is unchanged (but see Comment 2 below).

Check Apply Le Châtelier's principle to see that the reaction proceeds in the direction that lowers the increased concentration or raises the decreased concentration.

Comment 1. As you know, sulfur exists most commonly as S_8. How would this change in formula affect the answers? The balanced equation and Q_c would be

$$8H_2S(g) + 4O_2(g) \rightleftharpoons S_8(s) + 8H_2O(g) \qquad Q_c = \frac{[H_2O]^8}{[H_2S]^8[O_2]^4}$$

The value of K_c is different for this equation, but the changes described in the problem have the same effects. For example, in (a), if O_2 were added, the denominator of Q_c would increase, so $Q_c < K_c$. As above, the reaction would proceed to the right until $Q_c = K_c$ again. In other words, changes predicted by Le Châtelier's principle for a given reaction are not affected by a change in the balancing coefficients.

2. In (d), you saw adding a solid has no effect on the concentrations of other components: because *the* ***concentration*** *of the solid cannot change*, it does not appear in Q. But *the* ***amount*** *of solid can change*. Adding H_2S shifts the reaction to the right, and more S forms.

FOLLOW-UP PROBLEM 17.11 In a study of the chemistry of glass etching, an inorganic chemist examines the reaction between sand (SiO_2) and hydrogen fluoride at a temperature above the boiling point of water:

$$SiO_2(s) + 4HF(g) \rightleftharpoons SiF_4(g) + 2H_2O(g)$$

Predict the effect on $[SiF_4]$ when **(a)** $H_2O(g)$ is removed; **(b)** some liquid water is added; **(c)** HF is removed; **(d)** some sand is removed.

The Effect of a Change in Pressure (Volume)

Changes in pressure have significant effects only on equilibrium systems with gaseous components. Aside from phase changes, a change in pressure has a negligible effect on liquids and solids because they are nearly incompressible. Pressure changes can occur in three ways:

- Changing the concentration of a gaseous component
- Adding an inert gas (one that does not take part in the reaction)
- Changing the volume of the reaction vessel

We just considered the effect of changing the concentration of a component, and that reasoning holds here. Next, let's see why *adding an inert gas has no*

effect on the equilibrium position. Adding an inert gas does not change the volume, so all *reactant and product concentrations remain the same.* In other words, the volume and the number of moles of the reactant and product gases do not change, so their *partial pressures do not change.* Because we use these (unchanged) partial pressures in the reaction quotient, the equilibrium position cannot change. Moreover, the inert gas does not appear in Q, so it cannot have an effect.

On the other hand, changing the pressure by changing the volume often causes a large shift in the equilibrium position. Suppose we let the PCl_3-Cl_2-PCl_5 system come to equilibrium in a cylinder-piston assembly. Then, we press down on the piston to halve the volume: the gas pressure immediately doubles. To reduce this increase in gas pressure, the system responds by reducing the number of gas molecules. And it does so in the only possible way—by shifting the reaction toward the side with *fewer moles of gas,* in this case, toward the product side:

$$\begin{array}{ccc} PCl_3(g) + Cl_2(g) & \longrightarrow & PCl_5(g) \\ 2 \text{ mol gas} & \longrightarrow & 1 \text{ mol gas} \end{array}$$

Notice that *a change in volume results in a change in concentration:* a decrease in container volume raises the concentration, and an increase in volume lowers the concentration. Recall that $Q_c = \dfrac{[PCl_5]}{[PCl_3][Cl_2]}$. When the volume is halved, the concentrations double, but the denominator of Q_c is the product of two concentrations, so it quadruples while the numerator only doubles. Thus, Q_c becomes less than K_c. As a result, the system forms more PCl_5 and a new equilibrium position is reached. Because it is just another way to change the concentration, *a change in pressure due to a change in volume does* ***not*** *alter* K_c.

Thus, for a system that contains gases at equilibrium, in which the amount (mol) of gas, n_{gas}, changes during the reaction (Figure 17.8):

- If the volume becomes smaller (pressure is higher), the reaction shifts so that the total number of gas molecules decreases.
- If the volume becomes larger (pressure is lower), the reaction shifts so that the total number of gas molecules increases.

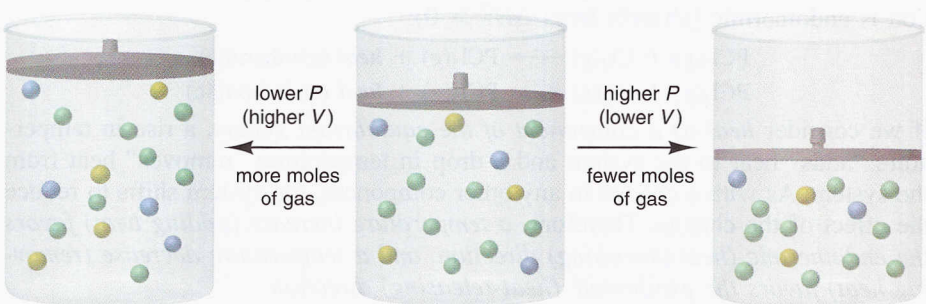

Figure 17.8 The effect of pressure (volume) on a system at equilibrium. The system of gases *(center)* is at equilibrium. For the reaction

an increase in pressure *(right)* decreases the volume, so the reaction shifts to the right to make fewer molecules. A decrease in pressure *(left)* increases the volume, so the reaction shifts to the left to make more molecules.

In many cases, however, n_{gas} does not change ($\Delta n_{gas} = 0$). For example,

$$\begin{array}{ccc} H_2(g) + I_2(g) & \rightleftharpoons & 2HI(g) \\ 2 \text{ mol gas} & \longrightarrow & 2 \text{ mol gas} \end{array}$$

Q_c has the same number of terms in the numerator and denominator:

$$Q_c = \frac{[HI]^2}{[H_2][I_2]} = \frac{[HI][HI]}{[H_2][I_2]}$$

Therefore, a change in volume has the same effect on the numerator and denominator. Thus, *if* $\Delta n_{gas} = 0$*, there is no effect on the equilibrium position.*

SAMPLE PROBLEM 17.12 Predicting the Effect of a Change in Volume (Pressure) on the Equilibrium Position

Problem How would you change the volume of each of the following reactions to *increase* the yield of the products?

(a) $CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g)$ **(b)** $S(s) + 3F_2(g) \rightleftharpoons SF_6(g)$

(c) $Cl_2(g) + I_2(g) \rightleftharpoons 2ICl(g)$

Plan Whenever gases are present, a change in volume causes a change in concentration. For reactions in which the number of moles of gas changes, if the volume decreases (pressure increases), the equilibrium position shifts to relieve the pressure by reducing the number of moles of gas. A volume increase (pressure decrease) has the opposite effect.

Solution **(a)** The only gas is the product CO_2. To make the system produce more CO_2, we increase the volume (decrease the pressure).

(b) With 3 mol of gas on the left and only 1 mol on the right, we decrease the volume (increase the pressure) to form more SF_6.

(c) The number of moles of gas is the same on both sides of the equation, so a change in volume (pressure) will have no effect on the yield of ICl.

Check Let's predict the relative values of Q_c and K_c. In (a), $Q_c = [CO_2]$, so increasing the volume will make $Q_c < K_c$, and the system will make more CO_2. In (b), $Q_c = [SF_6]/[F_2]^3$. Lowering the volume increases $[F_2]$ and $[SF_6]$ proportionately, but Q_c decreases because of the exponent 3 in the denominator. To make $Q_c = K_c$ again, $[SF_6]$ must increase. In (c), $Q_c = [ICl]^2/[Cl_2][I_2]$. A change in volume (pressure) affects the numerator (2 mol) and denominator (2 mol) equally, so it will have no effect.

FOLLOW-UP PROBLEM 17.12 Would you increase or decrease the pressure (via a volume change) of each of the following reaction mixtures to *decrease* the yield of products?

(a) $2SO_2(g) + O_2(g) \rightleftharpoons 2SO_3(g)$ **(b)** $4NH_3(g) + 5O_2(g) \rightleftharpoons 4NO(g) + 6H_2O(g)$

(c) $CaC_2O_4(s) \rightleftharpoons CaCO_3(s) + CO(g)$

The Effect of a Change in Temperature

Of the three types of disturbances—a change in concentration, in pressure, or in temperature—*only temperature changes alter K*. To see why, we must take the heat of reaction into account:

$$PCl_3(g) + Cl_2(g) \rightleftharpoons PCl_5(g) \quad \Delta H^0_{rxn} = -111 \text{ kJ}$$

The forward reaction is exothermic (releases heat; $\Delta H^0 < 0$), so the reverse reaction is endothermic (absorbs heat; $\Delta H^0 > 0$):

$$PCl_3(g) + Cl_2(g) \longrightarrow PCl_5(g) + \textbf{\textit{heat}} \text{ (exothermic)}$$

$$PCl_3(g) + Cl_2(g) \longleftarrow PCl_5(g) + \textbf{\textit{heat}} \text{ (endothermic)}$$

If we consider *heat as a component of the equilibrium system,* a rise in temperature "adds" heat to the system and a drop in temperature "removes" heat from the system. As with a change in any other component, the system shifts to reduce the effect of the change. Therefore, *a temperature increase (adding heat) favors the endothermic (heat-absorbing) direction, and a temperature decrease (removing heat) favors the exothermic (heat-releasing) direction.*

If we start with the system at equilibrium, Q_c equals K_c. Increase the temperature, and the system responds by decomposing some PCl_5 to PCl_3 and Cl_2, which absorbs the added heat. The denominator of Q_c becomes larger and the numerator smaller, so the system reaches a new equilibrium position at a smaller ratio of concentration terms, that is, a lower K_c. Similarly, the system responds to a drop in temperature by forming more PCl_5 from some PCl_3 and Cl_2, which releases more heat. The numerator of Q_c becomes larger, the denominator smaller, and the new equilibrium position has a higher K_c. Thus,

- *A temperature rise will increase K_c for a system with a positive ΔH^0_{rxn}.*
- *A temperature rise will decrease K_c for a system with a negative ΔH^0_{rxn}.*

Let's review these ideas with a sample problem.

SAMPLE PROBLEM 17.13 Predicting the Effect of a Change in Temperature on the Equilibrium Position

Problem How does an *increase* in temperature affect the equilibrium concentration of the underlined substance and K_c for each of the following reactions?

(a) $CaO(s) + H_2O(l) \rightleftharpoons \underline{Ca(OH)_2}(aq) \quad \Delta H^0 = -82$ kJ

(b) $CaCO_3(s) \rightleftharpoons CaO(s) + \underline{CO_2}(g) \quad \Delta H^0 = 178$ kJ

(c) $\underline{SO_2}(g) \rightleftharpoons S(s) + O_2(g) \quad \Delta H^0 = 297$ kJ

Plan We write each equation to show heat as a reactant or product. Increasing the temperature adds heat, so the system shifts to absorb the heat; that is, the endothermic reaction occurs. K_c will increase if the forward reaction is endothermic and decrease if it is exothermic.

Solution (a) $CaO(s) + H_2O(l) \rightleftharpoons Ca(OH)_2(aq) + \textbf{\textit{heat}}$

Adding heat shifts the system to the left: $[Ca(OH)_2]$ and K_c will decrease.

(b) $CaCO_3(s) + \textbf{\textit{heat}} \rightleftharpoons CaO(s) + CO_2(g)$

Adding heat shifts the system to the right: $[CO_2]$ and K_c will increase.

(c) $SO_2(g) + \textbf{\textit{heat}} \rightleftharpoons S(s) + O_2(g)$

Adding heat shifts the system to the right: $[SO_2]$ will decrease and K_c will increase.

Check You can check your answers by going through the reasoning for a *decrease* in temperature: heat is removed and the exothermic direction is favored. All the answers should be opposite.

FOLLOW-UP PROBLEM 17.13 How does a *decrease* in temperature affect the partial pressure of the underlined substance and the value of K_p for each of the following reactions?

(a) $C(\text{graphite}) + 2\underline{H_2}(g) \rightleftharpoons CH_4(g) \quad \Delta H^0 = -75$ kJ

(b) $\underline{N_2}(g) + O_2(g) \rightleftharpoons 2NO(g) \quad \Delta H^0 = 181$ kJ

(c) $P_4(s) + 10Cl_2(g) \rightleftharpoons 4\underline{PCl_5}(g) \quad \Delta H^0 = -1528$ kJ

The van't Hoff Equation: The Effect of *T* on *K* The *van't Hoff equation* shows how the equilibrium constant is affected by changes in temperature:

$$\ln \frac{K_2}{K_1} = -\frac{\Delta H^0_{rxn}}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right) \tag{17.10}$$

where K_1 is the equilibrium constant at T_1, K_2 is the equilibrium constant at T_2, and R is the universal gas constant (8.314 J/mol·K). If we know ΔH^0_{rxn} and K at one temperature, the van't Hoff equation allows us to find K at any other temperature (or to find ΔH^0_{rxn}, given the two K's at two T's).

Here's a typical problem that requires the van't Hoff equation. Coal gasification processes usually begin with the formation of syngas from carbon and steam:

$$C(s) + H_2O(g) \rightleftharpoons CO(g) + H_2(g) \quad \Delta H^0_{rxn} = 131 \text{ kJ/mol}$$

An engineer knows that K_p is only 9.36×10^{-17} at 25°C and therefore wants to find a temperature that allows a much higher yield. Calculate K_p at 700°C.

$$\ln \frac{K_2}{K_1} = -\frac{\Delta H^0_{rxn}}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

The temperatures must be converted, and we make the units of ΔH^0 and R consistent:

$$\ln\left(\frac{K_{p2}}{9.36\times10^{-17}}\right) = -\frac{131\times10^3 \text{ J/mol}}{8.314 \text{ J/mol·K}}\left(\frac{1}{973 \text{ K}} - \frac{1}{298 \text{ K}}\right)$$

$$\frac{K_{p2}}{9.36\times10^{-17}} = 8.51\times10^{15}$$

$$K_{p2} = 0.797$$

Temperature-Dependent System There is a striking similarity among expressions for the temperature dependence of K, k (rate constant), and P (equilibrium vapor pressure):

$$\ln\frac{K_2}{K_1} = -\frac{\Delta H^0_{rxn}}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

$$\ln\frac{k_2}{k_1} = -\frac{E_a}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

$$\ln\frac{P_2}{P_1} = -\frac{\Delta H_{vap}}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

Each concentration-related term (K, k, or P) is dependent on T through an energy term (ΔH^0_{rxn}, E_a, or ΔH_{vap}, respectively) divided by R. The similarity arises because the equations express the same relationship. K equals a ratio of rate constants, and $E_{a(fwd)} - E_{a(rev)} = \Delta H^0_{rxn}$. In the vapor pressure case, for the phase change $A(l) \rightleftharpoons A(g)$, the heat of reaction is equal to the heat of vaporization: $\Delta H_{vap} = \Delta H^0_{rxn}$. Also, the equilibrium constant equals the equilibrium vapor pressure: $K_p = P_A$.

Equation 17.10 confirms the qualitative prediction from Le Châtelier's principle: for a temperature rise, we have

$$T_2 > T_1 \quad \text{and} \quad 1/T_2 < 1/T_1, \quad \text{so } 1/T_2 - 1/T_1 < 0$$

Therefore,

- For an endothermic reaction ($\Delta H^0_{rxn} > 0$), the $-(\Delta H^0_{rxn}/R)$ term is < 0. With $1/T_2 - 1/T_1 < 0$, the right side of the equation is > 0. Thus, $\ln(K_2/K_1) > 0$, so $K_2 > K_1$.
- For an exothermic reaction ($\Delta H^0_{rxn} < 0$), the $-(\Delta H^0_{rxn}/R)$ term is > 0. With $1/T_2 - 1/T_1 < 0$, the right side of the equation is < 0. Thus, $\ln(K_2/K_1) < 0$, so $K_2 < K_1$.

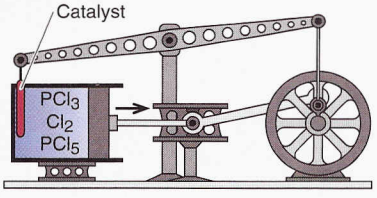
(For further practice with the van't Hoff equation, see Problems 17.73 and 17.74.)

The Lack of Effect of a Catalyst

Let's briefly consider a final external change to the reacting system: adding a catalyst. Recall from Chapter 16 that a catalyst speeds up a reaction by providing an alternative mechanism with a lower activation energy, thereby increasing the forward *and* reverse rates to the same extent. In other words, it shortens the time needed to attain the *final* concentrations. Thus, *a catalyst shortens the time it takes to reach equilibrium but has* ***no*** *effect on the equilibrium position.*

If, for instance, we add a catalyst to a mixture of PCl_3 and Cl_2 at 523 K, the system will attain the *same* equilibrium concentrations of PCl_3, Cl_2, and PCl_5 *more quickly* than it did without the catalyst. As you'll see in a moment, however, catalysts often play key roles in optimizing reaction systems. The upcoming Chemical Connections essays highlight two areas that apply equilibrium principles: the first examines metabolic processes in organisms, and the second describes a major industrial process.

Table 17.4 summarizes the effects of changing conditions on the position of equilibrium. Note that many changes alter the equilibrium position, but only temperature changes alter the value of the equilibrium constant.



Catalyzed Perpetual Motion? This engine consists of a piston attached to a flywheel, whose rocker arm holds a catalyst and moves in and out of the reaction in the cylinder. What if the catalyst *could* increase the rate of PCl_5 breakdown but not of its formation? In the cylinder, the catalyst would speed up the breakdown of PCl_5 to PCl_3 and Cl_2—1 mol of gas to 2 mol—increasing gas pressure and pushing the piston out. With the catalyst out of the cylinder, PCl_3 and Cl_2 would re-form PCl_5, lowering gas pressure and moving the piston in. The process would supply power with no input of external energy. If a catalyst could change the rate in only one direction, it would change K, and we could design some amazing machines!

Table 17.4 Effect of Various Disturbances on a System at Equilibrium

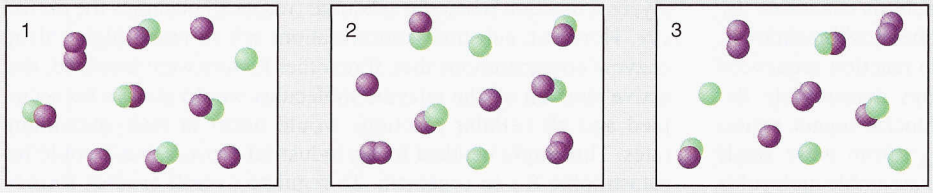
Disturbance	Net Direction of Reaction	Effect on Value of K
Concentration		
Increase [reactant]	Toward formation of product	None
Decrease [reactant]	Toward formation of reactant	None
Increase [product]	Toward formation of reactant	None
Decrease [product]	Toward formation of product	None
Pressure		
Increase P (decrease V)	Toward formation of fewer moles of gas	None
Decrease P (increase V)	Toward formation of more moles of gas	None
Increase P (add inert gas, no change in V)	None; concentrations unchanged	None
Temperature		
Increase T	Toward absorption of heat	Increases if $\Delta H^0_{rxn} > 0$ Decreases if $\Delta H^0_{rxn} < 0$
Decrease T	Toward release of heat	Increases if $\Delta H^0_{rxn} < 0$ Decreases if $\Delta H^0_{rxn} > 0$
Catalyst added	None; forward and reverse equilibrium attained sooner; rates increase equally	None

SAMPLE PROBLEM 17.14 Determining Equilibrium Parameters from Molecular Scenes

Problem For the reaction,

$$X(g) + Y_2(g) \rightleftharpoons XY(g) + Y(g) \qquad \Delta H > 0$$

the following molecular scenes depict different reaction mixtures (X = green, Y = purple):



(a) If $K_c = 2$ at the temperature of the reaction, which scene represents the mixture at equilibrium?
(b) Will the reaction mixtures in the other two scenes proceed toward reactants or toward products to reach equilibrium?
(c) For the mixture at equilibrium, how will a rise in temperature affect $[Y_2]$?

Plan **(a)** We are given the balanced equation and the value of K_c and must choose the scene representing the mixture at equilibrium. We write the expression for Q_c, and for each scene, count particles and plug in the numbers to solve for the value of Q_c. Whichever scene gives a Q_c equal to K_c represents the mixture at equilibrium. **(b)** To determine the direction each reaction proceeds in the other two scenes, we compare the value of Q_c with the given K_c. If $Q_c > K_c$, the numerator (product side) is too high, so the reaction proceeds toward reactants; if $Q_c < K_c$, the reaction proceeds toward products. **(c)** We are given the sign of ΔH and must see whether a rise in T (corresponding to supplying heat) will increase or decrease the amount of the reactant Y_2. We treat heat as a reactant or product and see whether adding heat shifts the reaction right or left.

Solution **(a)** For the reaction, we have

$$Q_c = \frac{[XY][Y]}{[X][Y_2]}$$

scene 1: $Q_c = \dfrac{5 \times 3}{1 \times 1} = 15$ scene 2: $Q_c = \dfrac{4 \times 2}{2 \times 2} = 2$ scene 3: $Q_c = \dfrac{3 \times 1}{3 \times 3} = \dfrac{1}{3}$

For scene 2, $Q_c = K_c$, so it represents the mixture at equilibrium.
(b) For scene 1, Q_c (15) $> K_c$ (2), so the reaction proceeds toward reactants. For scene 3, Q_c ($\frac{1}{3}$) $< K_c$ (2), so the reaction proceeds toward products.
(c) The reaction is endothermic, so heat acts as a reactant:

$$X(g) + Y_2(g) + \textit{heat} \rightleftharpoons XY(g) + Y(g)$$

Therefore, adding heat to the left shifts the reaction to the right, so $[Y_2]$ decreases.

Check **(a)** Remember that quantities in the numerator (or denominator) of Q_c are multiplied, not added. For example, the denominator for scene 1 is $1 \times 1 = 1$, not $1 + 1 = 2$.
(c) A good check is to imagine that $\Delta H < 0$ and see if you get the opposite result:

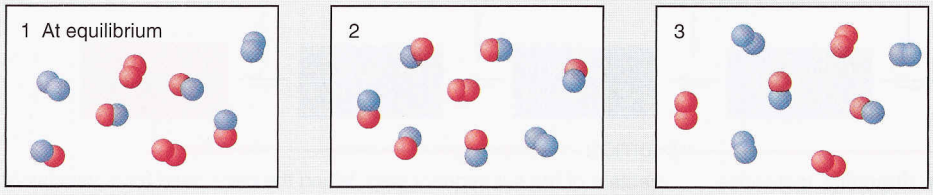
$$X(g) + Y_2(g) \rightleftharpoons XY(g) + Y(g) + \textit{heat}$$

If $\Delta H < 0$, adding heat would shift the reaction to the left and increase $[Y_2]$.

FOLLOW-UP PROBLEM 17.14 For the reaction

$$C_2(g) + D_2(g) \rightleftharpoons 2CD(g) \qquad \Delta H < 0$$

these molecular scenes depict different reaction mixtures (C = red and D = blue):



(a) Calculate the value of K_p. **(b)** In which direction will the reaction proceed for the mixtures *not* at equilibrium? **(c)** For the mixture at equilibrium, what effect will a rise in T have on the total moles of gas (increase, decrease, no effect)? Explain.

Design and Control of a Metabolic Pathway

Biological cells are microscopic wizards of chemical change. From the simplest bacterium to the most specialized neuron, every cell performs thousands of individual reactions that allow it to grow and reproduce, feed and excrete, move and communicate. Taken together, these chemical reactions constitute the cell's *metabolism*. These myriad feats of biochemical breakdown, synthesis, and energy flow are organized into reaction sequences called **metabolic pathways.** Some pathways disassemble the biopolymers in food into monomer building blocks: sugars, amino acids, and nucleotides. Others extract energy from these small molecules and then use much of the energy to assemble molecules with other functions, such as hormones, neurotransmitters, defensive toxins, and the cell's own biopolymers.

In principle, *each step in a metabolic pathway is a reversible reaction catalyzed by a specific enzyme* (Section 16.8). However, *equilibrium is never reached* in a pathway. As in other reaction sequences, the product of the first reaction becomes the reactant of the second, the product of the second becomes the reactant of the third, and so on. Consider the five-step pathway shown in Figure B17.1, in which one amino acid, threonine, is converted into another, isoleucine, in the cells of a bread mold. Threonine, supplied from a different region of the cell, forms ketobutyrate through the catalytic action of the first enzyme (reaction 1). The equilibrium position of reaction 1 continuously shifts to the right because the ketobutyrate is continuously removed as the reactant in reaction 2. Similarly, reaction 2 shifts to the right as its product is used in reaction 3. Each subsequent reaction shifts the equilibrium position of the previous reaction in the direction of product. The final product, isoleucine, is typically removed to make proteins elsewhere in the cell. Thus, *the entire pathway operates in one direction.*

This continuous shift in equilibrium position results in two major features of metabolic pathways. First, *each step proceeds with nearly 100% yield:* virtually every molecule of threonine that enters this region of the cell eventually changes to ketobutyrate, every molecule of ketobutyrate to the next product, and so on.

Second, *reactant and product concentrations remain constant* or vary within extremely narrow limits, even though the system never attains equilibrium. This situation, called a *steady state,* is different in a basic way from those we have studied so far. In equilibrium systems, equal reaction rates in *opposing* directions give rise to constant concentrations of reactants and products. In steady-state systems, on the other hand, the rates of reactions in *one* direction—into, through, and out of the system—give rise to nearly constant concentrations of intermediates. Ketobutyrate, for example, is formed via reaction 1 just as fast as it is used via reaction 2, so its concentration is kept constant. (You can establish a steady-state amount of water by filling a sink and then opening the faucet and drain so that water enters just as fast as it leaves.)

It is critical that a cell regulate the concentration of the final product of a pathway. Recall from Chapter 16 that an enzyme catalyzes a reaction when the substrate (reactant) occupies the *active site.* However, substrate concentrations are so much higher than enzyme concentrations that, if no other factors were involved, the active sites on all the enzyme molecules would always be occupied and all cellular reactions would occur at their maximum rates. This might be ideal for an industrial process, but it could be catastrophic for an organism. To regulate overall product formation, the rates of certain key steps are controlled by *regulatory enzymes,* which contain an *inhibitor site* on their surface in addition to an active site. The enzyme's three-dimensional structure is such that when the inhibitor site is occupied, the shape of the active site is deformed and the reaction cannot be catalyzed (Figure B17.2).

In the simplest case of metabolic control (Figure B17.1), *the final product of the pathway is also the inhibitor molecule, and the regulatory enzyme catalyzes the first step.* Suppose, for instance, that a bread mold cell is temporarily making less protein, so the isoleucine synthesized by the pathway in Figure B17.1 is not being removed as quickly. As the concentration of isoleucine rises, the chance increases that an isoleucine molecule will land on the inhibitor site of the first enzyme in the pathway, thereby inhibiting its own production. This process is called *end-product feedback inhibition.* More complex pathways have more elaborate regulatory schemes, but many operate through similar types of inhibitory feedback (see Problem 17.112). The exquisitely detailed regulation of a cell's numerous metabolic pathways arises directly from the principles of chemical kinetics and equilibrium.

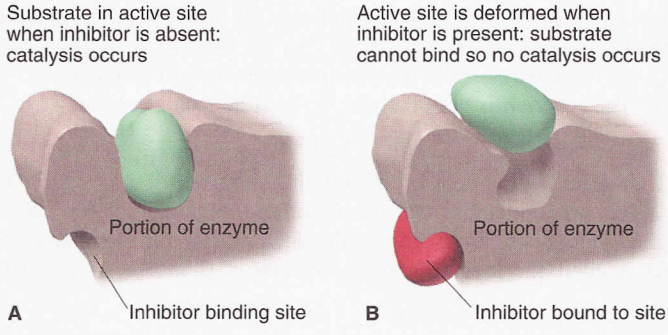


Figure B17.2 Effect of inhibitor binding on shape of active site. **A,** If inhibitor site is not occupied, the enzyme catalyzes the reaction. **B,** If inhibitor site is occupied, the enzyme molecule does not function.

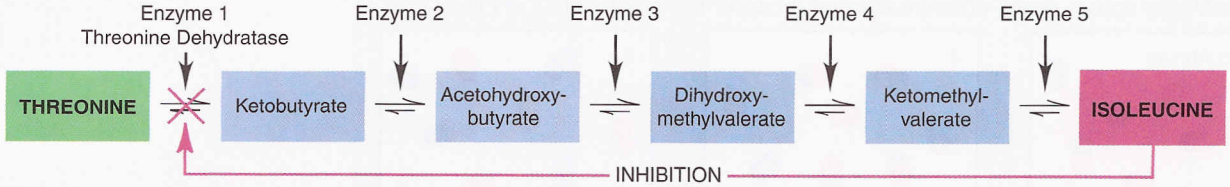

Figure B17.1 The biosynthesis of isoleucine from threonine. Isoleucine is synthesized from threonine in a sequence of five enzyme-catalyzed reactions. The unequal equilibrium arrows show that each step is reversible but is shifted toward product as each product becomes the reactant of the subsequent step. When the cell's need for isoleucine is temporarily satisfied, the concentration of isoleucine, the end product, builds up and inhibits the catalytic activity of threonine dehydratase, the first enzyme in the pathway.

The Haber Process for the Synthesis of Ammonia

Nitrogen occurs in many essential natural and synthetic compounds. By far the richest source of nitrogen is the atmosphere, where four of every five molecules are N_2. Despite this abundance, the supply of *usable* nitrogen for biological and manufacturing processes is limited because of the low chemical reactivity of N_2. Because of the strong triple bond holding the two N atoms together, the nitrogen atom is very difficult to "fix," that is, to combine with other atoms.

Natural nitrogen fixation occurs either through the elegant specificity of enzymes found in bacteria that live on plant roots or through the brute force of lightning. Nearly 13% of nitrogen fixation on Earth is accomplished industrially through the **Haber process** for the formation of ammonia from its elements:

$$N_2(g) + 3H_2(g) \rightleftharpoons 2NH_3(g) \qquad \Delta H^0_{rxn} = -91.8 \text{ kJ}$$

The process was developed by the German chemist Fritz Haber and first used in 1913. From its humble beginnings in a plant with a capacity of 12,000 tons a year, world production of ammonia has exploded to a current level of more than 110 million tons a year. On a mole basis, more ammonia is produced industrially than any other compound. Over 80% of this ammonia is used in fertilizer applications. In fact, the most common form of fertilizer is compressed anhydrous, liquid NH_3 injected directly into the soil (Figure B17.3). Other uses of NH_3 include the production of explosives, via the formation of HNO_3, and the making of nylons and other polymers. Smaller amounts are used as refrigerants, rubber stabilizers, and household cleaners and in the synthesis of pharmaceuticals and other organic chemicals.

The Haber process provides an excellent opportunity to apply equilibrium principles and see the compromises needed to make an industrial process economically worthwhile. From inspection of the balanced equation, we can see three ways to maximize the yield of ammonia:

1. *Decrease [NH_3]*. Ammonia is the product, so removing it as it forms will make the system produce more in a continual drive to reattain equilibrium.

Table B17.1 Effect of Temperature on K_c for Ammonia Synthesis

T (K)	K_c
200.	7.17×10^{15}
300.	2.69×10^{8}
400.	3.94×10^{4}
500.	1.72×10^{2}
600.	4.53×10^{0}
700.	2.96×10^{-1}
800.	3.96×10^{-2}

2. *Decrease volume (increase pressure)*. Because 4 mol of gas reacts to form 2 mol of gas, decreasing the volume will shift the equilibrium position toward fewer moles of gas, that is, toward ammonia formation.
3. *Decrease temperature*. Because the formation of ammonia is exothermic, decreasing the temperature (removing heat) will shift the equilibrium position toward the product, thereby increasing K_c (Table B17.1).

Therefore, the ideal conditions for maximizing the yield of ammonia are continual removal of NH_3 as it forms, high pressure, and low temperature. Figure B17.4 shows the percent yield of ammonia at various conditions of pressure and temperature. Note the almost complete conversion (98.3%) to ammonia at 1000 atm and the relatively low temperature of 473 K (200.°C).

Unfortunately, a problem arises that highlights the distinction between the principles of equilibrium and kinetics. Although the *yield* is favored by low temperature, the *rate* of formation is not. In fact, ammonia forms so slowly at low temperatures that the process becomes uneconomical. In practice, a compromise is achieved that optimizes yield *and* rate. High pressure and continuous removal are used to increase yield, but the temperature is

(continued)

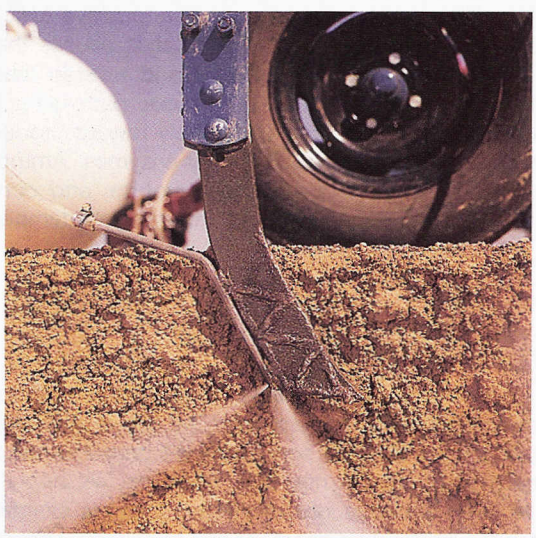

Figure B17.3 Liquid ammonia used as fertilizer.

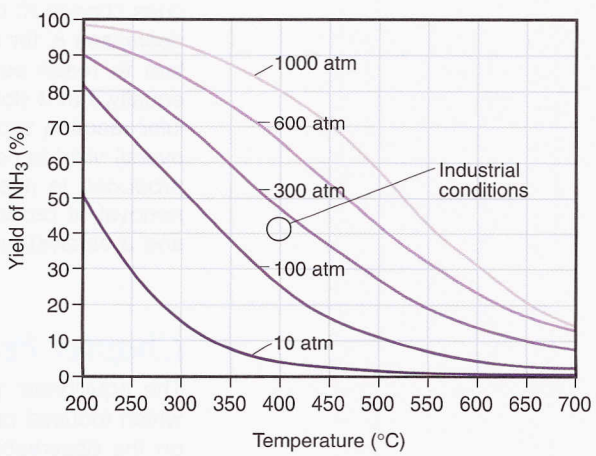

Figure B17.4 Percent yield of ammonia vs. temperature (°C) at five different operating pressures. At very high pressure and low temperature (*top left*), the yield is high, but the rate of formation is low. Industrial conditions (*circle*) are between 200 and 300 atm at about 400°C.

raised to a moderate level and a catalyst is used to increase the rate. Achieving the same rate without employing a catalyst would require much higher temperatures and would result in a much lower yield.

The stages in the industrial production of ammonia are shown schematically in Figure B17.5. To extend equipment life and minimize cost, modern ammonia plants operate at pressures of about 200 to 300 atm and temperatures of around 673 K (400.°C). The catalyst consists of 5-mm to 10-mm chunks of iron crystals embedded in a fused mixture of MgO, Al_2O_3, and SiO_2. The stoichiometric ratio of compressed reactant gases (N_2:H_2 = 1:3 by volume) is injected into the heated, pressurized reaction chamber, where it flows over the catalyst beds. Some of the heat needed is supplied by the enthalpy change of the reaction. The emerging equilibrium mixture, which contains about 35% NH_3 by volume, is cooled by refrigeration coils until the NH_3 (boiling point, −33.4°C) condenses and is removed. Because N_2 and H_2 have much lower boiling points than NH_3, they remain gaseous and are recycled by pumps back into the reaction chamber to continue the process.

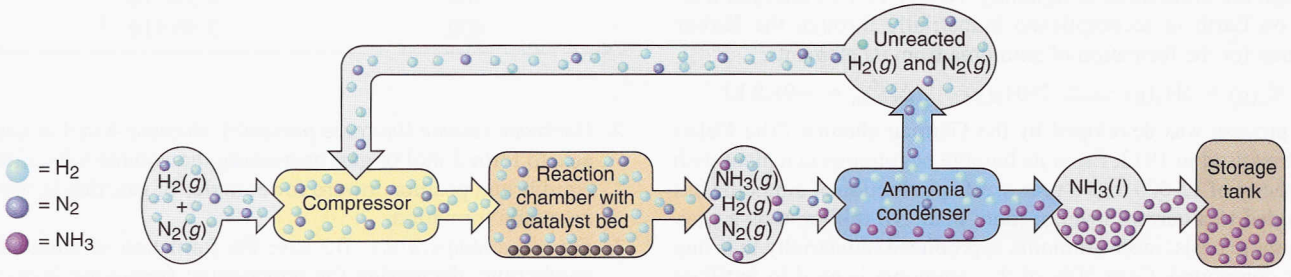

Figure B17.5 Key stages in the Haber process for synthesizing ammonia.

SECTION SUMMARY

Le Châtelier's principle states that if a system at equilibrium is disturbed, the system undergoes a net reaction that reduces the disturbance and allows equilibrium to be reattained. Changes in concentration cause a net reaction away from the added component or toward the removed component. For a reaction that involves a change in number of moles of gas, an increase in pressure (decrease in volume) causes a net reaction toward fewer moles of gas, and a decrease in pressure causes the opposite change. Although the equilibrium concentrations of components change as a result of concentration and volume changes, *K* does not change. A temperature change *does* change *K:* higher *T* increases *K* for an endothermic reaction (positive ΔH^0_{rxn}) and decreases *K* for an exothermic reaction (negative ΔH^0_{rxn}). A catalyst causes the system to reach equilibrium more quickly by speeding forward and reverse reactions equally, but it does not affect the equilibrium position. A metabolic pathway is a cellular reaction sequence in which each step is shifted completely toward product. Its overall yield is controlled by feedback inhibition of certain key enzymes. Ammonia is produced in a process favored by high pressure, low temperature, and continual removal of product. To make the process economical, an intermediate temperature and a catalyst are used.

Chapter Perspective

The equilibrium phenomenon is central to all natural systems. In this introduction, which focused primarily on gaseous systems, we discussed the nature of equilibrium on the observable and molecular levels, ways to solve relevant problems, and how conditions affect systems at equilibrium. In the next two chapters, we apply these ideas to acids and bases and to other aqueous ionic systems. Then we examine the fundamental relationship between the equilibrium constant and the energy change that accompanies a reaction to understand why chemical reactions occur.

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. The distinction between the rate and the extent of a reaction (Introduction)
2. Why a system attains dynamic equilibrium when forward and reverse reaction rates are equal (Section 17.1)
3. The equilibrium constant as a number that is equal to a particular ratio of rate constants and of concentration terms (Section 17.1)
4. How the magnitude of K is related to the extent of the reaction (Section 17.1)
5. Why the same equilibrium state is reached no matter what the starting concentrations of the reacting system (Section 17.2)
6. How the reaction quotient (Q) changes continuously until the system reaches equilibrium, at which point $Q = K$ (Section 17.2)
7. Why the form of Q is based exactly on the balanced equation *as written* (Section 17.2)
8. How the *sum* of reaction steps gives the overall reaction, and the *product* of Q's (or K's) gives the overall Q (or K) (Section 17.2)
9. Why pure solids and liquids do not appear in Q (Section 17.2)
10. How the interconversion of K_c and K_p is based on the ideal gas law and Δn_{gas} (Section 17.3)
11. How the reaction direction depends on the relative values of Q and K (Section 17.4)
12. How a reaction table is used to find an unknown quantity (concentration or pressure) (Section 17.5)
13. How assuming that the change in [reactant] is relatively small simplifies finding equilibrium quantities (Section 17.5)
14. How Le Châtelier's principle explains the effects of a change in concentration, pressure (volume), or temperature on a system at equilibrium and on K (Section 17.6)
15. Why a change in temperature *does* affect K (Section 17.6)
16. Why the addition of a catalyst does *not* affect K (Section 17.6)

Master These Skills

1. Writing the reaction quotient (Q) from a balanced equation (SP 17.1)
2. Writing Q and calculating K for a reaction consisting of more than one step (SP 17.2)
3. Writing Q and finding K for a reaction multiplied by a common factor (SP 17.3)
4. Writing Q for heterogeneous equilibria (Section 17.2)
5. Converting between K_c and K_p (SP 17.4)
6. Comparing Q and K to determine reaction direction (SP 17.5)
7. Substituting quantities (concentrations or pressures) into Q to find K (Section 17.5)
8. Using a reaction table to determine quantities and find K (SP 17.6)
9. Finding one equilibrium quantity from other equilibrium quantities and K (SP 17.7)
10. Finding an equilibrium quantity from initial quantities and K (SP 17.8)
11. Solving a quadratic equation for an unknown equilibrium quantity (Section 17.5)
12. Assuming that the change in [reactant] is relatively small to find equilibrium quantities and checking the assumption (SP 17.9)
13. Comparing the values of Q and K to find reaction direction and sign of x, the unknown change in a quantity (SP 17.10)
14. Using the relative values of Q and K to predict the effect of a change in concentration on the equilibrium position and on K (SP 17.11)
15. Using Le Châtelier's principle and Δn_{gas} to predict the effect of a change in pressure (volume) on the equilibrium position (SP 17.12)
16. Using Le Châtelier's principle and ΔH^0 to predict the effect of a change in temperature on the equilibrium position and on K (SP 17.13)
17. Using the van't Hoff equation to calculate K at one temperature given K at another temperature (Section 17.6)
18. Using molecular scenes to find equilibrium parameters (SP 17.14)

Key Terms

Section 17.1
equilibrium constant (K) (725)

Section 17.2
law of chemical equilibrium (law of mass action) (726)
reaction quotient (Q) (mass-action expression) (726)

Section 17.6
Le Châtelier's principle (745)
metabolic pathway (754)
Haber process (755)

Key Equations and Relationships

17.1 Defining equilibrium in terms of reaction rates (724):

$$\text{At equilibrium: } \text{rate}_{fwd} = \text{rate}_{rev}$$

17.2 Defining the equilibrium constant for the reaction $A \rightleftharpoons 2B$ (725):

$$K = \frac{k_{fwd}}{k_{rev}} = \frac{[B]_{eq}^2}{[A]_{eq}}$$

17.3 Defining the equilibrium constant in terms of the reaction quotient (726):

$$\text{At equilibrium: } Q = K$$

17.4 Expressing Q_c for the reaction $aA + bB \rightleftharpoons cC + dD$ (727):

$$Q_c = \frac{[C]^c[D]^d}{[A]^a[B]^b}$$

Key Equations and Relationships *(continued)*

17.5 Finding the overall K for a reaction sequence (728):

$$K_{\text{overall}} = K_1 \times K_2 \times K_3 \times \cdots$$

17.6 Finding K of a reaction from K of the reverse reaction (730):

$$K_{\text{fwd}} = \frac{1}{K_{\text{rev}}}$$

17.7 Finding K of a reaction multiplied by a factor n (730):

$$K' = K^n$$

17.8 Relating K based on pressures to K based on concentrations (734):

$$K_p = K_c(RT)^{\Delta n_{\text{gas}}}$$

17.9 Assuming that ignoring the concentration that reacts introduces no significant error (742):

$$[\text{A}]_{\text{init}} - [\text{A}]_{\text{reacting}} = [\text{A}]_{\text{eq}} \approx [\text{A}]_{\text{init}}$$

17.10 Finding K at one temperature given K at another (van't Hoff equation) (751):

$$\ln\frac{K_2}{K_1} = -\frac{\Delta H^0_{\text{rxn}}}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

Highlighted Figures and Tables

These figures (F) and tables (T) provide a review of key ideas.

T17.2 Ways of expressing Q and calculating K (732)
F17.5 Reaction direction and the relative sizes of Q and K (735)
F17.6 Steps in solving equilibrium problems (745)
T17.3 Effect of added Cl_2 on the PCl_3-Cl_2-PCl_5 system (747)
F17.8 Effect of pressure (volume) on equilibrium (749)
T17.4 Effects of disturbances on equilibrium (752)

Brief Solutions to Follow-up Problems

17.1 (a) $Q_c = \dfrac{[NO]^4[H_2O]^6}{[NH_3]^4[O_2]^5}$ (b) $Q_c = \dfrac{[N_2O][NO_2]}{[NO]^3}$

17.2 $H_2(g) + Br_2(g) \rightleftharpoons 2HBr(g)$;

$$Q_{c(\text{overall})} = \frac{[HBr]^2}{[H_2][Br_2]}$$

$$Q_{c(\text{overall})} = Q_{c1} \times Q_{c2} \times Q_{c3} = \frac{\cancel{[Br]^2}}{[Br_2]} \times \frac{[HBr]\cancel{[H]}}{\cancel{[Br]}[H_2]} \times \frac{[HBr]}{\cancel{[H]}\cancel{[Br]}} = \frac{[HBr]^2}{[H_2][Br_2]}$$

17.3 (a) $K_c = K_{c(\text{ref})}^{1/2} = 2.8\times10^4$

(b) $K_c = \left(\dfrac{1}{K_{c(\text{ref})}}\right)^{2/3} = 1.2\times10^{-6}$

17.4 $K_p = K_c(RT)^{-1} = 1.67\left(0.0821\ \dfrac{\text{atm·L}}{\text{mol·K}} \times 500.\ \text{K}\right)^{-1}$

$= 4.07\times10^{-2}$

17.5 $Q_p = \dfrac{(P_{CH_3Cl})(P_{HCl})}{(P_{CH_4})(P_{Cl_2})} = \dfrac{(0.24)(0.47)}{(0.13)(0.035)} = 25$;

$Q_p < K_p$, so CH_3Cl is forming.

17.6 From the reaction table for $2NO + O_2 \rightleftharpoons 2NO_2$,

$P_{O_2} = 1.000\ \text{atm} - x = 0.506\ \text{atm}$; $x = 0.494\ \text{atm}$

Also, $P_{NO} = 0.012$ atm and $P_{NO_2} = 0.988$ atm, so

$$K_p = \frac{0.988^2}{0.012^2(0.506)} = 1.3\times10^4$$

17.7 Since $\Delta n_{\text{gas}} = 0$, $K_p = K_c = 2.3\times10^{30} = \dfrac{(0.781)(0.209)}{P_{NO}^2}$

Thus, $P_{NO} = 2.7\times10^{-16}$ atm

17.8 From the reaction table, $[H_2] = [I_2] = x$; $[HI] = 0.242 - 2x$.

Thus, $K_c = 1.26\times10^{-3} = \dfrac{x^2}{(0.242 - 2x)^2}$

Taking the square root of both sides, ignoring the negative root, and solving gives $x = [H_2] = 8.02\times10^{-3}\ M$.

17.9 (a) Based on the reaction table, and assuming that $0.20\ M - x \approx 0.20\ M$,

$$K_c = 2.94\times10^{-10} \approx \frac{4x^2}{0.20} \qquad x \approx 3.8\times10^{-6}$$

Error $= 1.9\times10^{-3}\%$, so assumption is justified; therefore, at equilibrium, $[I_2] = 0.20\ M$ and $[I] = 7.6\times10^{-6}\ M$.

(b) Based on the same reaction table and assumption, $x \approx 0.10$; error is 50%, so assumption is *not* justified. Solve equation:

$$4x^2 + 0.209x - 0.042 = 0 \qquad x = 0.080\ M$$

Therefore, at equilibrium, $[I_2] = 0.12\ M$ and $[I] = 0.16\ M$.

17.10 (a) $Q_c = \dfrac{(0.0900)(0.0900)}{0.2100} = 3.86\times10^{-2}$

$Q_c < K_c$, so reaction proceeds to the right.

(b) From the reaction table,

$$[PCl_5] = 0.2100\ M - x = 0.2065\ M \qquad x = 0.0035\ M$$

So, $[Cl_2] = [PCl_3] = 0.0900\ M + x = 0.0935\ M$.

17.11 (a) $[SiF_4]$ increases; (b) decreases; (c) decreases; (d) no effect.

17.12 (a) Decrease P; (b) increase P; (c) increase P.

17.13 (a) P_{H_2} will decrease; K_p will increase; (b) P_{N_2} will increase; K_p will decrease; (c) P_{PCl_5} will increase; K_p will increase.

17.14 (a) Since $P = \dfrac{n}{V}RT$ and, in this case, V, R, and T cancel,

$$K_p = \frac{n_{CD}^2}{n_{C_2} \times n_{D_2}} = \frac{16}{(2)(2)} = 4$$

(b) Scene 2 to the left; scene 3 to the right. (c) There are 2 mol of gas on each side of the balanced equation, so there is no effect on total moles of gas.

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

The Equilibrium State and the Equilibrium Constant

Concept Review Questions

17.1 A change in reaction conditions increases the rate of a certain forward reaction more than that of the reverse reaction. What is the effect on the equilibrium constant and the concentrations of reactants and products at equilibrium?

17.2 When a chemical company employs a new reaction to manufacture a product, the chemists consider its rate (kinetics) and yield (equilibrium). How do each of these affect the usefulness of a manufacturing process?

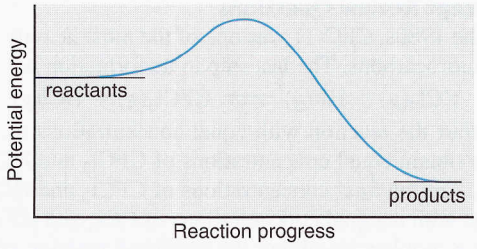
17.3 If there is no change in concentrations, why is the equilibrium state considered dynamic?

17.4 (a) Is K very large or very small for a reaction that goes essentially to completion? Explain. (b) White phosphorus, P_4, is produced by the reduction of phosphate rock, $Ca_3(PO_4)_2$. If exposed to oxygen, the waxy, white solid smokes, bursts into flames, and releases a large quantity of heat. Does the reaction

$$P_4(g) + 5O_2(g) \rightleftharpoons P_4O_{10}(s)$$

have a large or small equilibrium constant? Explain.

17.5 Does the following energy diagram depict a reaction in which K is small or large? Explain.



The Reaction Quotient and the Equilibrium Constant

(Sample Problems 17.1 to 17.3)

Concept Review Questions

17.6 For a given reaction at a given temperature, the value of K is constant. Is the value of Q also constant? Explain.

17.7 In a series of experiments on the thermal decomposition of lithium peroxide,

$$2Li_2O_2(s) \rightleftharpoons 2Li_2O(s) + O_2(g)$$

a chemist finds that, as long as some Li_2O_2 is present at the end of the experiment, the amount of O_2 obtained in a given container at a given T is the same. Explain.

17.8 In a study of the formation of HI from its elements,

$$H_2(g) + I_2(g) \rightleftharpoons 2HI(g)$$

equal amounts of H_2 and I_2 were placed in a container, which was then sealed and heated.

(a) On one set of axes, sketch concentration vs. time curves for H_2 and HI, and explain how Q changes as a function of time.

(b) Is the value of Q different if $[I_2]$ is plotted instead of $[H_2]$?

17.9 Explain the difference between a heterogeneous and a homogeneous equilibrium. Give an example of each.

17.10 Does Q for the formation of 1 mol of NO from its elements differ from Q for the decomposition of 1 mol of NO to its elements? Explain and give the relationship between the two Q's.

17.11 Does Q for the formation of 1 mol of NH_3 from H_2 and N_2 differ from Q for the formation of NH_3 from H_2 and 1 mol of N_2? Explain and give the relationship between the two Q's.

Skill-Building Exercises *(grouped in similar pairs)*

17.12 Balance each reaction and write its reaction quotient, Q_c:

(a) $NO(g) + O_2(g) \rightleftharpoons N_2O_3(g)$

(b) $SF_6(g) + SO_3(g) \rightleftharpoons SO_2F_2(g)$

(c) $SClF_5(g) + H_2(g) \rightleftharpoons S_2F_{10}(g) + HCl(g)$

17.13 Balance each reaction and write its reaction quotient, Q_c:

(a) $C_2H_6(g) + O_2(g) \rightleftharpoons CO_2(g) + H_2O(g)$

(b) $CH_4(g) + F_2(g) \rightleftharpoons CF_4(g) + HF(g)$

(c) $SO_3(g) \rightleftharpoons SO_2(g) + O_2(g)$

17.14 Balance each reaction and write its reaction quotient, Q_c:

(a) $NO_2Cl(g) \rightleftharpoons NO_2(g) + Cl_2(g)$

(b) $POCl_3(g) \rightleftharpoons PCl_3(g) + O_2(g)$

(c) $NH_3(g) + O_2(g) \rightleftharpoons N_2(g) + H_2O(g)$

17.15 Balance each reaction and write its reaction quotient, Q_c:

(a) $O_2(g) \rightleftharpoons O_3(g)$

(b) $NO(g) + O_3(g) \rightleftharpoons NO_2(g) + O_2(g)$

(c) $N_2O(g) + H_2(g) \rightleftharpoons NH_3(g) + H_2O(g)$

17.16 At a particular temperature, $K_c = 1.6\times10^{-2}$ for

$$2H_2S(g) \rightleftharpoons 2H_2(g) + S_2(g)$$

Calculate K_c for each of the following reactions:

(a) $\frac{1}{2}S_2(g) + H_2(g) \rightleftharpoons H_2S(g)$

(b) $5H_2S(g) \rightleftharpoons 5H_2(g) + \frac{5}{2}S_2(g)$

17.17 At a particular temperature, $K_c = 6.5\times10^{2}$ for

$$2NO(g) + 2H_2(g) \rightleftharpoons N_2(g) + 2H_2O(g)$$

Calculate K_c for each of the following reactions:

(a) $NO(g) + H_2(g) \rightleftharpoons \frac{1}{2}N_2(g) + H_2O(g)$

(b) $2N_2(g) + 4H_2O(g) \rightleftharpoons 4NO(g) + 4H_2(g)$

17.18 Balance each of the following examples of heterogeneous equilibria and write its reaction quotient, Q_c:

(a) $Na_2O_2(s) + CO_2(g) \rightleftharpoons Na_2CO_3(s) + O_2(g)$

(b) $H_2O(l) \rightleftharpoons H_2O(g)$

(c) $NH_4Cl(s) \rightleftharpoons NH_3(g) + HCl(g)$

17.19 Balance each of the following examples of heterogeneous equilibria and write its reaction quotient, Q_c:

(a) $H_2O(l) + SO_3(g) \rightleftharpoons H_2SO_4(aq)$

(b) $KNO_3(s) \rightleftharpoons KNO_2(s) + O_2(g)$

(c) $S_8(s) + F_2(g) \rightleftharpoons SF_6(g)$

17.20 Balance each of the following examples of heterogeneous equilibria and write its reaction quotient, Q_c:

(a) $NaHCO_3(s) \rightleftharpoons Na_2CO_3(s) + CO_2(g) + H_2O(g)$

(b) $SnO_2(s) + H_2(g) \rightleftharpoons Sn(s) + H_2O(g)$

(c) $H_2SO_4(l) + SO_3(g) \rightleftharpoons H_2S_2O_7(l)$

17.21 Balance each of the following examples of heterogeneous equilibria and write its reaction quotient, Q_c:

(a) $Al(s) + NaOH(aq) + H_2O(l) \rightleftharpoons Na[Al(OH)_4](aq) + H_2(g)$

(b) $CO_2(s) \rightleftharpoons CO_2(g)$
(c) $N_2O_5(s) \rightleftharpoons NO_2(g) + O_2(g)$

Problems in Context

17.22 Write Q_c for each of the following:
(a) Hydrogen chloride gas reacts with oxygen gas to produce chlorine gas and water vapor.
(b) Solid diarsenic trioxide reacts with fluorine gas to produce liquid arsenic pentafluoride and oxygen gas.
(c) Gaseous sulfur tetrafluoride reacts with liquid water to produce gaseous sulfur dioxide and hydrogen fluoride gas.
(d) Solid molybdenum(VI) oxide reacts with gaseous xenon difluoride to form liquid molybdenum(VI) fluoride, xenon gas, and oxygen gas.

17.23 The interhalogen ClF_3 is prepared in a two-step fluorination of chlorine gas:

$$Cl_2(g) + F_2(g) \rightleftharpoons ClF(g)$$
$$ClF(g) + F_2(g) \rightleftharpoons ClF_3(g)$$

(a) Balance each step and write the overall equation.
(b) Show that the overall Q_c equals the product of the Q_c's for the individual steps.

Expressing Equilibria with Pressure Terms: Relation Between K_c and K_p

(Sample Problem 17.4)

Concept Review Questions

17.24 Guldberg and Waage proposed the definition of the equilibrium constant as a certain ratio of *concentrations*. What relationship allows us to use a particular ratio of *partial pressures* (for a gaseous reaction) to express an equilibrium constant? Explain.

17.25 When are K_c and K_p equal, and when are they not?

17.26 A certain reaction at equilibrium has more moles of gaseous products than of gaseous reactants.
(a) Is K_c larger or smaller than K_p?
(b) Write a general statement about the relative sizes of K_c and K_p for any gaseous equilibrium.

Skill-Building Exercises *(grouped in similar pairs)*

17.27 Determine Δn_{gas} for each of the following reactions:
(a) $2KClO_3(s) \rightleftharpoons 2KCl(s) + 3O_2(g)$
(b) $2PbO(s) + O_2(g) \rightleftharpoons 2PbO_2(s)$
(c) $I_2(s) + 3XeF_2(s) \rightleftharpoons 2IF_3(s) + 3Xe(g)$

17.28 Determine Δn_{gas} for each of the following reactions:
(a) $MgCO_3(s) \rightleftharpoons MgO(s) + CO_2(g)$
(b) $2H_2(g) + O_2(g) \rightleftharpoons 2H_2O(l)$
(c) $HNO_3(l) + ClF(g) \rightleftharpoons ClONO_2(g) + HF(g)$

17.29 Calculate K_c for each of the following equilibria:
(a) $CO(g) + Cl_2(g) \rightleftharpoons COCl_2(g)$; $K_p = 3.9\times10^{-2}$ at 1000. K
(b) $S_2(g) + C(s) \rightleftharpoons CS_2(g)$; $K_p = 28.5$ at 500. K

17.30 Calculate K_c for each of the following equilibria:
(a) $H_2(g) + I_2(g) \rightleftharpoons 2HI(g)$; $K_p = 49$ at 730. K
(b) $2SO_2(g) + O_2(g) \rightleftharpoons 2SO_3(g)$; $K_p = 2.5\times10^{10}$ at 500. K

17.31 Calculate K_p for each of the following equilibria:
(a) $N_2O_4(g) \rightleftharpoons 2NO_2(g)$; $K_c = 6.1\times10^{-3}$ at 298 K
(b) $N_2(g) + 3H_2(g) \rightleftharpoons 2NH_3(g)$; $K_c = 2.4\times10^{-3}$ at 1000. K

17.32 Calculate K_p for each of the following equilibria:
(a) $H_2(g) + CO_2(g) \rightleftharpoons H_2O(g) + CO(g)$; $K_c = 0.77$ at 1020. K
(b) $3O_2(g) \rightleftharpoons 2O_3(g)$; $K_c = 1.8\times10^{-56}$ at 570. K

Reaction Direction: Comparing Q and K

(Sample Problem 17.5)

Concept Review Questions

17.33 When the numerical value of Q is less than K, in which direction does the reaction proceed to reach equilibrium? Explain.

17.34 What three criteria characterize a chemical system at equilibrium?

Skill-Building Exercises *(grouped in similar pairs)*

17.35 At 425°C, $K_p = 4.18\times10^{-9}$ for the reaction

$$2HBr(g) \rightleftharpoons H_2(g) + Br_2(g)$$

In one experiment, 0.20 atm of $HBr(g)$, 0.010 atm of $H_2(g)$, and 0.010 atm of $Br_2(g)$ are introduced into a container. Is the reaction at equilibrium? If not, in which direction will it proceed?

17.36 At 100°C, $K_p = 60.6$ for the reaction

$$2NOBr(g) \rightleftharpoons 2NO(g) + Br_2(g)$$

In a given experiment, 0.10 atm of each component is placed in a container. Is the system at equilibrium? If not, in which direction will the reaction proceed?

Problems in Context

17.37 The water-gas shift reaction plays a central role in the chemical methods for obtaining cleaner fuels from coal:

$$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g)$$

At a given temperature, $K_p = 2.7$. If 0.13 mol of CO, 0.56 mol of H_2O, 0.62 mol of CO_2, and 0.43 mol of H_2 are introduced into a 2.0-L flask, in which direction must the reaction proceed to reach equilibrium?

How to Solve Equilibrium Problems

(Sample Problems 17.6 to 17.10)

Concept Review Questions

17.38 In the 1980s, CFC-11 was one of the most heavily produced chlorofluorocarbons. The last step in its formation is

$$CCl_4(g) + HF(g) \rightleftharpoons CFCl_3(g) + HCl(g)$$

If you start the reaction with equal concentrations of CCl_4 and HF, you obtain equal concentrations of $CFCl_3$ and HCl at equilibrium. Are the final concentrations of $CFCl_3$ and HCl equal if you start with unequal concentrations of CCl_4 and HF? Explain.

17.39 For a problem involving the catalyzed reaction of methane and steam, the following reaction table was prepared:

Pressure (atm)	$CH_4(g)$	+ $2H_2O(g)$	$\rightleftharpoons$ $CO_2(g)$	+ $4H_2(g)$
Initial	0.30	0.40	0	0
Change	$-x$	$-2x$	$+x$	$+4x$
Equilibrium	$0.30 - x$	$0.40 - 2x$	x	$4x$

Explain the entries in the "Change" and "Equilibrium" rows.

17.40 (a) What is the basis of the approximation that avoids using the quadratic formula to find an equilibrium concentration?
(b) When should this approximation *not* be made?

Skill-Building Exercises *(grouped in similar pairs)*

17.41 In an experiment to study the formation of HI(g),

$$H_2(g) + I_2(g) \rightleftharpoons 2HI(g)$$

$H_2(g)$ and $I_2(g)$ were placed in a sealed container at a certain temperature. At equilibrium, $[H_2] = 6.50\times10^{-5}$ M, $[I_2] = 1.06\times10^{-3}$ M, and $[HI] = 1.87\times10^{-3}$ M. Calculate K_c for the reaction at this temperature.

17.42 Gaseous ammonia was introduced into a sealed container and heated to a certain temperature:

$$2NH_3(g) \rightleftharpoons N_2(g) + 3H_2(g)$$

At equilibrium, $[NH_3] = 0.0225\ M$, $[N_2] = 0.114\ M$, and $[H_2] = 0.342\ M$. Calculate K_c for the reaction at this temperature.

17.43 Gaseous PCl_5 decomposes according to the reaction

$$PCl_5(g) \rightleftharpoons PCl_3(g) + Cl_2(g)$$

In one experiment, 0.15 mol of $PCl_5(g)$ was introduced into a 2.0-L container. Construct the reaction table for this process.

17.44 Hydrogen fluoride, HF, can be made from the reaction

$$H_2(g) + F_2(g) \rightleftharpoons 2HF(g)$$

In one experiment, 0.10 mol of $H_2(g)$ and 0.050 mol of $F_2(g)$ are added to a 0.50-L flask. Write a reaction table for this process.

17.45 For the following reaction, $K_p = 6.5\times10^4$ at 308 K:

$$2NO(g) + Cl_2(g) \rightleftharpoons 2NOCl(g)$$

At equilibrium, $P_{NO} = 0.35$ atm and $P_{Cl_2} = 0.10$ atm. What is the equilibrium partial pressure of $NOCl(g)$?

17.46 For the following reaction, $K_p = 0.262$ at 1000°C:

$$C(s) + 2H_2(g) \rightleftharpoons CH_4(g)$$

At equilibrium, P_{H_2} is 1.22 atm. What is the equilibrium partial pressure of $CH_4(g)$?

17.47 Ammonium hydrogen sulfide decomposes according to the following reaction, for which $K_p = 0.11$ at 250°C:

$$NH_4HS(s) \rightleftharpoons H_2S(g) + NH_3(g)$$

If 55.0 g of $NH_4HS(s)$ is placed in a sealed 5.0-L container, what is the partial pressure of $NH_3(g)$ at equilibrium?

17.48 Hydrogen sulfide decomposes according to the following reaction, for which $K_c = 9.30\times10^{-8}$ at 700°C:

$$2H_2S(g) \rightleftharpoons 2H_2(g) + S_2(g)$$

If 0.45 mol of H_2S is placed in a 3.0-L container, what is the equilibrium concentration of $H_2(g)$ at 700°C?

17.49 Even at high T, the formation of nitric oxide is not favored:

$$N_2(g) + O_2(g) \rightleftharpoons 2NO(g) \qquad K_c = 4.10\times10^{-4} \text{ at } 2000°C$$

What is [NO] when a mixture of 0.20 mol of $N_2(g)$ and 0.15 mol of $O_2(g)$ reach equilibrium in a 1.0-L container at 2000°C?

17.50 Nitrogen dioxide decomposes according to the reaction

$$2NO_2(g) \rightleftharpoons 2NO(g) + O_2(g)$$

where $K_p = 4.48\times10^{-13}$ at a certain temperature. A pressure of 0.75 atm of NO_2 is introduced into a container and allowed to come to equilibrium. What are the equilibrium partial pressures of $NO(g)$ and $O_2(g)$?

17.51 Hydrogen iodide decomposes according to the reaction

$$2HI(g) \rightleftharpoons H_2(g) + I_2(g)$$

A sealed 1.50-L container initially holds 0.00623 mol of H_2, 0.00414 mol of I_2, and 0.0244 mol of HI at 703 K. When equilibrium is reached, the concentration of $H_2(g)$ is 0.00467 M. What are the concentrations of $HI(g)$ and $I_2(g)$?

17.52 Compound A decomposes according to the equation

$$A(g) \rightleftharpoons 2B(g) + C(g)$$

A sealed 1.00-L container initially contains 1.75×10^{-3} mol of A(g), 1.25×10^{-3} mol of B(g), and 6.50×10^{-4} mol of C(g) at 100°C. At equilibrium, [A] is $2.15\times10^{-3}\ M$. Find [B] and [C].

Problems in Context

17.53 In an analysis of interhalogen reactivity, 0.500 mol of ICl was placed in a 5.00-L flask, where it decomposed at a high T:

$$2ICl(g) \rightleftharpoons I_2(g) + Cl_2(g)$$

Calculate the equilibrium concentrations of I_2, Cl_2, and ICl ($K_c = 0.110$ at this temperature).

17.54 A United Nations toxicologist studying the properties of mustard gas, $S(CH_2CH_2Cl)_2$, a blistering agent used in warfare, prepares a mixture of 0.675 M SCl_2 and 0.973 M C_2H_4 and allows it to react at room temperature (20.0°C):

$$SCl_2(g) + 2C_2H_4(g) \rightleftharpoons S(CH_2CH_2Cl)_2(g)$$

At equilibrium, $[S(CH_2CH_2Cl)_2] = 0.350\ M$. Calculate K_p.

17.55 The first step in industrial production of nitric acid is the catalyzed oxidation of ammonia. Without a catalyst, a different reaction predominates:

$$4NH_3(g) + 3O_2(g) \rightleftharpoons 2N_2(g) + 6H_2O(g)$$

When 0.0150 mol of $NH_3(g)$ and 0.0150 mol of $O_2(g)$ are placed in a 1.00-L container at a certain temperature, the N_2 concentration at equilibrium is $1.96\times10^{-3}\ M$. Calculate K_c.

17.56 A key step in the extraction of iron from its ore is

$$FeO(s) + CO(g) \rightleftharpoons Fe(s) + CO_2(g) \qquad K_p = 0.403 \text{ at } 1000°C$$

This step occurs in the 700°C to 1200°C zone within a blast furnace. What are the equilibrium partial pressures of $CO(g)$ and $CO_2(g)$ when 1.00 atm of $CO(g)$ and excess $FeO(s)$ react in a sealed container at 1000°C?

Reaction Conditions and the Equilibrium State: Le Châtelier's Principle

(Sample Problems 17.11 to 17.14)

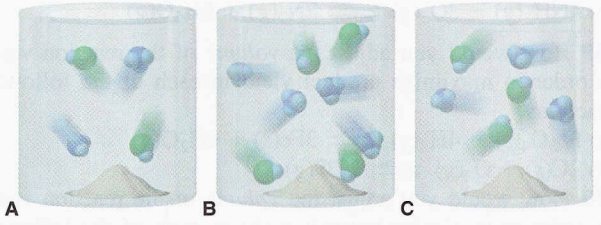
Concept Review Questions

17.57 What is meant by the word "disturbance" in the statement of Le Châtelier's principle?

17.58 What is the difference between the equilibrium position and the equilibrium constant of a reaction? Which changes as a result of a change in reactant concentration?

17.59 Scenes A, B, and C depict this reaction at three temperatures:

$$NH_4Cl(s) \rightleftharpoons NH_3(g) + HCl(g) \qquad \Delta H^0_{rxn} = 176 \text{ kJ}$$



(a) Which best represents the reaction mixture at the highest temperature? Explain.

(b) Which best represents the reaction mixture at the lowest temperature? Explain.

17.60 What is implied by the word "constant" in the term *equilibrium constant?* Give two reaction parameters that can be changed without changing the value of an equilibrium constant.

17.61 Le Châtelier's principle is related ultimately to the rates of the forward and reverse steps in a reaction. Explain (a) why an increase in reactant concentration shifts the equilibrium position to the right but does not change K; (b) why a decrease in V shifts the equilibrium position toward fewer moles of gas but does not change K; and (c) why a rise in T shifts the equilibrium position of an exothermic reaction toward reactants and also changes K.

17.62 Le Châtelier's principle predicts that a rise in the temperature of an endothermic reaction from T_1 to T_2 results in K_2 being larger than K_1. Explain.

Skill-Building Exercises *(grouped in similar pairs)*

17.63 Consider this equilibrium system:

$$CO(g) + Fe_3O_4(s) \rightleftharpoons CO_2(g) + 3FeO(s)$$

How does the equilibrium position shift as a result of each of the following disturbances?
(a) CO is added.
(b) CO_2 is removed by adding solid NaOH.
(c) Additional $Fe_3O_4(s)$ is added to the system.
(d) Dry ice is added at constant temperature.

17.64 Sodium bicarbonate undergoes thermal decomposition according to the reaction

$$2NaHCO_3(s) \rightleftharpoons Na_2CO_3(s) + CO_2(g) + H_2O(g)$$

How does the equilibrium position shift as a result of each of the following disturbances?
(a) 0.20 atm of argon gas is added.
(b) $NaHCO_3(s)$ is added.
(c) $Mg(ClO_4)_2(s)$ is added as a drying agent to remove H_2O.
(d) Dry ice is added at constant temperature.

17.65 Predict the effect of *increasing* the container volume on the amounts of each reactant and product in the following reactions:
(a) $F_2(g) \rightleftharpoons 2F(g)$
(b) $2CH_4(g) \rightleftharpoons C_2H_2(g) + 3H_2(g)$

17.66 Predict the effect of *increasing* the container volume on the amounts of each reactant and product in the following reactions:
(a) $CH_3OH(l) \rightleftharpoons CH_3OH(g)$
(b) $CH_4(g) + NH_3(g) \rightleftharpoons HCN(g) + 3H_2(g)$

17.67 Predict the effect of *decreasing* the container volume on the amounts of each reactant and product in the following reactions:
(a) $H_2(g) + Cl_2(g) \rightleftharpoons 2HCl(g)$
(b) $2H_2(g) + O_2(g) \rightleftharpoons 2H_2O(l)$

17.68 Predict the effect of *decreasing* the container volume on the amounts of each reactant and product in the following reactions:
(a) $C_3H_8(g) + 5O_2(g) \rightleftharpoons 3CO_2(g) + 4H_2O(l)$
(b) $4NH_3(g) + 3O_2(g) \rightleftharpoons 2N_2(g) + 6H_2O(g)$

17.69 How would you adjust the *volume* of the reaction vessel in order to maximize product yield in each of the following reactions?
(a) $Fe_3O_4(s) + 4H_2(g) \rightleftharpoons 3Fe(s) + 4H_2O(g)$
(b) $2C(s) + O_2(g) \rightleftharpoons 2CO(g)$

17.70 How would you adjust the *volume* of the reaction vessel in order to maximize product yield in each of the following reactions?
(a) $Na_2O_2(s) \rightleftharpoons 2Na(l) + O_2(g)$
(b) $C_2H_2(g) + 2H_2(g) \rightleftharpoons C_2H_6(g)$

17.71 Predict the effect of *increasing* the temperature on the amounts of products in the following reactions:
(a) $CO(g) + 2H_2(g) \rightleftharpoons CH_3OH(g) \quad \Delta H^0_{rxn} = -90.7$ kJ
(b) $C(s) + H_2O(g) \rightleftharpoons CO(g) + H_2(g) \quad \Delta H^0_{rxn} = 131$ kJ
(c) $2NO_2(g) \rightleftharpoons 2NO(g) + O_2(g)$ (endothermic)
(d) $2C(s) + O_2(g) \rightleftharpoons 2CO(g)$ (exothermic)

17.72 Predict the effect of *decreasing* the temperature on the amounts of reactants in the following reactions:
(a) $C_2H_2(g) + H_2O(g) \rightleftharpoons CH_3CHO(g) \quad \Delta H^0_{rxn} = -151$ kJ
(b) $CH_3CH_2OH(l) + O_2(g) \rightleftharpoons CH_3CO_2H(l) + H_2O(g)$
$\Delta H^0_{rxn} = -451$ kJ
(c) $2C_2H_4(g) + O_2(g) \rightleftharpoons 2CH_3CHO(g)$ (exothermic)
(d) $N_2O_4(g) \rightleftharpoons 2NO_2(g)$ (endothermic)

17.73 Deuterium (D or ^2H) is an isotope of hydrogen. The molecule D_2 undergoes an exchange reaction with ordinary H_2 that leads to isotopic equilibrium:

$$D_2(g) + H_2(g) \rightleftharpoons 2DH(g) \qquad K_p = 1.80 \text{ at } 298 \text{ K}$$

If ΔH^0_{rxn} is 0.32 kJ/mol DH, calculate K_p at 500. K.

17.74 The formation of methanol is important to the processing of new fuels. At 298 K, $K_p = 2.25\times10^4$ for the reaction

$$CO(g) + 2H_2(g) \rightleftharpoons CH_3OH(l)$$

If $\Delta H^0_{rxn} = -128$ kJ/mol CH_3OH, calculate K_p at 0°C.

Problems in Context

17.75 The minerals hematite (Fe_2O_3) and magnetite (Fe_3O_4) exist in equilibrium with atmospheric oxygen:

$$4Fe_3O_4(s) + O_2(g) \rightleftharpoons 6Fe_2O_3(s) \qquad K_p = 2.5\times10^{87} \text{ at } 298 \text{ K}$$

(a) Determine P_{O_2} at equilibrium. (b) Given that P_{O_2} in air is 0.21 atm, in which direction will the reaction proceed to reach equilibrium? (c) Calculate K_c at 298 K.

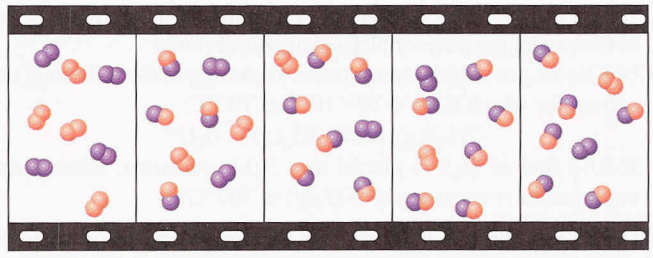
17.76 The oxidation of SO_2 is the key step in H_2SO_4 production:

$$SO_2(g) + \tfrac{1}{2}O_2(g) \rightleftharpoons SO_3(g) \qquad \Delta H^0_{rxn} = -99.2 \text{ kJ}$$

(a) What qualitative combination of T and P maximizes SO_3 yield?
(b) How does addition of O_2 affect Q? K?
(c) Why is catalysis used for this reaction?

Comprehensive Problems

17.77 The "filmstrip" represents five molecular-level scenes of a gaseous mixture as it reaches equilibrium over time:



X is purple and Y is orange: $X_2(g) + Y_2(g) \rightleftharpoons 2XY(g)$.
(a) Write the reaction quotient, Q, for this reaction.
(b) If each particle represents 0.1 mol of particles, calculate Q for each scene.
(c) If $K > 1$, is time progressing to the right or to the left? Explain.
(d) Calculate K at this temperature.
(e) If $\Delta H^0_{rxn} < 0$, which scene, if any, best represents the mixture at a higher temperature? Explain.
(f) Which scene, if any, best represents the mixture at a higher pressure (lower volume)? Explain.

17.78 The powerful chlorinating agent sulfuryl dichloride (SO_2Cl_2) can be prepared by the following two-step sequence:

$$H_2S(g) + O_2(g) \rightleftharpoons SO_2(g) + H_2O(g)$$
$$SO_2(g) + Cl_2(g) \rightleftharpoons SO_2Cl_2(g)$$

(a) Balance each step, and write the overall equation.
(b) Show that the overall Q_c equals the product of the Q_c's for the individual steps.

17.79 A mixture of 5.00 volumes of N_2 and 1.00 volume of O_2 passes through a heated furnace and reaches equilibrium at 900. K and 5.00 atm:

$$N_2(g) + O_2(g) \rightleftharpoons 2NO(g) \qquad K_p = 6.70\times10^{-10}$$

(a) What is the partial pressure of NO? (b) What is the concentration in micrograms per liter (μg/L) of NO in the mixture?

17.80 For the following equilibrium system, which of the changes will form more $CaCO_3$?

$$CO_2(g) + Ca(OH)_2(s) \rightleftharpoons CaCO_3(s) + H_2O(l) \qquad \Delta H^0 = -113 \text{ kJ}$$

(a) Decrease temperature at constant pressure (no phase change)
(b) Increase volume at constant temperature
(c) Increase partial pressure of CO_2
(d) Remove one-half of the initial $CaCO_3$

17.81 Ammonium carbamate (NH_2COONH_4) is a salt of carbamic acid that is found in the blood and urine of mammals. At 250.°C, $K_c = 1.58\times10^{-8}$ for the following equilibrium:

$$NH_2COONH_4(s) \rightleftharpoons 2NH_3(g) + CO_2(g)$$

If 7.80 g of NH_2COONH_4 is put into a 0.500-L evacuated container, what is the total pressure at equilibrium?

17.82 A study of the water-gas shift reaction (see Problem 17.37) was made in which equilibrium was reached with $[CO] = [H_2O] = [H_2] = 0.10\ M$ and $[CO_2] = 0.40\ M$. After 0.60 mol of H_2 is added to the 2.0-L container and equilibrium is re-established, what are the new concentrations of all the components?

17.83 Isolation of Group 8B(10) elements, used as industrial catalysts, involves a series of steps. For nickel, the sulfide ore is roasted in air: $Ni_3S_2(s) + O_2(g) \rightleftharpoons NiO(s) + SO_2(g)$. The metal oxide is reduced by the H_2 in water gas ($CO + H_2$) to impure Ni: $NiO(s) + H_2(g) \rightleftharpoons Ni(s) + H_2O(g)$. The CO in water gas then reacts with the metal in the Mond process to form gaseous nickel carbonyl, $Ni(s) + CO(g) \rightleftharpoons Ni(CO)_4(g)$, which is subsequently decomposed to the metal.
(a) Balance each of the three steps, and obtain an overall balanced equation for the conversion of Ni_3S_2 to $Ni(CO)_4$.
(b) Show that the overall Q_c is the product of the Q_c's for the individual reactions.

17.84 One of the most important industrial sources of ethanol is the reaction of steam with ethene derived from crude oil:

$$C_2H_4(g) + H_2O(g) \rightleftharpoons C_2H_5OH(g) \qquad \Delta H^0_{rxn} = -47.8 \text{ kJ} \qquad K_c = 9\times10^3 \text{ at 600. K}$$

(a) At equilibrium, $P_{C_2H_5OH} = 200.$ atm and $P_{H_2O} = 400.$ atm. Calculate $P_{C_2H_4}$.
(b) Is the highest yield of ethanol obtained at high or low pressures? High or low temperatures?
(c) Calculate K_c at 450. K.
(d) In manufacturing, the yield of ammonia is increased by condensing it to a liquid and removing it from the vessel. Would condensing the C_2H_5OH work in this process? Explain.

17.85 Which of the following situations represent equilibrium?
(a) Migratory birds fly north in summer and south in winter.
(b) In a grocery store, some carts are kept inside and some outside. Customers bring carts out to their cars, while store clerks bring carts in to replace those taken out.
(c) In a tug o' war, a ribbon tied to the center of the rope moves back and forth until one side loses, after which the ribbon goes all the way to the winner's side.
(d) As a stew is cooking, water in the stew vaporizes, and the vapor condenses on the lid to droplets that drip into the stew.

17.86 An industrial chemist introduces 2.0 atm of H_2 and 2.0 atm of CO_2 into a 1.00-L container at 25.0°C and then raises the temperature to 700.°C, at which $K_c = 0.534$:

$$H_2(g) + CO_2(g) \rightleftharpoons H_2O(g) + CO(g)$$

How many grams of H_2 are present at equilibrium?

17.87 As an EPA scientist studying catalytic converters and urban smog, you want to find K_c for the following reaction:

$$2NO_2(g) \rightleftharpoons N_2(g) + 2O_2(g) \qquad K_c = ?$$

Use the following data to find the unknown K_c:

$$\tfrac{1}{2}N_2(g) + \tfrac{1}{2}O_2(g) \rightleftharpoons NO(g) \qquad K_c = 4.8\times10^{-10}$$
$$2NO_2(g) \rightleftharpoons 2NO(g) + O_2(g) \qquad K_c = 1.1\times10^{-5}$$

17.88 An inorganic chemist places 1 mol of BrCl in container A and 0.5 mol of Br_2 and 0.5 mol of Cl_2 in container B. She seals the containers and heats them to 300°C. With time, both containers hold identical mixtures of BrCl, Br_2, and Cl_2.
(a) Write a balanced equation for the reaction in container A.
(b) Write the reaction quotient, Q, for this reaction.
(c) How do the values of Q in A and in B compare over time?
(d) Explain on the molecular level how it is possible for both containers to end up with identical mixtures.

17.89 An engineer examining the oxidation of SO_2 in the manufacture of sulfuric acid determines that $K_c = 1.7\times10^8$ at 600. K:

$$2SO_2(g) + O_2(g) \rightleftharpoons 2SO_3(g)$$

(a) At equilibrium, $P_{SO_3} = 300.$ atm and $P_{O_2} = 100.$ atm. Calculate P_{SO_2}.
(b) The engineer places a mixture of 0.0040 mol of $SO_2(g)$ and 0.0028 mol of $O_2(g)$ in a 1.0-L container and raises the temperature to 1000 K. At equilibrium, 0.0020 mol of $SO_3(g)$ is present. Calculate K_c and P_{SO_2} for this reaction at 1000. K.

17.90 Phosgene ($COCl_2$) is a toxic substance that forms readily from carbon monoxide and chlorine at elevated temperatures:

$$CO(g) + Cl_2(g) \rightleftharpoons COCl_2(g)$$

If 0.350 mol of each reactant is placed in a 0.500-L flask at 600 K, what are the concentrations of all three substances at equilibrium ($K_c = 4.95$ at this temperature)?

17.91 When 0.100 mol of $CaCO_3(s)$ and 0.100 mol of $CaO(s)$ are placed in an evacuated sealed 10.0-L container and heated to 385 K, $P_{CO_2} = 0.220$ atm after equilibrium is established:

$$CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g)$$

An additional 0.300 atm of $CO_2(g)$ is then pumped into the container. What is the total mass (in g) of $CaCO_3$ after equilibrium is re-established?

17.92 Use each of the following reaction quotients to write the balanced equation:

(a) $Q = \dfrac{[CO_2]^2[H_2O]^2}{[C_2H_4][O_2]^3}$ (b) $Q = \dfrac{[NH_3]^4[O_2]^7}{[NO_2]^4[H_2O]^6}$

17.93 Hydrogenation of carbon-carbon π bonds is important in the petroleum and food industries. The conversion of acetylene to ethylene is a simple example of the process:

$$C_2H_2(g) + H_2(g) \rightleftharpoons C_2H_4(g) \qquad K_c = 2.9\times10^8 \text{ at 2000. K}$$

The process is usually performed at much lower temperatures with the aid of a catalyst. Use ΔH^0_f values from Appendix B to calculate K_c for this reaction at 300. K.

17.94 In combustion studies of H_2 as an alternative fuel, you find evidence that the hydroxyl radical (HO) is formed in flames by the reaction $H(g) + \frac{1}{2}O_2(g) \rightleftharpoons HO(g)$. Use the following data to calculate K_c for the reaction:

$$\tfrac{1}{2}H_2(g) + \tfrac{1}{2}O_2(g) \rightleftharpoons HO(g) \qquad K_c = 0.58$$
$$\tfrac{1}{2}H_2(g) \rightleftharpoons H(g) \qquad K_c = 1.6\times10^{-3}$$

17.95 Highly toxic disulfur decafluoride decomposes by a free-radical process: $S_2F_{10}(g) \rightleftharpoons SF_4(g) + SF_6(g)$. In a study of the decomposition, S_2F_{10} was placed in a 2.0-L flask and heated

to 100°C; $[S_2F_{10}]$ was 0.50 *M* at equilibrium. More S_2F_{10} was added, and when equilibrium was reattained, $[S_2F_{10}]$ was 2.5 *M*. How did $[SF_4]$ and $[SF_6]$ change from the original to the new equilibrium position after the addition of more S_2F_{10}?

17.96 Aluminum is one of the most versatile metals. It is produced by the Hall-Heroult process, in which molten cryolite, Na_3AlF_6, is used as a solvent for the aluminum ore. Cryolite undergoes very slight decomposition with heat to produce a tiny amount of F_2, which escapes into the atmosphere above the solvent. K_c is 2×10^{-104} at 1300 K for the reaction:

$$Na_3AlF_6(l) \rightleftharpoons 3Na(l) + Al(l) + 3F_2(g)$$

What is the concentration of F_2 over a bath of molten cryolite at this temperature?

17.97 An equilibrium mixture of car exhaust gases consisting of 10.0 volumes of CO_2, 1.00 volume of unreacted O_2, and 50.0 volumes of unreacted N_2 leaves the engine at 4.0 atm and 800. K.

(a) Given this equilibrium, what is the partial pressure of CO?

$$2CO_2(g) \rightleftharpoons 2CO(g) + O_2(g) \qquad K_p = 1.4\times10^{-28} \text{ at } 800.\text{ K}$$

(b) Assuming the mixture has enough time to reach equilibrium, what is the concentration in picograms per liter (pg/L) of CO in the exhaust gas? (The actual concentration of CO in car exhaust is much higher because the gases do *not* reach equilibrium in the short transit time through the engine and exhaust system.)

17.98 Consider the following reaction:

$$3Fe(s) + 4H_2O(g) \rightleftharpoons Fe_3O_4(s) + 4H_2(g)$$

(a) What are the apparent oxidation states of Fe and of O in Fe_3O_4?

(b) Fe_3O_4 is a compound of iron in which Fe occurs in two oxidation states. What are the oxidation states of Fe in Fe_3O_4?

(c) At 900°C, K_c for the reaction is 5.1. If 0.050 mol of $H_2O(g)$ and 0.100 mol of Fe(*s*) are placed in a 1.0-L container at 900°C, how many grams of Fe_3O_4 are present at equilibrium?

Note: The synthesis of ammonia is a major process throughout the industrialized world. Problems 17.99 to 17.106 refer to various aspects of this all-important reaction:

$$N_2(g) + 3H_2(g) \rightleftharpoons 2NH_3(g) \qquad \Delta H^0_{rxn} = -91.8 \text{ kJ}$$

17.99 When ammonia is made industrially, the mixture of N_2, H_2, and NH_3 that emerges from the reaction chamber is far from equilibrium. Why does the plant supervisor use reaction conditions that produce less than the maximum yield of ammonia?

17.100 The following reaction is sometimes used to produce the H_2 needed for the synthesis of ammonia:

$$CH_4(g) + CO_2(g) \rightleftharpoons 2CO(g) + 2H_2(g)$$

(a) What is the percent yield of H_2 when an equimolar mixture of CH_4 and CO_2 with a total pressure of 20.0 atm reaches equilibrium at 1200. K, at which $K_p = 3.548\times10^6$?

(b) What is the percent yield of H_2 for this system at 1300. K, at which $K_p = 2.626\times10^7$?

(c) Use the van't Hoff equation to find ΔH^0_{rxn}.

17.101 The methane used to obtain H_2 for NH_3 manufacture is impure and usually contains other hydrocarbons, such as propane, C_3H_8. Imagine the reaction of propane occurring in two steps:

$$C_3H_8(g) + 3H_2O(g) \rightleftharpoons 3CO(g) + 7H_2(g) \qquad K_p = 8.175\times10^{15} \text{ at } 1200.\text{ K}$$

$$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g) \qquad K_p = 0.6944 \text{ at } 1200.\text{ K}$$

(a) Write the overall equation for the reaction of propane and steam to produce carbon dioxide and hydrogen.

(b) Calculate K_p for the overall process at 1200. K.

(c) When 1.00 volume of C_3H_8 and 4.00 volumes of H_2O, each at 1200. K and 5.0 atm, are mixed in a container, what is the final pressure? Assume the total volume remains constant, that the reaction is essentially complete, and that the gases behave ideally.

(d) What percentage of the C_3H_8 remains unreacted?

17.102 Using CH_4 and steam as a source of H_2 for NH_3 synthesis requires high temperatures. Rather than burning CH_4 separately to heat the mixture, it is more efficient to inject some oxygen into the reaction mixture. All of the H_2 is thus released for the synthesis, and the heat of combustion of CH_4 helps maintain the required temperature. Imagine the reaction occurring in two steps:

$$2CH_4(g) + O_2(g) \rightleftharpoons 2CO(g) + 4H_2(g) \qquad K_p = 9.34\times10^{28} \text{ at } 1000.\text{ K}$$

$$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g) \qquad K_p = 1.374 \text{ at } 1000.\text{ K}$$

(a) Write the overall equation for the reaction of methane, steam, and oxygen to form carbon dioxide and hydrogen.

(b) What is K_p for the overall reaction?

(c) What is K_c for the overall reaction?

(d) A mixture of 2.0 mol of CH_4, 1.0 mol of O_2, and 2.0 mol of steam with a total pressure of 30. atm reacts at 1000. K at constant volume. Assuming that the reaction is complete and the ideal gas law is a valid approximation, what is the final pressure?

17.103 A mixture of 3.00 volumes of H_2 and 1.00 volume of N_2 reacts at 344°C to form ammonia. The equilibrium mixture at 110. atm contains 41.49% NH_3 by volume. Calculate K_p for the reaction, assuming that the gases behave ideally.

17.104 One mechanism for the synthesis of ammonia proposes that N_2 and H_2 molecules catalytically dissociate into atoms:

$$N_2(g) \rightleftharpoons 2N(g) \quad \log K_p = -43.10$$

$$H_2(g) \rightleftharpoons 2H(g) \quad \log K_p = -17.30$$

(a) Find the partial pressure of N in N_2 at 1000. K and 200. atm.

(b) Find the partial pressure of H in H_2 at 1000. K and 600. atm.

(c) How many N atoms and H atoms are present per liter?

(d) Based on these answers, which of the following is a more reasonable step to continue the mechanism after the catalytic dissociation? Explain.

$$N(g) + H(g) \longrightarrow NH(g)$$

$$N_2(g) + H(g) \longrightarrow NH(g) + N(g)$$

17.105 Consider the formation of ammonia in two experiments.

(a) To a 1.00-L container at 727°C, 1.30 mol of N_2 and 1.65 mol of H_2 are added. At equilibrium, 0.100 mol of NH_3 is present. Calculate the equilibrium concentrations of N_2 and H_2, and find K_c for the reaction: $2NH_3(g) \rightleftharpoons N_2(g) + 3H_2(g)$.

(b) In a different 1.00-L container at the same temperature, equilibrium is established with 8.34×10^{-2} mol of NH_3, 1.50 mol of N_2, and 1.25 mol of H_2 present. Calculate K_c for the reaction: $NH_3(g) \rightleftharpoons \frac{1}{2}N_2(g) + \frac{3}{2}H_2(g)$.

(c) What is the relationship between the K_c values in parts (a) and (b)? Why aren't these values the same?

17.106 You are a member of a research team of chemists discussing the plans to operate an ammonia processing plant:

$$N_2(g) + 3H_2(g) \rightleftharpoons 2NH_3(g)$$

(a) The plant operates at close to 700 K, at which K_p is 1.00×10^{-4}, and employs the stoichiometric 1:3 ratio of N_2:H_2.

At equilibrium, the partial pressure of NH_3 is 50. atm. Calculate the partial pressures of each reactant and P_{total}.

(b) One member of the team makes the following suggestion: since the partial pressure of H_2 is cubed in the reaction quotient, the plant could produce the same amount of NH_3 if the reactants were in a 1:6 ratio of N_2:H_2 and could do so at a lower pressure, which would cut operating costs. Calculate the partial pressure of each reactant and P_{total} under these conditions, assuming an unchanged partial pressure of 50. atm for NH_3. Is the team member's argument valid?

17.107 The atmospheric breakdown of CO_2, the main greenhouse gas, to CO and O_2 is highly temperature dependent, with K_p varying over many orders of magnitude for a temperature range of 1000 K.

(a) At a low T, a flask initially contains 1.00 atm of CO_2. What is P_{CO} if $K_p = 1.00\times10^{22}$ at this temperature for the *formation* of CO_2 from CO and O_2?

(b) What is P_{total} in the flask at this low T?

(c) The same experiment is run at a high T, and 35% of the CO_2 decomposes. Calculate K_p for CO_2 formation at this T.

(d) What is P_{total} in the flask at this high T?

(e) Is CO_2 breakdown exothermic or endothermic? Explain.

17.108 The two most abundant atmospheric gases react to a tiny extent at 298 K in the presence of a catalyst:

$$N_2(g) + O_2(g) \rightleftharpoons 2NO(g) \qquad K_p = 4.35\times10^{-31}$$

(a) What are the equilibrium pressures of the three components when the atmospheric partial pressures of O_2 (0.210 atm) and of N_2 (0.780 atm) are put into an evacuated 1.00-L flask at 298 K with catalyst?

(b) What is P_{total} in the container?

(c) Find K_c for this reaction at 298 K.

17.109 The oxidation of nitric oxide is favored at 457 K:

$$2NO(g) + O_2(g) \rightleftharpoons 2NO_2(g) \qquad K_p = 1.3\times10^{4}$$

(a) Calculate K_c at 457 K.

(b) Find ΔH^0_{rxn} from standard heats of formation.

(c) At what temperature does $K_c = 6.4\times10^{9}$?

17.110 The kinetics and equilibrium of the decomposition of hydrogen iodide have been studied extensively:

$$2HI(g) \rightleftharpoons H_2(g) + I_2(g)$$

(a) At 298 K, $K_c = 1.26\times10^{-3}$ for this reaction. Calculate K_p.

(b) Calculate K_c for the *formation* of HI at 298 K.

(c) Calculate ΔH^0_{rxn} for HI decomposition from ΔH^0_f values.

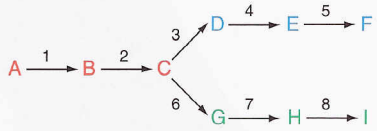
(d) At 729 K, $K_c = 2.0\times10^{-2}$ for HI decomposition. Calculate ΔH_{rxn} for this reaction from the van't Hoff equation.

17.111 Isopentyl alcohol reacts with pure acetic acid to form isopentyl acetate, the essence of banana oil:

$$C_5H_{11}OH + CH_3COOH \rightleftharpoons CH_3COOC_5H_{11} + H_2O$$

A student adds a drying agent to remove H_2O and thus increase the yield of banana oil. Is this approach reasonable? Explain.

17.112 Many essential metabolites are products in branched pathways, such as the one shown below:



One method of control of these pathways occurs through inhibition of the first enzyme specific for a branch.

(a) Which enzyme is inhibited by F?

(b) Which enzyme is inhibited by I?

(c) What disadvantage would there be if F inhibited enzyme 1?

(d) What disadvantage would there be if F inhibited enzyme 6?

17.113 For the equilibrium

$$H_2S(g) \rightleftharpoons 2H_2(g) + S_2(g) \qquad K_c = 9.0\times10^{-8} \text{ at } 700°C$$

the initial concentrations of the three gases are 0.300 M H_2S, 0.300 M H_2, and 0.150 M S_2. Determine the equilibrium concentrations of the gases.

17.114 Glauber's salt, $Na_2SO_4\cdot10H_2O$, was used by J. R. Glauber in the 17th century as a medicinal agent. At 25°C, $K_p = 4.08\times10^{-25}$ for the loss of water of hydration from Glauber's salt:

$$Na_2SO_4\cdot10H_2O(s) \rightleftharpoons Na_2SO_4(s) + 10H_2O(g)$$

(a) What is the vapor pressure of water at 25°C in a closed container holding a sample of $Na_2SO_4\cdot10H_2O(s)$?

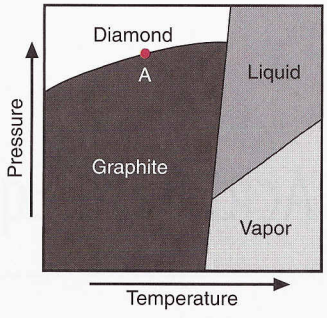
(b) How do the following changes affect the ratio (higher, lower, same) of hydrated form to anhydrous form for the system above?

(1) Add more $Na_2SO_4(s)$ (2) Reduce the container volume

(3) Add more water vapor (4) Add N_2 gas

17.115 In a study of synthetic fuels, 0.100 mol of CO and 0.100 mol of water vapor are added to a 20.00-L container at 900.°C, and they react to form CO_2 and H_2. At equilibrium, [CO] is 2.24×10^{-3} M. (a) Calculate K_c at this temperature. (b) Calculate P_{total} in the flask at equilibrium. (c) How many moles of CO must be added to double this pressure? (d) After P_{total} is doubled and the system reattains equilibrium, what is $[CO]_{eq}$?

17.116 Synthetic diamonds are made under conditions of high temperature (2000 K) and high pressure (10^{10} Pa; 10^5 atm) in the presence of catalysts. The phase diagram for carbon is useful for finding the conditions for the formation of natural and synthetic diamonds. Along the diamond-graphite line, the two allotropes are in equilibrium. (a) At point A, what is the sign of ΔH for the formation of diamond from graphite? Explain. (b) Which allotrope is denser? Explain.



At last! In this titration of HCl with NaOH, the first swirls of phenolphthalein indicator changing from colorless to magenta signal the balance being tipped from acidic to basic solution. In this chapter, we'll examine acids and bases from several vantage points and see how to apply the principles of equilibrium to their reactions.

18.8 Generalizing the Brønsted-Lowry Concept: The Leveling Effect

18.9 Electron-Pair Donation and the Lewis Acid-Base Definition
Molecules as Lewis Acids
Metal Cations as Lewis Acids
Overview of Acid-Base Definitions

Acids and bases have been used as laboratory chemicals since the time of the alchemists, and they remain indispensable, not only in academic and industrial labs, but in the home as well (Table 18.1).

Notice that some of the acids (e.g., acetic and citric) have a sour taste. In fact, sourness had been a defining property since the 17th century: an acid was any substance that had a sour taste; reacted with active metals, such as aluminum and zinc, to produce hydrogen gas; and turned certain organic compounds characteristic colors. (We discuss *indicators* later and in Chapter 19.) A base was any substance that had a bitter taste and slippery feel and turned the same organic compounds different characteristic colors. (Please remember *NEVER* to taste or touch laboratory chemicals; instead, try some acetic acid in the form of vinegar on your next salad.) Moreover, it was known that *when acids and bases react, each cancels the properties of the other in a process called neutralization.* But definitions in science evolve because, as descriptions become too limited, they must be replaced by broader ones. Although the early definitions of acids and bases described distinctive properties, they inevitably gave way to definitions based on molecular behavior.

IN THIS CHAPTER . . . We develop three definitions of acids and bases that allow us to understand ever-increasing numbers of reactions. In the process, we apply the principles of chemical equilibrium to this essential group of substances. After presenting the classical (Arrhenius) acid-base definition, we examine acid dissociation to see why acids vary in strength. The pH scale is introduced as a means of comparing the acidity or basicity of aqueous solutions. Then, we'll see that the Brønsted-Lowry acid-base definition greatly expands the meaning of "base," along with the scope of chemical changes considered acid-base reactions. We explore the molecular structures of acids and bases to rationalize variations in their strengths and see that the very designations "acid" and "base" depend on relative strengths and on the solvent. Finally, we'll see that the Lewis acid-base definition expands the meaning of "acid" and acid-base behavior even further.

Concepts & Skills to Review

before you study this chapter

- role of water as solvent (Section 4.1)
- writing ionic equations (Section 4.2)
- acids, bases, and acid-base reactions (Section 4.4)
- proton transfer in acid-base reactions (Section 4.4)
- properties of an equilibrium constant (Section 17.2)
- solving equilibrium problems (Section 17.5)

Table 18.1 Some Common Acids and Bases and Their Household Uses

Substance	Use
Acids	
Acetic acid, CH_3COOH	Flavoring, preservative
Citric acid, $H_3C_6H_5O_7$	Flavoring
Phosphoric acid, H_3PO_4	Rust remover
Boric acid, H_3BO_3	Mild antiseptic, insecticide
Aluminum salts, $NaAl(SO_4)_2 \cdot 12H_2O$	In baking powder, with sodium hydrogen carbonate
Hydrochloric acid (muriatic acid), HCl	Brick and ceramic tile cleaner
Bases	
Sodium hydroxide (lye), NaOH	Oven and drain cleaners
Ammonia, NH_3	Household cleaner
Sodium carbonate, Na_2CO_3	Water softener, grease remover
Sodium hydrogen carbonate, $NaHCO_3$	Fire extinguisher, rising agent in cake mixes (baking soda), mild antacid
Sodium phosphate, Na_3PO_4	Cleaner for surfaces before painting or wallpapering

Pioneers of Acid-Base Chemistry Three 17th-century chemists laid the foundations of acid-base chemistry. Johann Glauber (1604–1668) became renowned for his ability to prepare acids and their salts. Glauber's salt ($Na_2SO_4 \cdot 10H_2O$) is still used today for preparing dyes and printing textiles. Otto Tachenius (c. 1620–1690) is credited with first recognizing that a salt is the product of the reaction between an acid and a base. Robert Boyle (1627–1691), in addition to studying gas behavior, fostered the use of spot tests, flame colors, fume odors, and precipitates to analyze reactions. He was the first to associate the color change in syrup of violets (an organic dye) with the acidic or basic nature of the test solution.

18.1 ACIDS AND BASES IN WATER

Although water is not an essential participant in all modern acid-base definitions, most laboratory work with acids and bases involves water, as do most environmental, biological, and industrial applications. Recall from our discussion in Chapter 4 that *water is a product in all reactions between strong acids and strong bases:*

$$HCl(aq) + NaOH(aq) \longrightarrow NaCl(aq) + H_2O(l)$$

Indeed, as the net ionic equation of this reaction shows, water is *the* product:

$$H^+(aq) + OH^-(aq) \longrightarrow H_2O(l)$$

Furthermore, whenever an acid dissociates in water, solvent molecules participate in the reaction:

$$HA(g \text{ or } l) + H_2O(l) \longrightarrow A^-(aq) + H_3O^+(aq)$$

As you saw in that earlier discussion, water surrounds the proton to form H-bonded species with the general formula $H(H_2O)_n^+$. Because the proton is so small, its charge density is very high, so its attraction to water is especially strong. The proton bonds covalently to one of the lone electron pairs of a water molecule's O atom to form a **hydronium ion, H_3O^+,** which forms H bonds to several other water molecules (see Figure 4.4, p. 139). To emphasize the active role of water and the nature of the proton-water interaction, the hydrated proton is usually shown in the text as $H_3O^+(aq)$, although in some cases this hydrated species is shown more simply as $H^+(aq)$.

Release of H^+ or OH^- and the Classical Acid-Base Definition

The earliest and simplest definition of acids and bases that reflects their molecular nature was suggested by Svante Arrhenius, whose work on the rate constant we encountered in Chapter 16. In the **classical** (or **Arrhenius**) **acid-base definition,** acids and bases are classified in terms of their formulas and their behavior *in water:*

- An *acid* is a substance that has H in its formula and dissociates in water to yield H_3O^+.
- A *base* is a substance that has OH in its formula and dissociates in water to yield OH^-.

Some typical Arrhenius acids are HCl, HNO_3, and HCN, and some typical bases are NaOH, KOH, and $Ba(OH)_2$. Although Arrhenius bases contain discrete OH^- ions in their structures, Arrhenius acids *never* contain H^+ ions. On the contrary, these acids contain *covalently bonded H atoms that ionize in water.*

When an acid and a base react, they undergo **neutralization.** The meaning of acid-base reactions has changed along with the definitions of acid and base, but in the Arrhenius sense, neutralization occurs when *the H^+ ion from the acid and the OH^- ion from the base combine to form H_2O.* This description explains an observation that puzzled many of Arrhenius's colleagues. They observed that all neutralization reactions between what we now call strong acids and strong bases (those that dissociate completely in water) had the same heat of reaction. No matter which strong acid and base reacted, and no matter which salt formed, ΔH^0_{rxn} was about −56 kJ per mole of water formed. Arrhenius suggested that the heat of reaction was always the same because the actual reaction was always the same—a hydrogen ion and a hydroxide ion formed water:

$$H^+(aq) + OH^-(aq) \longrightarrow H_2O(l) \qquad \Delta H^0_{rxn} = -55.9 \text{ kJ}$$

The dissolved salt that formed along with the water, for example, NaCl in the reaction of sodium hydroxide with hydrochloric acid,

$$Na^+(aq) + OH^-(aq) + H^+(aq) + Cl^-(aq) \longrightarrow Na^+(aq) + Cl^-(aq) + H_2O(l)$$

did not affect the ΔH^0_{rxn} but existed as hydrated spectator ions.

Despite its importance at the time, limitations in the classical definition soon became apparent. Arrhenius and many others realized that even though some substances do *not* have OH in their formulas, they still behave as bases. For example, NH_3 and K_2CO_3 also yield OH^- in water. As you'll see shortly, broader acid-base definitions are required to include these species.

Variation in Acid Strength: The Acid-Dissociation Constant (K_a)

Acids and bases differ greatly in their *strength* in water, that is, in the amount of H_3O^+ or OH^- produced per mole of substance dissolved. We generally classify acids and bases as either strong or weak, according to the extent of their dissociation into ions in water (see Table 4.2, p. 144). Remember, however, that a *gradation* in strength exists, as we'll examine quantitatively in a moment. Acids and bases are electrolytes in water, so this classification of acid and base strength correlates with our earlier classification of electrolyte strength: *strong electrolytes dissociate completely, and weak electrolytes dissociate partially.*

Animation: Dissociation of Strong and Weak Acids
Online Learning Center

- *Strong acids dissociate completely into ions in water* (Figure 18.1):

$$HA(g \text{ or } l) + H_2O(l) \longrightarrow H_3O^+(aq) + A^-(aq)$$

In a dilute solution of a strong acid, *virtually no HA molecules are present;* that is, $[H_3O^+] \approx [HA]_{init}$. In other words, $[HA]_{eq} \approx 0$, so the value of K_c is extremely large:

$$Q_c = \frac{[H_3O^+][A^-]}{[HA][H_2O]} \qquad \text{(at equilibrium, } Q_c = K_c >> 1\text{)}$$

Because the reaction is essentially complete, it is not very useful to express it as an equilibrium process. In a dilute aqueous nitric acid solution, for example, there are virtually no undissociated nitric acid molecules:

$$HNO_3(l) + H_2O(l) \longrightarrow H_3O^+(aq) + NO_3^-(aq)$$

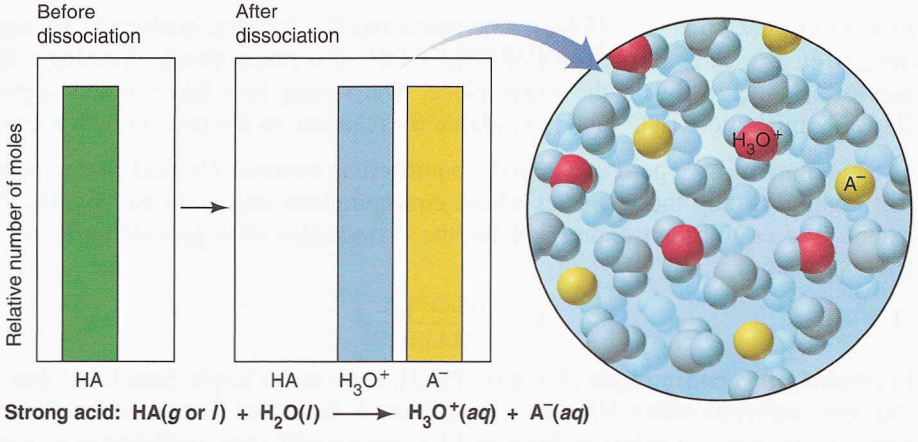

Figure 18.1 The extent of dissociation for strong acids. The bar graphs show the relative numbers of moles of species before *(left)* and after *(right)* acid dissociation occurs. When a strong acid dissolves in water, it dissociates completely, yielding $H_3O^+(aq)$ and $A^-(aq)$ ions; virtually no HA molecules are present.

- *Weak acids dissociate very slightly into ions in water* (Figure 18.2):

$$HA(aq) + H_2O(l) \rightleftharpoons H_3O^+(aq) + A^-(aq)$$

In a dilute solution of a weak acid, *the great majority of HA molecules are undissociated*. Thus, $[H_3O^+] << [HA]_{init}$. In other words, $[HA]_{eq} \approx [HA]_{init}$, so the value of K_c is very small. Hydrocyanic acid is an example of a weak acid:

$$HCN(aq) + H_2O(l) \rightleftharpoons H_3O^+(aq) + CN^-(aq)$$

$$Q_c = \frac{[H_3O^+][CN^-]}{[HCN][H_2O]} \qquad \text{(at equilibrium, } Q_c = K_c << 1\text{)}$$

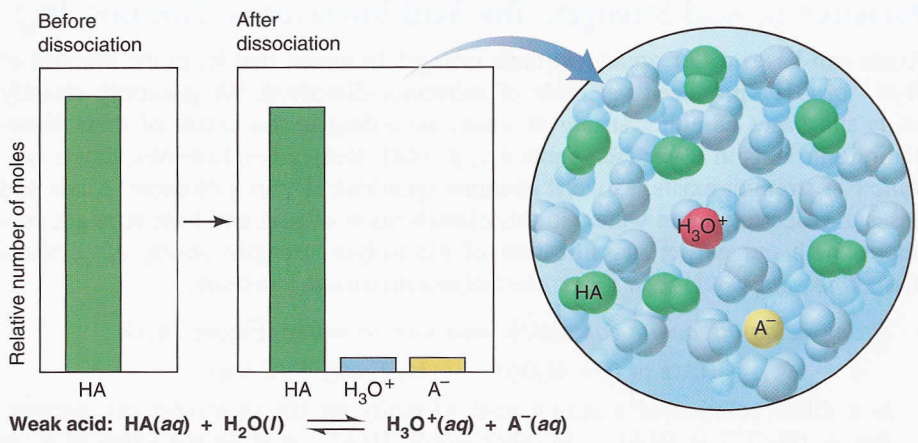

Figure 18.2 The extent of dissociation for weak acids. In contrast to a strong acid in water (see Figure 18.1), a weak acid dissociates very little, remaining mostly as intact acid molecules and, thus, yielding relatively few $H_3O^+(aq)$ and $A^-(aq)$ ions.

(From here on, brackets with no subscript mean molar concentration *at equilibrium;* that is, [X] means $[X]_{eq}$. In this chapter, we are dealing with systems *at equilibrium*, so instead of writing Q and stating that Q equals K at equilibrium, we'll express K directly as a collection of equilibrium concentration terms.)

Because of the effect of concentration on rate (Section 16.6), this dramatic difference in $[H_3O^+]$ causes a dramatic difference in the reaction rate when an equal concentration of a strong or a weak acid reacts with an active metal, such as zinc (Figure 18.3):

$$Zn(s) + 2H_3O^+(aq) \longrightarrow Zn^{2+}(aq) + 2H_2O(l) + H_2(g)$$

In a strong acid, such as 1 *M* HCl, zinc reacts rapidly, forming bubbles of H_2 vigorously. In a weak acid, such as 1 *M* CH_3COOH, zinc reacts slowly, forming bubbles of H_2 sluggishly on the metal piece. The strong acid has a much higher $[H_3O^+]$; much more H_3O^+ ion is available for reaction, so the rate is much higher.

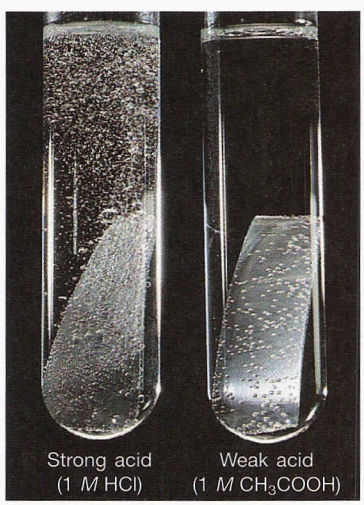

Figure 18.3 Reaction of zinc with a strong and a weak acid. In the reaction of zinc with a strong acid (*left*), the higher concentration of H_3O^+ results in rapid formation of H_2 (bubbles). In a weak acid (*right*), the H_3O^+ concentration is much lower, so formation of H_2 is much slower.

The Meaning of K_a There is a *specific* equilibrium constant for acid dissociation that highlights only those species whose concentrations change to any significant extent. The equilibrium expression for the dissociation of a general *weak acid, HA,* in water is

$$K_c = \frac{[H_3O^+][A^-]}{[HA][H_2O]}$$

In general, the concentration of water, $[H_2O]$, is so much larger than [HA] that it changes negligibly when HA dissociates; thus, it is treated as a constant. Therefore, as you saw for solids in Section 17.2, we simplify the equilibrium expression by multiplying $[H_2O]$ by K_c to define a new equilibrium constant, the **acid-dissociation constant** (or **acid-ionization constant**), K_a:

$$K_c[H_2O] = K_a = \frac{[H_3O^+][A^-]}{[HA]} \qquad (18.1)$$

Like any equilibrium constant, K_a is a number whose magnitude is temperature dependent and tells how far to the right the reaction has proceeded to reach equilibrium. Thus, *the stronger the acid, the higher the* $[H_3O^+]$ *at equilibrium, and the larger the* K_a*:*

$$\text{Stronger acid} \Longrightarrow \text{higher } [H_3O^+] \Longrightarrow \text{larger } K_a$$

The range of values for the acid-dissociation constants of weak acids extends over many orders of magnitude. Listed below are some benchmark K_a values for typical weak acids to give you a general idea of the fraction of HA molecules that dissociate into ions:

- For a weak acid with a relatively high K_a ($\sim 10^{-2}$), a 1 *M* solution has ~10% of the HA molecules dissociated. The K_a of chlorous acid ($HClO_2$) is 1.1×10^{-2}, and 1 *M* $HClO_2$ is 10.% dissociated.
- For a weak acid with a moderate K_a ($\sim 10^{-5}$), a 1 *M* solution has ~0.3% of the HA molecules dissociated. The K_a of acetic acid (CH_3COOH) is 1.8×10^{-5}, and 1 *M* CH_3COOH is 0.42% dissociated.
- For a weak acid with a relatively low K_a ($\sim 10^{-10}$), a 1 *M* solution has ~0.001% of the HA molecules dissociated. The K_a of HCN is 6.2×10^{-10}, and 1 *M* HCN is 0.0025% dissociated.

Thus, for solutions of the same initial HA concentration, *the smaller the* K_a*, the lower the percent dissociation of HA:*

$$\text{Smaller } K_a \Longrightarrow \text{lower \% dissociation of HA} \Longrightarrow \text{weaker acid}$$

Table 18.2 lists K_a values in water of some weak *monoprotic* acids, those with one ionizable proton. (A more extensive list appears in Appendix C.) Strong acids are absent because they do not have meaningful K_a values. Note that the ionizable proton in organic acids is attached to oxygen in the —COOH group; the H atoms bonded to C atoms do *not* ionize. (In Section 18.4, we discuss the behavior of polyprotic acids, those with more than one ionizable proton.)

Table 18.2 K_a Values for Some Monoprotic Acids at 25°C

Name (Formula)	Lewis Structure*	K_a
Chlorous acid ($HClO_2$)		1.1×10^{-2}
Nitrous acid (HNO_2)		7.1×10^{-4}
Hydrofluoric acid (HF)		6.8×10^{-4}
Formic acid (HCOOH)		1.8×10^{-4}
Acetic acid (CH_3COOH)		1.8×10^{-5}
Propanoic acid (CH_3CH_2COOH)		1.3×10^{-5}
Hypochlorous acid (HClO)		2.9×10^{-8}
Hydrocyanic acid (HCN)		6.2×10^{-10}

ACID STRENGTH

*Red type indicates the ionizable proton; all atoms have zero formal charge.

Classifying the Relative Strengths of Acids and Bases

Using a table of acid-dissociation constants is the surest way to quantify relative acid strengths, but you can often classify acids and bases qualitatively as strong or weak just from their formulas:

- *Strong acids*. Two types of strong acids, with examples that *you should memorize,* are
  1. The hydrohalic acids HCl, HBr, and HI
  2. Oxoacids in which the number of O atoms exceeds the number of ionizable protons by two or more, such as HNO_3, H_2SO_4, and $HClO_4$; for example, in H_2SO_4, 4 O's − 2 H's = 2
- *Weak acids*. There are many *more* weak acids than strong ones. Four types, with examples, are
  1. The hydrohalic acid HF
  2. Those acids in which H is not bonded to O or to halogen, such as HCN and H_2S
  3. Oxoacids in which the number of O atoms equals or exceeds by one the number of ionizable protons, such as HClO, HNO_2, and H_3PO_4
  4. Carboxylic acids (general formula RCOOH), such as CH_3COOH and C_6H_5COOH
- *Strong bases*. Water-soluble compounds containing O^{2-} or OH^- ions are strong bases. The cations are usually those of the most active metals:
  1. M_2O or MOH, where M = Group 1A(1) metal (Li, Na, K, Rb, Cs)
  2. MO or $M(OH)_2$, where M = Group 2A(2) metal (Ca, Sr, Ba)
     [MgO and $Mg(OH)_2$ are only slightly soluble in water, but the soluble portion dissociates completely.]
- *Weak bases*. Many compounds with an electron-rich nitrogen atom are weak bases (none are Arrhenius bases). The common structural feature is an N atom that has a lone electron pair (shown here in the formulas):
  1. Ammonia ($\ddot{N}H_3$)
  2. Amines (general formula $R\ddot{N}H_2$, $R_2\ddot{N}H$, or $R_3\ddot{N}$), such as $CH_3CH_2\ddot{N}H_2$, $(CH_3)_2\ddot{N}H$, $(C_3H_7)_3\ddot{N}$, and $C_5H_5\ddot{N}$

SAMPLE PROBLEM 18.1 Classifying Acid and Base Strength from the Chemical Formula

Problem Classify each of the following compounds as a strong acid, weak acid, strong base, or weak base:

(a) H_2SeO_4 **(b)** $(CH_3)_2CHCOOH$
(c) KOH **(d)** $(CH_3)_2CHNH_2$

Plan We examine the formula and classify each acid or base, using the text descriptions. Particular points to note for acids are the numbers of O atoms relative to H atoms and the presence of the —COOH group. For bases, note the nature of the cation or the presence of an N atom that has a lone pair.

Solution **(a)** Strong acid: H_2SeO_4 is an oxoacid in which the number of O atoms exceeds the number of ionizable protons by two.

(b) Weak acid: $(CH_3)_2CHCOOH$ is a carboxylic acid, as indicated by the —COOH group.

(c) Strong base: KOH is one of the Group 1A(1) hydroxides.

(d) Weak base: $(CH_3)_2CHNH_2$ has a lone pair on the N and is an amine.

FOLLOW-UP PROBLEM 18.1 Which member of each pair is the stronger acid or base?

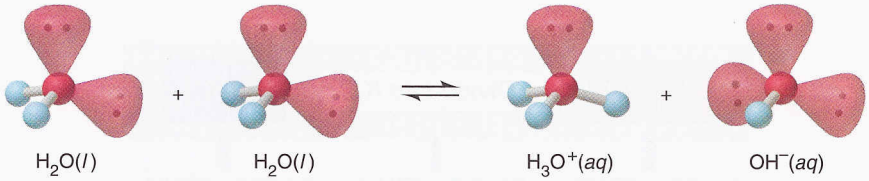
(a) HClO or $HClO_3$ **(b)** HCl or CH_3COOH **(c)** NaOH or CH_3NH_2

SECTION SUMMARY

Acids and bases are essential substances in home, industry, and the environment. In aqueous solution, water combines with the proton released from an acid to form the hydrated species represented by $H_3O^+(aq)$. In the classical (Arrhenius) definition, acids contain H and yield H_3O^+ in water, bases contain OH and yield OH^- in water, and an acid-base reaction (neutralization) is the reaction of H^+ and OH^- to form H_2O. Acid strength depends on $[H_3O^+]$ relative to [HA] in aqueous solution. Strong acids dissociate completely and weak acids slightly. The extent of dissociation is expressed by the acid-dissociation constant, K_a. Weak acids have K_a values ranging from about 10^{-1} to 10^{-12}. Acids and bases can be classified qualitatively as strong or weak based on their formulas.

18.2 AUTOIONIZATION OF WATER AND THE pH SCALE

Before we discuss the next major definition of acid-base behavior, let's examine a crucial property of water that enables us to quantify $[H_3O^+]$ in any aqueous system: *water is an extremely weak electrolyte*. The electrical conductivity of tap water is due almost entirely to dissolved ions, but even water that has been repeatedly distilled and deionized exhibits a tiny conductance. The reason is that water itself dissociates into ions very slightly in an equilibrium process known as **autoionization** (or self-ionization):



The Equilibrium Nature of Autoionization: The Ion-Product Constant for Water (K_w)

Like any equilibrium process, the autoionization of water is described quantitatively by an equilibrium constant:

$$K_c = \frac{[H_3O^+][OH^-]}{[H_2O]^2}$$

Because the concentration of H_2O is essentially constant here, we simplify this equilibrium expression by including the constant $[H_2O]^2$ term with the value of K_c to obtain a new equilibrium constant, the **ion-product constant for water, K_w:**

$$K_c[H_2O]^2 = K_w = [H_3O^+][OH^-] = 1.0\times10^{-14} \text{ (at 25°C)} \qquad (18.2)$$

Notice that *one H_3O^+ ion and one OH^- ion appear for each H_2O molecule that dissociates*. Therefore, in pure water, we find that

$$[H_3O^+] = [OH^-] = \sqrt{1.0\times10^{-14}} = 1.0\times10^{-7}\ M \text{ (at 25°C)}$$

Pure water has a concentration of about 55.5 M $\left(\text{that is, } \frac{1000 \text{ g/L}}{18.02 \text{ g/mol}}\right)$, so these equilibrium concentrations are attained when only 1 in 555 million water molecules dissociates reversibly into ions!

Autoionization of water has two major consequences for aqueous acid-base chemistry:

1. *A change in $[H_3O^+]$ causes an inverse change in $[OH^-]$*, and vice versa:

Higher $[H_3O^+] \Longrightarrow$ lower $[OH^-]$ and Higher $[OH^-] \Longrightarrow$ lower $[H_3O^+]$

Recall from our discussion of Le Châtelier's principle (Section 17.6) that a change in concentration of either ion shifts the equilibrium position, but it does *not* change the equilibrium constant. Therefore, if some acid is added, $[H_3O^+]$ increases, and so $[OH^-]$ must decrease; if some base is added, $[OH^-]$ increases, and so $[H_3O^+]$ must decrease. However, the addition of H_3O^+ or OH^- merely leads to the formation of H_2O, so the value of K_w is maintained.

2. *Both ions are present in all aqueous systems.* Thus, all acidic solutions contain a low concentration of OH^- ions, and all basic solutions contain a low concentration of H_3O^+ ions. The equilibrium nature of autoionization allows us to define "acidic" and "basic" solutions in terms of relative magnitudes of $[H_3O^+]$ and $[OH^-]$:

In an *acidic* solution, $[H_3O^+] > [OH^-]$
In a *neutral* solution, $[H_3O^+] = [OH^-]$
In a *basic* solution, $[H_3O^+] < [OH^-]$

Figure 18.4 summarizes these relationships and the relative solution acidity. Moreover, if you know the value of K_w at a particular temperature and the concentration of one of these ions, you can easily calculate the concentration of the other ion by solving for it from the K_w expression:

$$[H_3O^+] = \frac{K_w}{[OH^-]} \quad \text{or} \quad [OH^-] = \frac{K_w}{[H_3O^+]}$$

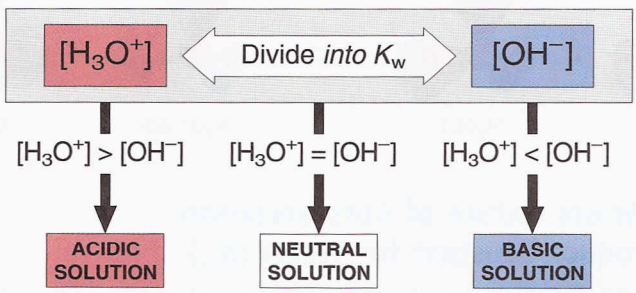


Figure 18.4 **The relationship between $[H_3O^+]$ and $[OH^-]$ and the relative acidity of solutions.**

SAMPLE PROBLEM 18.2 Calculating $[H_3O^+]$ and $[OH^-]$ in Aqueous Solution

Problem A research chemist adds a measured amount of HCl gas to pure water at 25°C and obtains a solution with $[H_3O^+] = 3.0\times10^{-4}\ M$. Calculate $[OH^-]$. Is the solution neutral, acidic, or basic?

Plan We use the known value of K_w at 25°C (1.0×10^{-14}) and the given $[H_3O^+]$ ($3.0\times10^{-4}\ M$) to solve for $[OH^-]$. Then, referring to Figure 18.4, we compare $[H_3O^+]$ with $[OH^-]$ to determine whether the solution is acidic, basic, or neutral.

Solution Calculating $[OH^-]$:

$$[OH^-] = \frac{K_w}{[H_3O^+]} = \frac{1.0\times10^{-14}}{3.0\times10^{-4}}$$

$$= 3.3\times10^{-11}\ M$$

Because $[H_3O^+] > [OH^-]$, the solution is acidic.

Check It makes sense that adding an acid to water results in an acidic solution. Moreover, because $[H_3O^+]$ is greater than $10^{-7}\ M$, $[OH^-]$ must be less than $10^{-7}\ M$ to give a constant K_w.

FOLLOW-UP PROBLEM 18.2 Calculate $[H_3O^+]$ in a solution that is at 25°C and has $[OH^-] = 6.7\times10^{-2}\ M$. Is the solution neutral, acidic, or basic?

Expressing the Hydronium Ion Concentration: The pH Scale

In aqueous solutions, $[H_3O^+]$ can vary from about 10 M to 10^{-15} M. To handle numbers with negative exponents more conveniently in calculations, we convert them to positive numbers using a numerical system called a *p-scale,* the negative of the common (base-10) logarithm of the number. Applying this numerical system to $[H_3O^+]$ gives **pH,** the negative logarithm of $[H^+]$ (or $[H_3O^+]$):

$$\text{pH} = -\log [H_3O^+] \tag{18.3}$$

What is the pH of 10^{-12} M H_3O^+ solution?

$$\text{pH} = -\log [H_3O^+] = -\log 10^{-12} = (-1)(-12) = 12$$

Similarly, a 10^{-3} M H_3O^+ solution has a pH of 3, and a 5.4×10^{-4} M H_3O^+ solution has a pH of 3.27:

$$\text{pH} = -\log [H_3O^+] = (-1)(\log 5.4 + \log 10^{-4}) = 3.27$$

As with any measurement, the number of significant figures in a pH value reflects the precision with which the concentration is known. However, it is a logarithm, so the number of significant figures in the concentration equals the number of digits *to the right of the decimal point in the logarithm* (see Appendix A). In the preceding example, 5.4×10^{-4} M has two significant figures, so its negative logarithm, 3.27, has two digits to the right of the decimal point.

Note in particular that *the higher the pH, the lower the $[H_3O^+]$.* Therefore, *an acidic solution has a lower pH (higher $[H_3O^+]$) than a basic solution.* At 25°C in pure water, $[H_3O^+]$ is 1.0×10^{-7} M, so

pH of a neutral solution	= 7.00
pH of an acidic solution	< 7.00
pH of a basic solution	> 7.00

Figure 18.5 shows that the pH values of some familiar aqueous solutions fall within a range of 0 to 14.

Another important point arises when we compare $[H_3O^+]$ in different solutions. Because the pH scale is logarithmic, a solution of pH 1.0 has an $[H_3O^+]$ that is 10 times higher than that of a pH 2.0 solution, 100 times higher than that of a pH 3.0 solution, and so forth. To find the $[H_3O^+]$ from the pH, you perform the opposite arithmetic process; that is, you find the negative antilog of pH:

$$[H_3O^+] = 10^{-\text{pH}}$$

A p-scale is used to express other quantities as well:

- Hydroxide ion concentration can be expressed as pOH:

$$\text{pOH} = -\log [OH^-]$$

Acidic solutions have a higher pOH (lower $[OH^-]$) than basic solutions.

- Equilibrium constants can be expressed as pK:

$$pK = -\log K$$

A low pK corresponds to a high K. A reaction that reaches equilibrium with mostly products present (that proceeds far to the right) has a low pK (high K), whereas one that has mostly reactants present at equilibrium has a high pK (low K). Table 18.3 shows this relationship for aqueous equilibria of some weak acids.

Table 18.3 The Relationship Between K_a and pK_a

Acid Name (Formula)	K_a at 25°C	pK_a
Hydrogen sulfate ion (HSO_4^-)	1.0×10^{-2}	1.99
Nitrous acid (HNO_2)	7.1×10^{-4}	3.15
Acetic acid (CH_3COOH)	1.8×10^{-5}	4.74
Hypobromous acid (HBrO)	2.3×10^{-9}	8.64
Phenol (C_6H_5OH)	1.0×10^{-10}	10.00

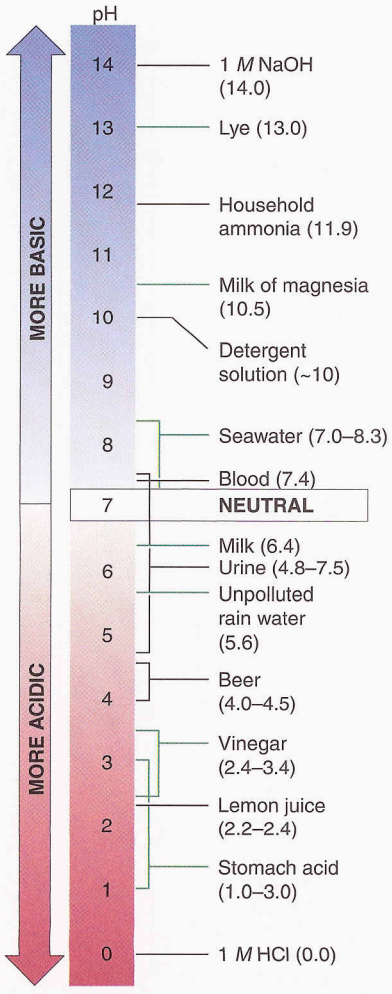

Figure 18.5 The pH values of some familiar aqueous solutions.

	$[H_3O^+]$	pH	$[OH^-]$	pOH
BASIC	1.0×10^{-15}	15.00	1.0×10^{1}	−1.00
	1.0×10^{-14}	14.00	1.0×10^{0}	0.00
	1.0×10^{-13}	13.00	1.0×10^{-1}	1.00
	1.0×10^{-12}	12.00	1.0×10^{-2}	2.00
	1.0×10^{-11}	11.00	1.0×10^{-3}	3.00
	1.0×10^{-10}	10.00	1.0×10^{-4}	4.00
	1.0×10^{-9}	9.00	1.0×10^{-5}	5.00
	1.0×10^{-8}	8.00	1.0×10^{-6}	6.00
NEUTRAL	1.0×10^{-7}	7.00	1.0×10^{-7}	7.00
ACIDIC	1.0×10^{-6}	6.00	1.0×10^{-8}	8.00
	1.0×10^{-5}	5.00	1.0×10^{-9}	9.00
	1.0×10^{-4}	4.00	1.0×10^{-10}	10.00
	1.0×10^{-3}	3.00	1.0×10^{-11}	11.00
	1.0×10^{-2}	2.00	1.0×10^{-12}	12.00
	1.0×10^{-1}	1.00	1.0×10^{-13}	13.00
	1.0×10^{0}	0.00	1.0×10^{-14}	14.00
	1.0×10^{1}	−1.00	1.0×10^{-15}	15.00

Figure 18.6 The relations among $[H_3O^+]$, pH, $[OH^-]$, and pOH. Because K_w is constant, $[H_3O^+]$ and $[OH^-]$ are interdependent, and they change in opposite directions as the acidity or basicity of the aqueous solution increases. The pH and pOH are interdependent in the same way. Note that at 25°C, the product of $[H_3O^+]$ and $[OH^-]$ is 1.0×10^{-14}, and the sum of pH and pOH is 14.00.

The Relations Among pH, pOH, and pK_w Taking the negative log of both sides of the K_w expression gives a very useful relationship among pK_w, pH, and pOH:

$$K_w = [H_3O^+][OH^-] = 1.0\times10^{-14} \text{ (at 25°C)}$$

$$-\log K_w = (-\log [H_3O^+]) + (-\log [OH^-]) = -\log (1.0\times10^{-14})$$

$$pK_w = pH + pOH = 14.00 \quad \text{(at 25°C)} \tag{18.4}$$

Thus, the sum of pH and pOH is 14.00 in any aqueous solution at 25°C. With pH, pOH, $[H_3O^+]$, and $[OH^-]$ interrelated through K_w, knowing any one of the values allows us to determine the others (Figure 18.6).

SAMPLE PROBLEM 18.3 Calculating $[H_3O^+]$, pH, $[OH^-]$, and pOH

Problem In an art restoration project, a conservator prepares copper-plate etching solutions by diluting concentrated HNO_3 to 2.0 *M*, 0.30 *M*, and 0.0063 *M* HNO_3. Calculate $[H_3O^+]$, pH, $[OH^-]$, and pOH of the three solutions at 25°C.

Plan We know from its formula that HNO_3 is a strong acid, so it dissociates completely; thus, $[H_3O^+] = [HNO_3]_{init}$. We use the given concentrations and the value of K_w at 25°C (1.0×10^{-14}) to find $[H_3O^+]$ and $[OH^-]$ and then use them to calculate pH and pOH.

Solution Calculating the values for 2.0 *M* HNO_3:

$$[H_3O^+] = 2.0\ M$$

$$pH = -\log [H_3O^+] = -\log 2.0 = -0.30$$

$$[OH^-] = \frac{K_w}{[H_3O^+]} = \frac{1.0\times10^{-14}}{2.0} = 5.0\times10^{-15}\ M$$

$$pOH = -\log (5.0\times10^{-15}) = 14.30$$

Calculating the values for 0.30 *M* HNO_3:

$$[H_3O^+] = 0.30\ M$$

$$pH = -\log [H_3O^+] = -\log 0.30 = 0.52$$

$$[OH^-] = \frac{K_w}{[H_3O^+]} = \frac{1.0\times10^{-14}}{0.30} = 3.3\times10^{-14}\ M$$

$$pOH = -\log (3.3\times10^{-14}) = 13.48$$

Calculating the values for 0.0063 *M* HNO_3:

$$[H_3O^+] = 6.3\times10^{-3}\ M$$

$$pH = -\log [H_3O^+] = -\log (6.3\times10^{-3}) = 2.20$$

$$[OH^-] = \frac{K_w}{[H_3O^+]} = \frac{1.0\times10^{-14}}{6.3\times10^{-3}} = 1.6\times10^{-12}\ M$$

$$pOH = -\log (1.6\times10^{-12}) = 11.80$$

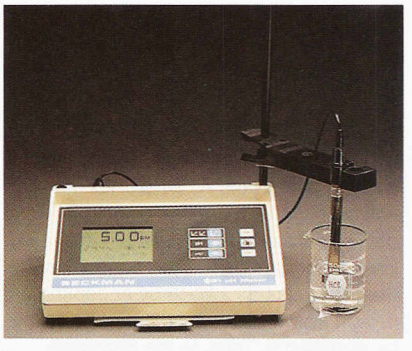
Check As the solution becomes more dilute, $[H_3O^+]$ decreases, so pH increases, as we expect. An $[H_3O^+]$ greater than 1.0 *M*, as in 2.0 *M* HNO_3, gives a positive log, so it results in a negative pH. The arithmetic seems correct because pH + pOH = 14.00 in each case.
Comment On most calculators, finding the pH requires several keystrokes. For example, to find the pH of 6.3×10^{-3} *M* HNO_3 solution, you enter: 6.3, EXP, 3, +/−, log, +/−.

FOLLOW-UP PROBLEM 18.3 A solution of NaOH has a pH of 9.52. What is its pOH, $[H_3O^+]$, and $[OH^-]$ at 25°C?

Measuring pH In the laboratory, pH values are usually obtained with an acid-base indicator or, more precisely, with an instrument called a pH meter. **Acid-base indicators** are organic molecules whose colors depend on the acidity or basicity of the solution in which they are dissolved. The pH of a solution is estimated quickly with *pH paper*, a paper strip impregnated with one or a mixture of indicators. A drop of test solution is placed on the paper strip, and the color of the strip is compared with a color chart, as shown in Figure 18.7A.

The *pH meter* measures $[H_3O^+]$ by means of two electrodes immersed in the test solution. One electrode provides a stable reference voltage; the other has an extremely thin, conducting, glass membrane that separates a known internal $[H_3O^+]$ from the unknown external $[H_3O^+]$. The difference in $[H_3O^+]$ creates a voltage difference across the membrane, which is measured and displayed in pH units (Figure 18.7B). We examine this process further in Chapter 21.

A



B

Figure 18.7 Methods for measuring the pH of an aqueous solution. A, A few drops of the solution are placed on a strip of pH paper, and the color is compared with the color chart. **B,** The electrodes of a pH meter immersed in the test solution measure $[H_3O^+]$. (In this instrument, the two electrodes are housed in one probe.)

SECTION SUMMARY

Pure water has a low conductivity because it autoionizes to a small extent. This process is described by an equilibrium reaction whose equilibrium constant is the ion-product constant for water, K_w (1.0×10^{-14} at 25°C). Thus, $[H_3O^+]$ and $[OH^-]$ are inversely related: in acidic solution, $[H_3O^+]$ is greater than $[OH^-]$; the reverse is true in basic solution; and the two are equal in neutral solution. To express small values of $[H_3O^+]$ more simply, we use the pH scale (pH = −log $[H_3O^+]$). A high pH represents a low $[H_3O^+]$. Similarly, pOH = −log $[OH^-]$, and p*K* = −log *K*. In acidic solutions, pH < 7.00; in basic solutions, pH > 7.00; and in neutral solutions, pH = 7.00. The sum of pH and pOH equals pK_w (14.00 at 25°C).

18.3 PROTON TRANSFER AND THE BRØNSTED-LOWRY ACID-BASE DEFINITION

Earlier we noted a major shortcoming of the classical (Arrhenius) definition: many substances that yield OH^- ions when they dissolve in water do not contain OH in their formulas. Examples include ammonia, the amines, and many salts of weak acids, such as NaF. Another limitation of the Arrhenius definition was that water had to be the solvent for acid-base reactions. In the early 20th century, J. N. Brønsted and T. M. Lowry suggested definitions that remove these limitations. (Recall that we discussed their ideas briefly in Section 4.4.) According to the **Brønsted-Lowry acid-base definition,**

- *An acid is a* ***proton donor,*** *any species that donates an* H^+ *ion.* An acid must contain H in its formula; HNO_3 and $H_2PO_4^-$ are two of many examples. All Arrhenius acids are Brønsted-Lowry acids.

- *A base is a **proton acceptor,** any species that accepts an H^+ ion.* A base must contain a lone pair of electrons to bind the H^+ ion; a few examples are NH_3, CO_3^{2-}, and F^-, as well as OH^-. Brønsted-Lowry bases are not Arrhenius bases, but all Arrhenius bases contain the Brønsted-Lowry base OH^-.

From the Brønsted-Lowry perspective, the only requirement for an acid-base reaction is that *one species donate a proton and another species accept it: an acid-base reaction is a proton-transfer process.* Acid-base reactions can occur between gases, in nonaqueous solutions, and in heterogeneous mixtures, as well as in aqueous solutions.

An acid and a base always work together in the transfer of a proton. In other words, one species behaves as an acid only if another species *simultaneously* behaves as a base, and vice versa. Even when an acid or a base merely dissolves in water, an acid-base reaction occurs because water acts as the other partner. Consider two typical acidic and basic solutions:

1. *Acid donates a proton to water* (Figure 18.8A). When HCl dissolves in water, an H^+ ion (a proton) is transferred from HCl to H_2O, where it becomes attached to a lone pair of electrons on the O atom, forming H_3O^+. In effect, HCl (the acid) has *donated* the H^+, and H_2O (the base) has *accepted* it:

$$HCl(g) + H_2\ddot{O}(l) \longrightarrow Cl^-(aq) + H_3\ddot{O}^+(aq)$$

2. *Base accepts a proton from water* (Figure 18.8B). In an aqueous solution of ammonia, proton transfer also occurs. An H^+ from H_2O attaches to the N atom's lone pair, forming NH_4^+. Having transferred an H^+, the H_2O becomes an OH^- ion:

$$\ddot{N}H_3(aq) + H_2O(l) \rightleftharpoons NH_4^+(aq) + OH^-(aq)$$

In this case, H_2O (the acid) has *donated* the H^+, and NH_3 (the base) has *accepted* it. Thus, H_2O is *amphoteric:* it acts as a base in one case and as an acid in the other. As you'll see, many other species are amphoteric as well.

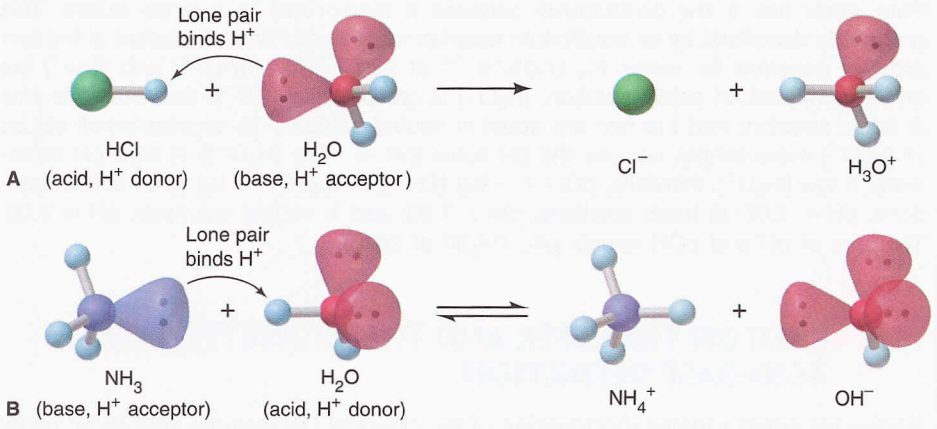


Figure 18.8 Proton transfer as the essential feature of a Brønsted-Lowry acid-base reaction. A, When HCl dissolves in water, it acts as an acid by donating a proton to water, which acts as a base by accepting it. **B,** In aqueous solution, NH_3 acts as a base by accepting a proton from water, which acts as an acid by donating it. Thus, in the Brønsted-Lowry sense, an acid-base reaction occurs in both cases.

The Conjugate Acid-Base Pair

The Brønsted-Lowry definition provides a new way to look at acid-base reactions because it focuses on the reactants *and* the products. For example, let's examine the reaction between hydrogen sulfide and ammonia:

$$H_2S + NH_3 \rightleftharpoons HS^- + NH_4^+$$

In the forward reaction, H_2S acts as an acid by donating an H^+ to NH_3, which acts as a base. The reverse reaction involves another acid-base pair. The ammonium ion, NH_4^+, acts as an acid by donating an H^+ to the hydrogen sulfide ion,

HS^-, which acts as a base. Notice that the acid, H_2S, becomes a base, HS^-, and the base, NH_3, becomes an acid, NH_4^+.

In Brønsted-Lowry terminology, H_2S and HS^- are a **conjugate acid-base pair:** HS^- is the conjugate base of the acid H_2S. Similarly, NH_3 and NH_4^+ form a conjugate acid-base pair: NH_4^+ is the conjugate acid of the base NH_3. *Every acid has a conjugate base, and every base has a conjugate acid.* Thus, for any conjugate acid-base pair,

- The conjugate base has one *fewer* H and one *more* minus charge than the acid.
- The conjugate acid has one *more* H and one *fewer* minus charge than the base.

A Brønsted-Lowry acid-base reaction occurs when *an acid and a base react to form their conjugate base and conjugate acid, respectively:*

$$\text{acid}_1 + \text{base}_2 \rightleftharpoons \text{base}_1 + \text{acid}_2$$

Table 18.4 shows some Brønsted-Lowry acid-base reactions. Notice that

- Each reaction has an acid and a base as reactants *and* as products, and these comprise two conjugate acid-base pairs.
- Acids and bases can be neutral, cationic, or anionic.
- The same species can be an acid or a base, depending on the other species reacting. Water behaves this way in reactions 1 and 4, and HPO_4^{2-} does so in reactions 4 and 6.

Table 18.4 The Conjugate Pairs in Some Acid-Base Reactions

	Acid	+	Base	⇌	Base	+	Acid
	Conjugate Pair						
			Conjugate Pair				
Reaction 1	HF	+	H_2O	⇌	F^-	+	H_3O^+
Reaction 2	HCOOH	+	CN^-	⇌	$HCOO^-$	+	HCN
Reaction 3	NH_4^+	+	CO_3^{2-}	⇌	NH_3	+	HCO_3^-
Reaction 4	$H_2PO_4^-$	+	OH^-	⇌	HPO_4^{2-}	+	H_2O
Reaction 5	H_2SO_4	+	$N_2H_5^+$	⇌	HSO_4^-	+	$N_2H_6^{2+}$
Reaction 6	HPO_4^{2-}	+	SO_3^{2-}	⇌	PO_4^{3-}	+	HSO_3^-

SAMPLE PROBLEM 18.4 Identifying Conjugate Acid-Base Pairs

Problem The following reactions are important environmental processes. Identify the conjugate acid-base pairs.

(a) $H_2PO_4^-(aq) + CO_3^{2-}(aq) \rightleftharpoons HCO_3^-(aq) + HPO_4^{2-}(aq)$

(b) $H_2O(l) + SO_3^{2-}(aq) \rightleftharpoons OH^-(aq) + HSO_3^-(aq)$

Plan To find the conjugate pairs, we find the species that donated an H^+ (acid) and the species that accepted it (base). The acid (or base) on the left becomes its conjugate base (or conjugate acid) on the right. Remember, the conjugate acid has one more H and one fewer minus charge than its conjugate base.

Solution **(a)** $H_2PO_4^-$ has one more H^+ than HPO_4^{2-}; CO_3^{2-} has one fewer H^+ than HCO_3^-. Therefore, $H_2PO_4^-$ and HCO_3^- are the acids, and HPO_4^{2-} and CO_3^{2-} are the bases. The conjugate acid-base pairs are $H_2PO_4^-/HPO_4^{2-}$ and HCO_3^-/CO_3^{2-}.

(b) H_2O has one more H^+ than OH^-; SO_3^{2-} has one fewer H^+ than HSO_3^-. The acids are H_2O and HSO_3^-; the bases are OH^- and SO_3^{2-}. The conjugate acid-base pairs are H_2O/OH^- and HSO_3^-/SO_3^{2-}.

FOLLOW-UP PROBLEM 18.4 Identify the conjugate acid-base pairs:

(a) $CH_3COOH(aq) + H_2O(l) \rightleftharpoons CH_3COO^-(aq) + H_3O^+(aq)$

(b) $H_2O(l) + F^-(aq) \rightleftharpoons OH^-(aq) + HF(aq)$

Relative Acid-Base Strength and the Net Direction of Reaction

The net *direction* of an acid-base reaction depends on the relative strengths of the acids and bases involved. *A reaction proceeds to the greater extent in the direction in which a stronger acid and stronger base form a weaker acid and weaker base.* If the stronger acid and base are written on the left, the net direction is to the right, so $K_c > 1$.

The net direction of the reaction of H_2S and NH_3 is to the right ($K_c > 1$) because H_2S is a stronger acid than NH_4^+, the other acid present, and NH_3 is a stronger base than HS^-, the other base:

$$\underset{\text{stronger acid}}{H_2S} + \underset{\text{stronger base}}{NH_3} \rightleftharpoons \underset{\text{weaker base}}{HS^-} + \underset{\text{weaker acid}}{NH_4^+}$$

You might think of the process as *a competition for the proton between the two bases,* NH_3 and HS^-, in which NH_3 wins.

Similarly, the extent of acid (HA) dissociation in water depends on a competition for the proton between the two bases, A^- and H_2O. When the acid HNO_3 dissolves in water, it transfers an H^+ to the base, H_2O, forming the conjugate base of HNO_3, which is NO_3^-, and the conjugate acid of H_2O, which is H_3O^+:

$$\underset{\text{stronger acid}}{HNO_3} + \underset{\text{stronger base}}{H_2O} \longrightarrow \underset{\text{weaker base}}{NO_3^-} + \underset{\text{weaker acid}}{H_3O^+}$$

(In this case, the net direction is so far to the right that it would be inappropriate to show an equilibrium arrow.) HNO_3 is a stronger acid than H_3O^+, and H_2O is a stronger base than NO_3^-. Thus, with strong acids such as HNO_3, the H_2O wins the competition for the proton because A^- (NO_3^-) is a much weaker base. On the other hand, with weak acids such as HF, the A^- (F^-) wins because it is a stronger base than H_2O:

$$\underset{\text{weaker acid}}{HF} + \underset{\text{weaker base}}{H_2O} \rightleftharpoons \underset{\text{stronger base}}{F^-} + \underset{\text{stronger acid}}{H_3O^+}$$

Based on evidence gathered from the results of many such reactions, we can rank conjugate pairs in terms of the ability of the acid to transfer its proton (Figure 18.9). Note, especially, that *a weaker acid has a stronger conjugate base.* This makes perfect sense: the acid gives up its proton less readily because its conjugate base holds it more strongly. We can use this list to predict the direction of a reaction between any two pairs, that is, whether the equilibrium position lies predominantly to the right ($K_c > 1$) or to the left ($K_c < 1$). *An acid-base reaction proceeds to the right if the acid reacts with a base that is lower on the list* because this combination produces a weaker conjugate base and a weaker conjugate acid.

SAMPLE PROBLEM 18.5 Predicting the Net Direction of an Acid-Base Reaction

Problem Predict the net direction and whether K_c is greater or less than 1 for each of the following reactions (assume equal initial concentrations of all species):

(a) $H_2PO_4^-(aq) + NH_3(aq) \rightleftharpoons NH_4^+(aq) + HPO_4^{2-}(aq)$

(b) $H_2O(l) + HS^-(aq) \rightleftharpoons OH^-(aq) + H_2S(aq)$

Plan We first identify the conjugate acid-base pairs. To predict the direction, we consult Figure 18.9 to see which acid and base are stronger. The stronger acid and base form the weaker acid and base, so the reaction proceeds in that net direction. If the reaction *as written* proceeds to the right, then [products] is higher than [reactants], and $K_c > 1$.

Solution **(a)** The conjugate pairs are $H_2PO_4^-/HPO_4^{2-}$ and NH_4^+/NH_3. $H_2PO_4^-$ is higher on the list of acids, so it is stronger than NH_4^+; and NH_3 is lower on the list of bases, so

it is stronger than HPO_4^{2-}. Therefore,

$$H_2PO_4^-(aq) + NH_3(aq) \rightleftharpoons NH_4^+(aq) + HPO_4^{2-}(aq)$$
stronger acid + stronger base ⟶ weaker acid + weaker base

The net direction is right, so $K_c > 1$.

(b) The conjugate pairs are H_2O/OH^- and H_2S/HS^-. H_2S is higher on the list of acids, and OH^- is lower on the list of bases. Thus, we have

$$H_2O(l) + HS^-(aq) \rightleftharpoons OH^-(aq) + H_2S(aq)$$
weaker acid + weaker base ⟵ stronger base + stronger acid

The net direction is left, so $K_c < 1$.

FOLLOW-UP PROBLEM 18.5 Explain with balanced equations, in which you show the net direction of the reaction, each of the following observations:
(a) You smell ammonia when NH_3 dissolves in water.
(b) The odor goes away when you add an excess of HCl to the solution in part (a).
(c) The odor returns when you add an excess of NaOH to the solution in part (b).

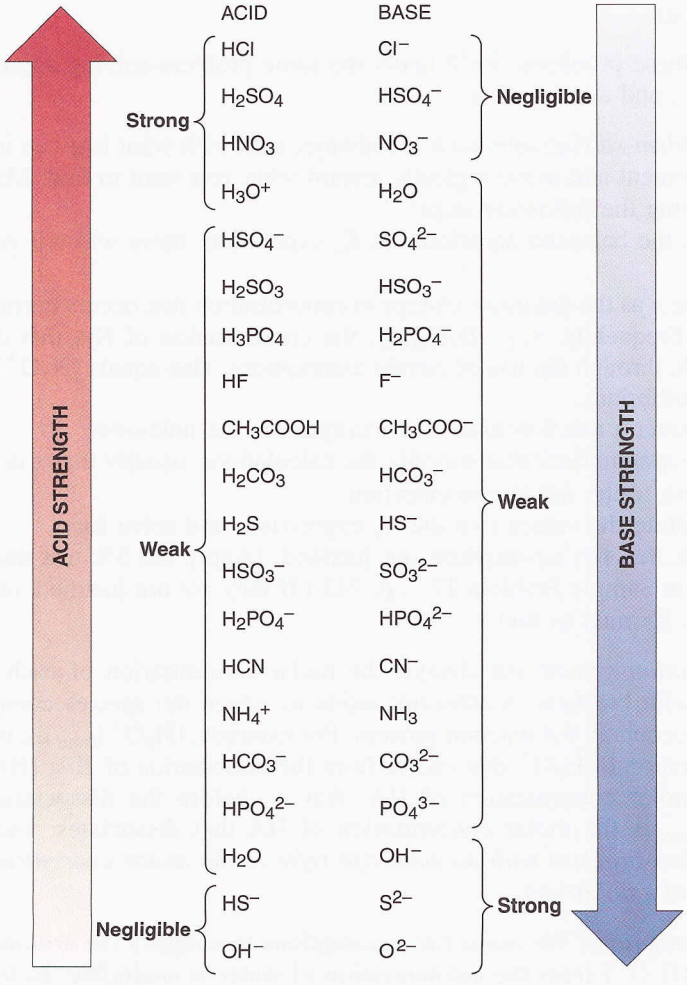

Figure 18.9 Strengths of conjugate acid-base pairs. The stronger the acid is, the weaker its conjugate base. The strongest acid appears at top left and the strongest base at bottom right. When an acid reacts with a base farther down the list, the reaction proceeds to the right ($K_c > 1$).

SECTION SUMMARY

The Brønsted-Lowry acid-base definition does not require that bases contain OH or that acid-base reactions occur in aqueous solution. It defines an acid as a species that donates a proton and a base as one that accepts it. An acid and a base act together in proton transfer. When an acid donates a proton, it becomes the conjugate base; when a base accepts a proton, it becomes the conjugate acid. In an acid-base reaction, acids and bases form their conjugates. A stronger acid has a weaker conjugate base, and vice versa. Thus, the reaction proceeds in the net direction in which a stronger acid and base form a weaker base and acid.

18.4 SOLVING PROBLEMS INVOLVING WEAK-ACID EQUILIBRIA

Just as you saw in Chapter 17 for equilibrium problems in general, there are two general types of equilibrium problems involving weak acids and their conjugate bases:

1. Given equilibrium concentrations, find K_a.
2. Given K_a and some concentration information, find the other equilibrium concentrations.

For all of these problems, we'll apply the same problem-solving approach, notation system, and assumptions:

- *The problem-solving approach.* As always, start with what is given in the problem statement and move logically toward what you want to find. Make a habit of applying the following steps:
  1. Write the balanced equation and K_a expression; these will tell you what to find.
  2. Define x as the unknown change in concentration that occurs during the reaction. Frequently, $x = [HA]_{dissoc}$, the concentration of HA that dissociates, which, through the use of certain assumptions, also equals $[H_3O^+]$ and $[A^-]$ at equilibrium.
  3. Construct a reaction table that incorporates the unknown.
  4. Make assumptions that simplify the calculations, usually that x is very small relative to the initial concentration.
  5. Substitute the values into the K_a expression, and solve for x.
  6. Check that the assumptions are justified. (Apply the 5% test that was first used in Sample Problem 17.9, p. 742.) If they are not justified, use the quadratic formula to find x.

- *The notation system.* As always, the molar concentration of each species is shown with brackets. A subscript refers to where the species comes from or when it occurs in the reaction process. For example, $[H_3O^+]_{from\ HA}$ is the molar concentration of H_3O^+ that comes from the dissociation of HA; $[HA]_{init}$ is the initial molar concentration of HA, that is, before the dissociation occurs; $[HA]_{dissoc}$ is the molar concentration of HA that dissociates; and so forth. Recall that *brackets with no subscript refer to the molar concentration of the species at equilibrium.*

- *The assumptions.* We make two assumptions to simplify the arithmetic:
  1. The $[H_3O^+]$ from the autoionization of water is negligible. In fact, it is so much smaller than the $[H_3O^+]$ from the dissociation of HA that we can neglect it:

$$[H_3O^+] = [H_3O^+]_{from\ HA} + [H_3O^+]_{from\ H_2O} \approx [H_3O^+]_{from\ HA}$$

Indeed, Le Châtelier's principle tells us that $[H_3O^+]_{from\ HA}$ *decreases* the extent of autoionization of water, so $[H_3O^+]_{from\ H_2O}$ in the HA solution is even less than $[H_3O^+]$ in pure water. Note that each molecule of HA that dissociates forms one H_3O^+ and one A^-, so $[A^-] = [H_3O^+]$.

2. A weak acid has a small K_a. Therefore, it dissociates to such a small extent that we can neglect the change in its concentration to find its equilibrium concentration:

$$[HA] = [HA]_{init} - [HA]_{dissoc} \approx [HA]_{init}$$

Finding K_a Given Concentrations

This type of problem involves finding K_a of a weak acid from the concentration of one of the species in solution, usually H_3O^+ from a given pH:

$$HA(aq) + H_2O(l) \rightleftharpoons H_3O^+(aq) + A^-(aq)$$

$$K_a = \frac{[H_3O^+][A^-]}{[HA]}$$

A common approach is to prepare an aqueous solution of HA and measure its pH. You prepared the solution, so you know $[HA]_{init}$. You can calculate $[H_3O^+]$ from the measured pH and then determine $[A^-]$ and $[HA]$ at equilibrium from the assumptions you make. At this point, you substitute these values into the K_a expression and solve for K_a. We'll go through the entire approach in Sample Problem 18.6 and then simplify later problems by omitting some of the recurring steps.

SAMPLE PROBLEM 18.6 Finding K_a of a Weak Acid from pH of Its Solution

Problem Phenylacetic acid ($C_6H_5CH_2COOH$, simplified here to HPAc; see photo) builds up in the blood of persons with phenylketonuria, an inherited disorder that, if untreated, causes mental retardation and death. A study of the acid shows that the pH of 0.12 *M* HPAc is 2.62. What is the K_a of phenylacetic acid?

Plan We are given $[HPAc]_{init}$ (0.12 *M*) and the pH (2.62) and must find K_a. We first write the equation for HPAc dissociation and the expression for K_a to see which values we need to find:

$$HPAc(aq) + H_2O(l) \rightleftharpoons H_3O^+(aq) + PAc^-(aq) \qquad K_a = \frac{[H_3O^+][PAc^-]}{[HPAc]}$$

- To find $[H_3O^+]$: We know the pH, so we can find $[H_3O^+]$. Because a pH of 2.62 is more than four pH units (10^4-fold) *lower* than the pH of pure water itself (pH = 7.0), we can assume that $[H_3O^+]_{from\ HPAc} >> [H_3O^+]_{from\ H_2O}$. Therefore, $[H_3O^+]_{from\ HPAc} + [H_3O^+]_{from\ H_2O} \approx [H_3O^+]_{from\ HPAc} \approx [H_3O^+]$.
- To find $[PAc^-]$: Because each HPAc that dissociates forms one H_3O^+ and one PAc^-, $[H_3O^+] \approx [PAc^-]$.
- To find [HPAc]: We know $[HPAc]_{init}$. Because HPAc is a weak acid, we assume that very little dissociates, so $[HPAc]_{init} - [HPAc]_{dissoc} = [HPAc] \approx [HPAc]_{init}$.

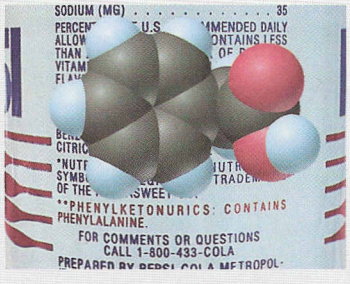
We set up a reaction table, make the assumptions, substitute the equilibrium values, solve for K_a, and then check the assumptions.

Solution Calculating $[H_3O^+]$:

$$[H_3O^+] = 10^{-pH} = 10^{-2.62} = 2.4\times10^{-3}\ M$$

Setting up the reaction table, with $x = [HPAc]_{dissoc} = [H_3O^+]_{from\ HPAc} = [PAc^-] \approx [H_3O^+]$:

Concentration (*M*)	HPAc(*aq*)	+	$H_2O(l)$	$\rightleftharpoons$	$H_3O^+(aq)$	+	$PAc^-(aq)$
Initial	0.12		—		1×10^{-7}		0
Change	$-x$		—		$+x$		$+x$
Equilibrium	$0.12 - x$		—		$x + (<1\times10^{-7})$		x



Phenylalanine, one of the amino acids that make up aspartame, is metabolized to phenylacetic acid (model).

Making the assumptions:

1. The calculated $[H_3O^+]$ $(2.4\times10^{-3}\ M)$ >> $[H_3O^+]_{\text{from } H_2O}$ $(<1\times10^{-7}\ M)$, so we assume that $[H_3O^+] \approx [H_3O^+]_{\text{from HPAc}} = x$ (the change in [HPAc])
2. HPAc is a weak acid, so we assume that $[\text{HPAc}] = 0.12\ M - x \approx 0.12\ M$.

Solving for the equilibrium concentrations:

$$x \approx [H_3O^+] = [PAc^-] = 2.4\times10^{-3}\ M$$

$$[\text{HPAc}] = 0.12\ M - x = 0.12\ M - (2.4\times10^{-3}\ M) \approx 0.12\ M \text{ (to 2 sf)}$$

Substituting these values into K_a:

$$K_a = \frac{[H_3O^+][PAc^-]}{[\text{HPAc}]} \approx \frac{(2.4\times10^{-3})(2.4\times10^{-3})}{0.12} = 4.8\times10^{-5}$$

Checking the assumptions by finding the percent error in concentration:

1. For $[H_3O^+]_{\text{from } H_2O}$: $\dfrac{1\times10^{-7}\ M}{2.4\times10^{-3}\ M} \times 100 = 4\times10^{-3}\%$ (<5%; assumption is justified).
2. For $[\text{HPAc}]_{\text{dissoc}}$: $\dfrac{2.4\times10^{-3}\ M}{0.12\ M} \times 100 = 2.0\%$ (<5%; assumption is justified). We had already shown above that, to two significant figures, the concentration had not changed, so this check was not really necessary.

Check The $[H_3O^+]$ makes sense: pH 2.62 should give $[H_3O^+]$ between 10^{-2} and $10^{-3}\ M$. The K_a calculation also seems in the correct range: $(10^{-3})^2/10^{-1} = 10^{-5}$, and this value seems reasonable for a weak acid.

Comment $[H_3O^+]_{\text{from } H_2O}$ is so small relative to $[H_3O^+]_{\text{from HA}}$ that, from here on, we will disregard it and enter it as zero in reaction tables.

FOLLOW-UP PROBLEM 18.6 The conjugate acid of ammonia is NH_4^+, a weak acid. If a 0.2 M NH_4Cl solution has a pH of 5.0, what is the K_a of NH_4^+?

Finding Concentrations Given K_a

The second type of equilibrium problem involving weak acids gives some concentration data and the K_a value and asks for the equilibrium concentration of some component. Such problems are very similar to those we solved in Chapter 17 in which a substance with a given initial concentration reacted to an unknown extent (see Sample Problems 17.8 to 17.10).

SAMPLE PROBLEM 18.7 Determining Concentrations from K_a and Initial [HA]

Problem Propanoic acid (CH_3CH_2COOH, which we simplify as HPr) is a carboxylic acid whose salts are used to retard mold growth in foods. What is the $[H_3O^+]$ of 0.10 M HPr ($K_a = 1.3\times10^{-5}$)?

Plan We know the initial concentration (0.10 M) and K_a (1.3×10^{-5}) of HPr, and we need to find $[H_3O^+]$. First, we write the balanced equation and the expression for K_a:

$$HPr(aq) + H_2O(l) \rightleftharpoons H_3O^+(aq) + Pr^-(aq) \qquad K_a = \frac{[H_3O^+][Pr^-]}{[HPr]} = 1.3\times10^{-5}$$

We know $[HPr]_{init}$ but not [HPr]. If we let $x = [HPr]_{dissoc}$, x is also $[H_3O^+]_{\text{from HPr}}$ and $[Pr^-]$ because each HPr that dissociates yields one H_3O^+ and one Pr^-. With this information, we can set up a reaction table. In solving for x, we assume that, because HPr has a small K_a, it dissociates very little; therefore, $[HPr]_{init} - x = [HPr] \approx [HPr]_{init}$. After we find x, we check the assumption.

Solution Setting up a reaction table, with $x = [HPr]_{dissoc} = [H_3O^+]_{\text{from HPr}} = [Pr^-] = [H_3O^+]$:

Concentration (M)	$HPr(aq)$	+	$H_2O(l)$	$\rightleftharpoons$	$H_3O^+(aq)$	+	$Pr^-(aq)$
Initial	0.10		—		0		0
Change	$-x$		—		$+x$		$+x$
Equilibrium	$0.10 - x$		—		x		x

Making the assumption: K_a is small, so x is small compared with $[HPr]_{init}$; therefore, $0.10\ M - x \approx 0.10\ M$. Substituting into the K_a expression and solving for x:

$$K_a = \frac{[H_3O^+][Pr^-]}{[HPr]} = 1.3\times10^{-5} \approx \frac{(x)(x)}{0.10}$$

$$x \approx \sqrt{(0.10)(1.3\times10^{-5})} = 1.1\times10^{-3}\ M = [H_3O^+]$$

Checking the assumption:

For $[HPr]_{dissoc}$: $\dfrac{1.1\times10^{-3}\ M}{0.10\ M} \times 100 = 1.1\%$ (<5%; assumption is justified).

Check The $[H_3O^+]$ seems reasonable for a dilute solution of a weak acid with a moderate K_a. By reversing the calculation, we can check the math: $(1.1\times10^{-3})^2/0.10 = 1.2\times10^{-5}$, which is within rounding of the given K_a.

Comment In these problems, we assume that the concentration of HA that dissociates ($[HA]_{dissoc} = x$) can be neglected because K_a is relatively small. However, this is true only if $[HA]_{init}$ is relatively large. Here's a benchmark to see if the assumption is justified:

- If $\dfrac{[HA]_{init}}{K_a} > 400$, the assumption is justified: neglecting x introduces an error < 5%.
- If $\dfrac{[HA]_{init}}{K_a} < 400$, the assumption is *not* justified; neglecting x introduces an error > 5%, so we solve a quadratic equation to find x.

The latter situation occurs in the follow-up problem.

FOLLOW-UP PROBLEM 18.7 Cyanic acid (HOCN) is an extremely acrid, unstable substance. What is the $[H_3O^+]$ and pH of 0.10 M HOCN ($K_a = 3.5\times10^{-4}$)?

The Effect of Concentration on the Extent of Acid Dissociation

If we repeat the calculation in Sample Problem 18.7, but start with a lower [HPr], we observe a very interesting fact about the extent of dissociation of a weak acid. Suppose the initial concentration of HPr is one-tenth as much, 0.010 M rather than 0.10 M. After filling in the reaction table and making the same assumptions, we find that

$$x = [HPr]_{dissoc} = 3.6\times10^{-4}\ M$$

Now, let's compare the percentages of HPr molecules dissociated at the two different initial acid concentrations, using the relationship

$$\text{Percent HA dissociated} = \frac{[HA]_{dissoc}}{[HA]_{init}} \times 100 \qquad (18.5)$$

Case 1: $[HPr]_{init} = 0.10\ M$

$$\text{Percent dissociated} = \frac{1.1\times10^{-3}\ M}{1.0\times10^{-1}\ M} \times 100 = 1.1\%$$

Case 2: $[HPr]_{init} = 0.010\ M$

$$\text{Percent dissociated} = \frac{3.6\times10^{-4}\ M}{1.0\times10^{-2}\ M} \times 100 = 3.6\%$$

As the initial acid concentration decreases, the percent dissociation of the acid increases. Don't confuse the *concentration* of HA dissociated with the *percent* HA dissociated. The $[HA]_{dissoc}$ is lower in the diluted HA solution because the actual *number* of dissociated HA molecules is smaller. It is the *fraction* (and thus the *percent*) of dissociated HA molecules that increases with dilution.

This phenomenon is analogous to a change in container volume (pressure) for gases at equilibrium (see the discussion in Section 17.6). In that situation, an increase in volume shifts the equilibrium position to favor more moles of gas. In the case of HA dissociation, the available volume increases as solvent is added and the solution is diluted; this increase in volume shifts the equilibrium position to favor more moles of ions.

The Behavior of Polyprotic Acids

Acids with more than one ionizable proton are **polyprotic acids.** In a solution of a polyprotic acid, one proton at a time dissociates from the acid molecule, and each dissociation step has a different K_a. For example, phosphoric acid is a triprotic acid (three ionizable protons), so it has three K_a values:

$$H_3PO_4(aq) + H_2O(l) \rightleftharpoons H_2PO_4^-(aq) + H_3O^+(aq)$$

$$K_{a1} = \frac{[H_2PO_4^-][H_3O^+]}{[H_3PO_4]} = 7.2\times10^{-3}$$

$$H_2PO_4^-(aq) + H_2O(l) \rightleftharpoons HPO_4^{2-}(aq) + H_3O^+(aq)$$

$$K_{a2} = \frac{[HPO_4^{2-}][H_3O^+]}{[H_2PO_4^-]} = 6.3\times10^{-8}$$

$$HPO_4^{2-}(aq) + H_2O(l) \rightleftharpoons PO_4^{3-}(aq) + H_3O^+(aq)$$

$$K_{a3} = \frac{[PO_4^{3-}][H_3O^+]}{[HPO_4^{2-}]} = 4.2\times10^{-13}$$

As you can see from the relative K_a values, H_3PO_4 is a much stronger acid than $H_2PO_4^-$, which is much stronger than HPO_4^{2-}. Table 18.5 lists some common polyprotic acids and their K_a values. (A more extensive list is presented in Appendix C.) Notice that, in every case, the first proton comes off to a much greater extent than the second and, where applicable, the second ionizes to a much greater extent than the third:

$$K_{a1} > K_{a2} > K_{a3}$$

This trend makes sense: it is more difficult for an H^+ ion to leave a singly charged anion (such as $H_2PO_4^-$) than to leave a neutral molecule (such as H_3PO_4), and more difficult still for it to leave a doubly charged anion (HPO_4^{2-}). Successive acid dissociation constants typically differ by several orders of magnitude. This fact greatly simplifies pH calculations involving polyprotic acids because *we can usually neglect the H_3O^+ coming from the subsequent dissociations.*

Table 18.5 Successive K_a Values for Some Polyprotic Acids at 25°C

Name (Formula)	Lewis Structure*	K_{a1}	K_{a2}	K_{a3}
Oxalic acid ($H_2C_2O_4$)		5.6×10^{-2}	5.4×10^{-5}	
Sulfurous acid (H_2SO_3)		1.4×10^{-2}	6.5×10^{-8}	
Phosphoric acid (H_3PO_4)		7.2×10^{-3}	6.3×10^{-8}	4.2×10^{-13}
Arsenic acid (H_3AsO_4)		6×10^{-3}	1.1×10^{-7}	3×10^{-12}
Carbonic acid (H_2CO_3)		4.5×10^{-7}	4.7×10^{-11}	
Hydrosulfuric acid (H_2S)		9×10^{-8}	1×10^{-17}	

ACID STRENGTH

*Red type indicates the ionizable protons.

SAMPLE PROBLEM 18.8 Calculating Equilibrium Concentrations for a Polyprotic Acid

Problem Ascorbic acid ($H_2C_6H_6O_6$; H_2Asc for this problem), known as vitamin C, is a diprotic acid ($K_{a1} = 1.0\times10^{-5}$ and $K_{a2} = 5\times10^{-12}$) found in citrus fruit. Calculate $[H_2Asc]$, $[HAsc^-]$, $[Asc^{2-}]$, and the pH of 0.050 M H_2Asc.

Plan We know the initial concentration (0.050 M) and both K_a's for H_2Asc, and we have to calculate the equilibrium concentrations of all species and convert $[H_3O^+]$ to pH. We first write the equations and K_a expressions:

$$H_2Asc(aq) + H_2O(l) \rightleftharpoons HAsc^-(aq) + H_3O^+(aq) \qquad K_{a1} = \frac{[HAsc^-][H_3O^+]}{[H_2Asc]} = 1.0\times10^{-5}$$

$$HAsc^-(aq) + H_2O(l) \rightleftharpoons Asc^{2-}(aq) + H_3O^+(aq) \qquad K_{a2} = \frac{[Asc^{2-}][H_3O^+]}{[HAsc^-]} = 5\times10^{-12}$$

Then we assume the following:

1. Because $K_{a1} >> K_{a2}$, dissociation of the first proton produces almost all the H_3O^+: $[H_3O^+]_{\text{from } H_2Asc} >> [H_3O^+]_{\text{from } HAsc^-}$.
2. Because K_{a1} is small, the amount of H_2Asc that dissociates can be neglected relative to the initial concentration: $[H_2Asc]_{init} \approx [H_2Asc]$.

We set up a reaction table for the first dissociation, with x equal to the concentration of H_2Asc that dissociates, and then solve for $[H_3O^+]$ and $[HAsc^-]$. Because the second dissociation occurs to a much lesser extent than the first, we can substitute values from the first directly to find $[Asc^{2-}]$ of the second.

Solution Setting up a reaction table with $x = [H_2Asc]_{dissoc} = [HAsc^-] \approx [H_3O^+]$:

Concentration (M)	$H_2Asc(aq)$	+	$H_2O(l)$	$\rightleftharpoons$	$H_3O^+(aq)$	+	$HAsc^-(aq)$
Initial	0.050		—		0		0
Change	$-x$		—		$+x$		$+x$
Equilibrium	$0.050 - x$		—		x		x

Making the assumptions:

1. Because $K_{a2} << K_{a1}$, $[H_3O^+]_{\text{from } HAsc^-} << [H_3O^+]_{\text{from } H_2Asc}$. Therefore,
$$[H_3O^+]_{\text{from } H_2Asc} \approx [H_3O^+]$$
2. Because K_{a1} is small, $[H_2Asc]_{init} - x = [H_2Asc] \approx [H_2Asc]_{init}$. Thus,
$$[H_2Asc] = 0.050\ M - x \approx 0.050\ M$$

Substituting into the expression for K_{a1} and solving for x:

$$K_{a1} = \frac{[H_3O^+][HAsc^-]}{[H_2Asc]} = 1.0\times10^{-5} \approx \frac{x^2}{0.050}$$

$$x = [HAsc^-] \approx [H_3O^+] \approx 7.1\times10^{-4}\ M$$

$$pH = -\log [H_3O^+] = -\log (7.1\times10^{-4}) = 3.15$$

Checking the assumptions:

1. $[H_3O^+]_{\text{from } HAsc^-} << [H_3O^+]_{\text{from } H_2Asc}$: For any second dissociation that does occur, we have
$$[H_3O^+]_{\text{from } HAsc^-} \approx \sqrt{[HAsc^-](K_{a2})} = \sqrt{(7.1\times10^{-4})(5\times10^{-12})} = 6\times10^{-8}\ M$$
This is even less than $[H_3O^+]_{\text{from } H_2O}$, so the assumption is justified.
2. $[H_2Asc]_{dissoc} << [H_2Asc]_{init}$: $\dfrac{7.1\times10^{-4}\ M}{0.050\ M} \times 100 = 1.4\%$ (<5%; assumption is justified).

Also, from the Comment in Sample Problem 18.7, note that

$$\frac{[H_2Asc]_{init}}{K_{a1}} = \frac{0.050}{1.0\times10^{-5}} = 5000 > 400$$

Calculating $[Asc^{2-}]$:

$$K_{a2} = \frac{[H_3O^+][Asc^{2-}]}{[HAsc^-]} \quad \text{and} \quad [Asc^{2-}] = \frac{(K_{a2})[HAsc^-]}{[H_3O^+]}$$

$$[Asc^{2-}] = \frac{(5\times10^{-12})(7.1\times10^{-4})}{7.1\times10^{-4}} = 5\times10^{-12}\ M$$

Check $K_{a1} >> K_{a2}$, so it makes sense that $[HAsc^-] >> [Asc^{2-}]$ because Asc^{2-} is produced only in the second (much weaker) dissociation. Both K_a's are small, so all concentrations except $[H_2Asc]$ should be much lower than the original 0.050 *M*.

FOLLOW-UP PROBLEM 18.8 Oxalic acid (HOOC—COOH, or $H_2C_2O_4$) is the simplest diprotic carboxylic acid. Its commercial uses include bleaching straw and leather and removing rust and ink stains. Calculate $[H_2C_2O_4]$, $[HC_2O_4^-]$, $[C_2O_4^{2-}]$, and the pH of a 0.150 *M* $H_2C_2O_4$ solution. Use K_a values from Appendix C.

SECTION SUMMARY

Two common types of weak-acid equilibrium problems involve finding K_a from a concentration and finding a concentration from K_a. We summarize the information in a reaction table, and we simplify the arithmetic by assuming (1) $[H_3O^+]_{\text{from } H_2O}$ is so small relative to $[H_3O^+]_{\text{from HA}}$ that it can be neglected, and (2) weak acids dissociate so little that $[HA]_{init} \approx [HA]$ at equilibrium. The *fraction* of weak acid molecules that dissociates is greater in a more dilute solution, even though the total $[H_3O^+]$ is less. Polyprotic acids have more than one ionizable proton, but we assume that the first dissociation provides virtually all the H_3O^+.

18.5 WEAK BASES AND THEIR RELATION TO WEAK ACIDS

By focusing on where the proton comes from and goes to, the Brønsted-Lowry concept expands the definition of a base to encompass a host of species that the Arrhenius definition excludes: a base is any species that accepts a proton; to do so, *the base must have a lone electron pair.* (The lone electron pair also plays the central role in the Lewis acid-base definition, as you'll see later in this chapter.)

Now let's examine the equilibrium system of a weak base and focus, as we did for weak acids, on aqueous solutions. When a base (B) dissolves, it accepts a proton from H_2O, which acts here as an acid, leaving behind an OH^- ion:

$$B(aq) + H_2O(aq) \rightleftharpoons BH^+(aq) + OH^-(aq)$$

This general reaction for a base in water is described by the following equilibrium expression:

$$K_c = \frac{[BH^+][OH^-]}{[B][H_2O]}$$

Based on our earlier reasoning that $[H_2O]$ is treated as a constant in aqueous reactions, we include $[H_2O]$ in the value of K_c and obtain the **base-dissociation constant** (or **base-ionization constant**), K_b:

$$K_b = \frac{[BH^+][OH^-]}{[B]} \qquad (18.6)$$

Despite the name "base-dissociation constant," *no base dissociates in the process,* as you can see from the reaction.

As in the relation between pK_a and K_a, we know that pK_b, the negative logarithm of the base-dissociation constant, decreases with increasing K_b (that is, increasing base strength). In aqueous solution, the two large classes of weak bases are nitrogen-containing molecules, such as ammonia and the amines, and the anions of weak acids.

Molecules as Weak Bases: Ammonia and the Amines

Ammonia is the simplest nitrogen-containing compound that acts as a weak base in water:

$$NH_3(aq) + H_2O(l) \rightleftharpoons NH_4^+(aq) + OH^-(aq) \qquad K_b = 1.76\times10^{-5} \text{ (at 25°C)}$$

Table 18.6 K_b Values for Some Molecular (Amine) Bases at 25°C

Name (Formula)	Lewis Structure*	K_b
Diethylamine [$(CH_3CH_2)_2NH$]		8.6×10^{-4}
Dimethylamine [$(CH_3)_2NH$]		5.9×10^{-4}
Methylamine (CH_3NH_2)		4.4×10^{-4}
Ammonia (NH_3)		1.76×10^{-5}
Pyridine (C_5H_5N)		1.7×10^{-9}
Aniline ($C_6H_5NH_2$)		4.0×10^{-10}

BASE STRENGTH

*Blue type indicates the basic nitrogen and its lone pair.

Despite labels on reagent bottles that read "ammonium hydroxide," an aqueous solution of ammonia consists largely of *unprotonated* NH_3 molecules, as you can see from its small K_b value. In a 1.0 M NH_3 solution, for example, $[OH^-] = [NH_4^+] = 4.2\times10^{-3}\ M$, so about 99.58% of the NH_3 is not ionized. Table 18.6 shows the K_b values for a few common molecular bases. (A more extensive list appears in Appendix C.)

If one or more of the H atoms in NH_3 is replaced by an organic group (designated as R), an *amine* results: RNH_2, R_2NH, or R_3N (Section 15.4; see Figure 15.15). The key structural feature of these organic compounds, as in all Brønsted-Lowry bases, is *a lone pair of electrons that can bind the proton donated by the acid*. Figure 18.10 depicts this process for methylamine, the simplest amine.

Finding the pH of a solution of a molecular weak base is a problem very similar to the type involving a weak acid. We write the equilibrium expression, set up a reaction table to find $[base]_{reacting}$, make the usual assumptions, and then solve for $[OH^-]$. The main difference is that we must convert $[OH^-]$ to $[H_3O^+]$ in order to calculate pH.

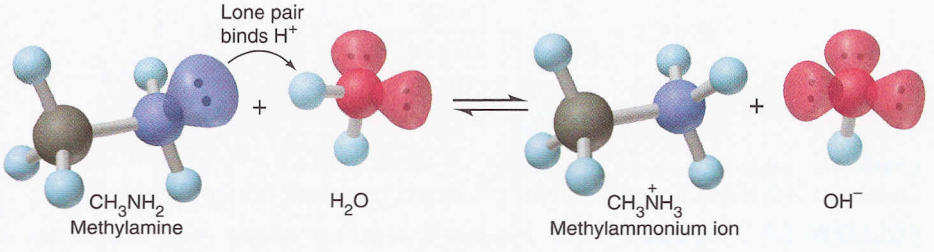


Figure 18.10 Abstraction of a proton from water by methylamine. The amines are organic derivatives of ammonia. Methylamine, the simplest amine, acts as a base in water by accepting a proton, thereby increasing $[OH^-]$.

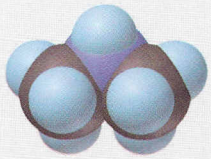


Dimethylamine

SAMPLE PROBLEM 18.9 Determining pH from K_b and Initial [B]

Problem Dimethylamine, $(CH_3)_2NH$ (see margin), a key intermediate in detergent manufacture, has a K_b of 5.9×10^{-4}. What is the pH of 1.5 M $(CH_3)_2NH$?

Plan We know the initial concentration (1.5 M) and K_b (5.9×10^{-4}) of $(CH_3)_2NH$ and have to find the pH. The amine reacts with water to form OH^-, so we have to find $[OH^-]$ and then calculate $[H_3O^+]$ and pH. The balanced equation and K_b expression are

$$(CH_3)_2NH(aq) + H_2O(l) \rightleftharpoons (CH_3)_2NH_2^+(aq) + OH^-(aq)$$

$$K_b = \frac{[(CH_3)_2NH_2^+][OH^-]}{[(CH_3)_2NH]}$$

Because $K_b >> K_w$, the $[OH^-]$ from the autoionization of water is negligible, and we disregard it. Therefore,

$$[OH^-]_{\text{from base}} = [(CH_3)_2NH_2^+] = [OH^-]$$

Because K_b is small, we assume that the amount of amine reacting is small, so

$$[(CH_3)_2NH]_{\text{init}} - [(CH_3)_2NH]_{\text{reacting}} = [(CH_3)_2NH] \approx [(CH_3)_2NH]_{\text{init}}$$

We proceed as usual, setting up a reaction table, making the assumption, and solving for x. Then we check the assumption and convert $[OH^-]$ to $[H_3O^+]$ using K_w; finally, we calculate pH.

Solution Setting up the reaction table, with

$$x = [(CH_3)_2NH]_{\text{reacting}} = [(CH_3)_2NH_2^+] = [OH^-]$$

Concentration (M)	$(CH_3)_2NH(aq)$	+	$H_2O(l)$	$\rightleftharpoons$	$(CH_3)_2NH_2^+(aq)$	+	$OH^-(aq)$
Initial	1.5		—		0		0
Change	$-x$		—		$+x$		$+x$
Equilibrium	$1.5 - x$		—		x		x

Making the assumption:
K_b is small, so $[(CH_3)_2NH]_{\text{init}} \approx [(CH_3)_2NH]$; thus, $1.5\ M - x \approx 1.5\ M$.
Substituting into the K_b expression and solving for x:

$$K_b = \frac{[(CH_3)_2NH_2^+][OH^-]}{[(CH_3)_2NH]}$$

$$= 5.9\times10^{-4} \approx \frac{x^2}{1.5}$$

$$x = [OH^-] \approx 3.0\times10^{-2}\ M$$

Checking the assumption:

$$\frac{3.0\times10^{-2}\ M}{1.5\ M} \times 100 = 2.0\%\ (<5\%;\ \text{assumption is justified})$$

Note that the Comment in Sample Problem 18.7 applies to weak bases as well:

$$\frac{[B]_{\text{init}}}{K_b} = \frac{1.5}{5.9\times10^{-4}} = 2.5\times10^3 > 400$$

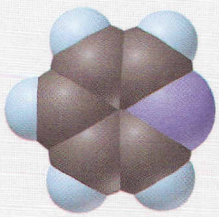
Calculating pH:

$$[H_3O^+] = \frac{K_w}{[OH^-]} = \frac{1.0\times10^{-14}}{3.0\times10^{-2}} = 3.3\times10^{-13}\ M$$

$$\text{pH} = -\log(3.3\times10^{-13})$$

$$= 12.48$$

Check The value of x seems reasonable: $\sqrt{(\sim6\times10^{-4})(1.5)} = \sqrt{9\times10^{-4}} = 3\times10^{-2}$. Because $(CH_3)_2NH$ is a weak base, the pH should be several pH units greater than 7.



Pyridine

FOLLOW-UP PROBLEM 18.9 Pyridine (C_5H_5N, see margin) plays a major role in organic syntheses as a solvent and base. It has a pK_b of 8.77. What is the pH of 0.10 M pyridine?

Anions of Weak Acids as Weak Bases

The other large group of Brønsted-Lowry bases consists of anions of weak acids:*

$$A^-(aq) + H_2O(l) \rightleftharpoons HA(aq) + OH^-(aq) \qquad K_b = \frac{[HA][OH^-]}{[A^-]}$$

For example, F^-, the anion of the weak acid HF, acts as a weak base:

$$F^-(aq) + H_2O(l) \rightleftharpoons HF(aq) + OH^-(aq) \qquad K_b = \frac{[HF][OH^-]}{[F^-]}$$

Why is a solution of HA acidic and a solution of A^- basic? Let's approach the question by examining the relative concentrations of species present in 1 *M* HF and in 1 *M* NaF:

1. *The acidity of HA(aq).* Because HF is a weak acid, most of the HF exists in undissociated form. A small fraction of the HF molecules do dissociate, donating their protons to H_2O and yielding small concentrations of $H_3O^+$and F^-. The equilibrium position of the system lies far to the left:

$$HF(aq) + H_2O(l) \rightleftharpoons H_3O^+(aq) + F^-(aq)$$

Water molecules also contribute minute amounts of $H_3O^+$and OH^-, but these concentrations are extremely small:

$$2H_2O(l) \rightleftharpoons H_3O^+(aq) + OH^-(aq)$$

Of all the species present—HF, H_2O, H_3O^+, F^-, and OH^-—the two that can influence the acidity of the solution are H_3O^+, predominantly from HF, and OH^- from water. The solution is acidic because $[H_3O^+]_{\text{from HF}} >> [OH^-]_{\text{from } H_2O}$.

2. *The basicity of $A^-(aq)$.* Now, consider the species present in 1 *M* NaF. The salt dissociates completely to yield a relatively large concentration of F^-. The Na^+ ion behaves as a spectator, but some F^-reacts as a weak base with water to produce a very small amount of HF (and of OH^-):

$$F^-(aq) + H_2O(l) \rightleftharpoons HF(aq) + OH^-(aq)$$

As before, water dissociation contributes minute amounts of $H_3O^+$and OH^-. Thus, in addition to the Na^+ ion, the species present are the same as in the HF solution: HF, H_2O, H_3O^+, F^-, and OH^-. The two species that affect the acidity are OH^-, predominantly from the F^- reaction with water, and H_3O^+ from water. In this case, $[OH^-]_{\text{from } F^-} >> [H_3O^+]_{\text{from } H_2O}$, so the solution is basic.

To summarize, *the factor that determines the acidity or basicity of an HA solution or an A^- solution is the relative concentration of HA versus A^- in each solution:*

- In an HA solution, $[HA] >> [A^-]$ and $[H_3O^+]_{\text{from HA}} >> [OH^-]_{\text{from } H_2O}$, so the solution is acidic.
- In an A^- solution, $[A^-] >> [HA]$ and $[OH^-]_{\text{from } A^-} >> [H_3O^+]_{\text{from } H_2O}$, so the solution is basic.

The Relation Between K_a and K_b of a Conjugate Acid-Base Pair

An important relationship exists between the K_a of HA and the K_b of A^-, which we can see by treating the two dissociation reactions as a reaction sequence and adding them together:

$$\begin{array}{r} \cancel{HA} + H_2O \rightleftharpoons H_3O^+ + \cancel{A^-} \\ \cancel{A^-} + H_2O \rightleftharpoons \cancel{HA} + OH^- \\ \hline 2H_2O \rightleftharpoons H_3O^+ + OH^- \end{array}$$

*This equation and equilibrium expression are sometimes referred to as a *hydrolysis reaction* and a *hydrolysis constant*, K_h, because water is dissociated (hydrolyzed), and its parts end up in the products. Actually, except for the charge on the base, this process is the same as the proton-abstraction process with molecular bases such as ammonia, so a new term and equilibrium constant are unnecessary. That is, K_h is just another symbol for K_b, so we'll use K_b throughout.

The sum of the two dissociation reactions is the autoionization of water. Recall from Chapter 17 that, for a reaction that is the *sum* of two or more reactions, the overall equilibrium constant is the *product* of the individual equilibrium constants. Therefore, writing the expressions for each reaction gives

$$\frac{[H_3O^+][A^-]}{[HA]} \times \frac{[HA][OH^-]}{[A^-]} = [H_3O^+][OH^-]$$

or

$$K_a \times K_b = K_w \qquad (18.7)$$

This relationship allows us to find K_a of the acid in a conjugate pair given K_b of the base, and vice versa. Let's use this relationship to obtain a key piece of data for solving equilibrium problems. Reference tables typically have K_a and K_b values for molecular species only. The K_b for F^- or the K_a for $CH_3NH_3^+$, for example, does not appear in standard tables, but you can calculate either value simply by looking up the value for the molecular conjugate species and relating it to K_w. To find the K_b value for F^-, for instance, we look up the K_a value for HF and relate it to K_w:

$$K_a \text{ of HF} = 6.8\times10^{-4} \text{ (from Appendix C)}$$

So, we have

$$K_a \text{ of HF} \times K_b \text{ of } F^- = K_w$$

or

$$K_b \text{ of } F^- = \frac{K_w}{K_a \text{ of HF}} = \frac{1.0\times10^{-14}}{6.8\times10^{-4}} = 1.5\times10^{-11}$$

We can use this calculated K_b value to finish solving the problem.

SAMPLE PROBLEM 18.10 Determining the pH of a Solution of A^-

Problem Sodium acetate (CH_3COONa, or NaAc for this problem) has applications in photographic development and textile dyeing. What is the pH of 0.25 *M* NaAc? K_a of acetic acid (HAc) is 1.8×10^{-5}.

Plan From the formula (NaAc) and the fact that all sodium salts are water soluble, we know that the initial concentration of acetate ion, Ac^-, is 0.25 *M*. We also know the K_a of the parent acid, HAc (1.8×10^{-5}). We have to find the pH of the solution of Ac^-, which acts as a base in water:

$$Ac^-(aq) + H_2O(l) \rightleftharpoons HAc(aq) + OH^-(aq) \qquad K_b = \frac{[HAc][OH^-]}{[Ac^-]}$$

If we calculate $[OH^-]$, we can find $[H_3O^+]$ and convert it to pH. To solve for $[OH^-]$, we need the K_b of Ac^-, which we obtain from the K_a of HAc and K_w. All sodium salts are soluble, so we know that $[Ac^-] = 0.25$ *M*. Our usual assumption is that $[Ac^-]_{init} \approx [Ac^-]$.

Solution Setting up the reaction table, with $x = [Ac^-]_{reacting} = [HAc] = [OH^-]$:

Concentration (*M*)	$Ac^-(aq)$	+	$H_2O(l)$	$\rightleftharpoons$	$HAc(aq)$	+	$OH^-(aq)$
Initial	0.25		—		0		0
Change	$-x$		—		$+x$		$+x$
Equilibrium	$0.25 - x$		—		x		x

Solving for K_b:

$$K_b = \frac{K_w}{K_a} = \frac{1.0\times10^{-14}}{1.8\times10^{-5}} = 5.6\times10^{-10}$$

Making the assumption: Because K_b is small, $0.25 - x \approx 0.25$ *M*.
Substituting into the expression for K_b and solving for x:

$$K_b = \frac{[HAc][OH^-]}{[Ac^-]} = 5.6\times10^{-10} \approx \frac{x^2}{0.25} \qquad x = [OH^-] \approx 1.2\times10^{-5}\ M$$

Checking the assumption:

$$\frac{1.2\times10^{-5}\ M}{0.25\ M} \times 100 = 4.8\times10^{-3}\% \text{ (<5%; assumption is justified)}$$

Note that

$$\frac{0.25}{5.6\times10^{-10}} = 4.5\times10^{8} > 400$$

Solving for pH:

$$[H_3O^+] = \frac{K_w}{[OH^-]} = \frac{1.0\times10^{-14}}{1.2\times10^{-5}} = 8.3\times10^{-10}\,M$$

$$pH = -\log(8.3\times10^{-10}) = 9.08$$

Check The K_b calculation seems reasonable: $\sim10\times10^{-15}/2\times10^{-5} = 5\times10^{-10}$. Because Ac^- is a weak base, $[OH^-] > [H_3O^+]$; thus, pH > 7, which makes sense.

FOLLOW-UP PROBLEM 18.10 Sodium hypochlorite (NaClO) is the active ingredient in household laundry bleach. What is the pH of 0.20 *M* NaClO?

SECTION SUMMARY

The extent to which a weak base accepts a proton from water to form OH^- is expressed by a base-dissociation constant, K_b. Brønsted-Lowry bases include NH_3 and amines and the anions of weak acids. All produce basic solutions by accepting H^+ from water, which yields OH^- and thus makes $[H_3O^+] < [OH^-]$. A solution of HA is acidic because $[HA] >> [A^-]$, so $[H_3O^+] > [OH^-]$. A solution of A^- is basic because $[A^-] >> [HA]$, so $[OH^-] > [H_3O^+]$. By multiplying the expressions for K_a of HA and K_b of A^-, we obtain K_w. This relationship allows us to calculate either K_a of BH^+, the cationic conjugate acid of a molecular weak base B, or K_b of A^-, the anionic conjugate base of a molecular weak acid HA.

18.6 MOLECULAR PROPERTIES AND ACID STRENGTH

The strength of an acid depends on its ability to donate a proton, which depends in turn on the strength of the bond to the acidic proton. In this section, we apply trends in atomic and bond properties to determine the trends in acid strength of nonmetal hydrides and oxoacids and discuss the acidity of hydrated metal ions.

Trends in Acid Strength of Nonmetal Hydrides

Two factors determine how easily a proton is released from a nonmetal hydride: the electronegativity of the central nonmetal (E) and the strength of the E—H bond. Figure 18.11 displays two periodic trends:

1. *Across a period, nonmetal hydride acid strength increases.* Across a period, the electronegativity of the nonmetal E determines the trend. As E becomes more electronegative, electron density around H is withdrawn, and the E—H bond becomes more polar. As a result, an H^+ is released more easily to an O atom of a surrounding water molecule. In aqueous solution, the hydrides of Groups 3A(13) to 5A(15) do not behave as acids, but an increase in acid strength is seen in Groups 6A(16) and 7A(17). Thus, HCl is a stronger acid than H_2S because Cl is more electronegative (EN = 3.0) than S (EN = 2.5). The same relationship holds across each period.

2. *Down a group, nonmetal hydride acid strength increases.* Down a group, E—H bond strength determines the trend. As E becomes larger, the E—H bond becomes longer and weaker, so H^+ comes off more easily.* Thus, the hydrohalic acids increase in strength down the group:

$$HF << HCl < HBr < HI$$

A similar trend in increasing acid strength is seen down Group 6A(16). (The trend in hydrohalic acid strength is not seen in aqueous solution, where HCl, HBr, and HI are all equally strong; we discuss how this trend is observed in Section 18.8.)

*Actually, bond energy refers to bond breakage that forms an H atom, whereas acidity refers to bond breakage that forms an H^+ ion, so the two processes are not the same. Nevertheless, the magnitudes of the two types of bond breakage parallel each other.

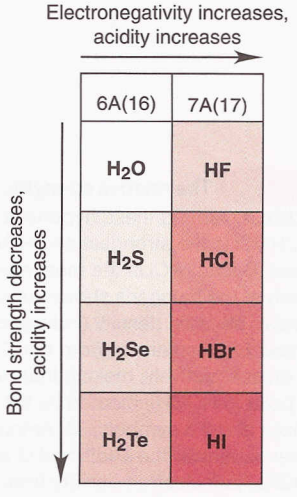


Figure 18.11 The effect of atomic and molecular properties on nonmetal hydride acidity. As the electronegativity of the nonmetal (E) bonded to the ionizable proton increases *(left to right)*, the acidity increases. As the length of the E—H bond increases *(top to bottom)*, the bond strength decreases, so the acidity increases. (In water, HCl, HBr, and HI are equally strong, for reasons discussed in Section 18.8.)

Trends in Acid Strength of Oxoacids

All oxoacids have the acidic H atom bonded to an O atom, so bond strength (length) is not a factor in their acidity, though it is with the nonmetal hydrides. Rather, as you saw in Section 14.8, two factors determine the acid strength of oxoacids: the electronegativity of the central nonmetal (E) and the number of O atoms.

1. *For oxoacids with the **same** number of oxygens around E, acid strength increases with the electronegativity of E.* Consider the hypohalous acids (written here as HOE, where E is a halogen atom). The more electronegative E is, the more electron density it pulls from the O—H bond; the more polar the O—H bond becomes, the more easily H^+ is lost (Figure 18.12A). Because electronegativity decreases down the group, we predict that acid strength decreases: HOCl > HOBr > HOI. Our prediction is confirmed by the K_a values:

K_a of HOCl $= 2.9\times10^{-8}$ K_a of HOBr $= 2.3\times10^{-9}$ K_a of HOI $= 2.3\times10^{-11}$

We also predict (correctly) that in Group 6A(16), H_2SO_4 is stronger than H_2SeO_4; in Group 5A(15), H_3PO_4 is stronger than H_3AsO_4, and so forth.

2. *For oxoacids with **different** numbers of oxygens around a given E, acid strength increases with number of O atoms.* The electronegative O atoms pull electron density away from E, which makes the O—H bond more polar. The more O atoms present, the greater the shift in electron density, and the more easily the H^+ ion comes off (Figure 18.12B). Therefore, we predict, for instance, that chlorine oxoacids (written here as $HOClO_n$, with n from 0 to 3) increase in strength in the order HOCl < HOClO < $HOClO_2$ < $HOClO_3$. Once again, the K_a values support the prediction:

K_a of HOCl (hypochlorous acid) $= 2.9\times10^{-8}$
K_a of $HClO_2$ (chlorous acid) $= 1.12\times10^{-2}$
K_a of $HOClO_2$ (chloric acid) ≈ 1
K_a of $HOClO_3$ (perchloric acid) $= >10^7$

It follows from this that HNO_3 is stronger than HNO_2, that H_2SO_4 is stronger than H_2SO_3, and so forth.

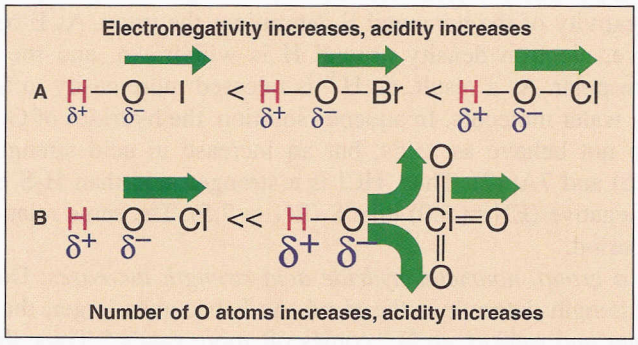

Figure 18.12 The relative strengths of oxoacids. A, Among these hypohalous acids, HOCl is the strongest and HOI the weakest. Because Cl is the most electronegative of the halogens shown here, it withdraws electron density (indicated by thickness of green arrow) from the O—H bond most effectively, making that bond most polar in HOCl (indicated by the relative sizes of the δ symbols). **B,** Among the chlorine oxoacids, the additional O atoms in $HOClO_3$ pull electron density from the O—H bond, making the bond much more polar than that in HOCl.

Acidity of Hydrated Metal Ions

The aqueous solutions of certain metal ions are acidic because the *hydrated* metal ion transfers an H^+ ion to water. Consider a general metal nitrate, $M(NO_3)_n$, as it dissolves in water. The ions separate and become bonded to a specific number

of surrounding H_2O molecules. This equation shows the hydration of the cation (M^{n+}) with H_2O molecules; hydration of the anion (NO_3^-) is indicated by (*aq*):

$$M(NO_3)_n(s) + xH_2O(l) \longrightarrow M(H_2O)_x^{n+}(aq) + nNO_3^-(aq)$$

If the metal ion, M^{n+}, is *small and highly charged,* it has a high charge density and withdraws sufficient electron density from the O—H bonds of these bonded water molecules for a proton to be released. That is, the hydrated cation, $M(H_2O)_x^{n+}$, acts as a typical Brønsted-Lowry acid. In the process, the bound H_2O molecule that releases the proton becomes a bound OH^- ion:

$$M(H_2O)_x^{n+}(aq) + H_2O(l) \rightleftharpoons M(H_2O)_{x-1}OH^{(n-1)+}(aq) + H_3O^+(aq)$$

Each type of hydrated metal ion that releases a proton has a characteristic K_a value. Table 18.7 shows some common examples (also see Appendix C).

Aluminum ion, for example, has the small size and high positive charge needed to produce an acidic solution. When an aluminum salt, such as $Al(NO_3)_3$, dissolves in water, the following steps occur:

$$Al(NO_3)_3(s) + 6H_2O(l) \longrightarrow Al(H_2O)_6^{3+}(aq) + 3NO_3^-(aq)$$

[dissolution and hydration]

$$Al(H_2O)_6^{3+}(aq) + H_2O(l) \rightleftharpoons Al(H_2O)_5OH^{2+}(aq) + H_3O^+(aq)$$

[dissociation of weak acid]

Note the formulas of the hydrated metal ions in the last step. When H^+ is released, the number of bound H_2O molecules decreases by 1 (from 6 to 5) and the number of bound OH^- ions increases by 1 (from 0 to 1), which reduces the ion's positive charge by 1 (from 3 to 2) (Figure 18.13).

Through its ability to withdraw electron density from the O—H bonds of the bonded water molecules, a small, highly charged central metal ion behaves like a central electronegative atom in an oxoacid. Salts of most M^{2+} and M^{3+} ions yield acidic aqueous solutions.

Table 18.7 K_a Values of Some Hydrated Metal Ions at 25°C

Free Ion	Hydrated Ion	K_a
Fe^{3+}	$Fe(H_2O)_6^{3+}(aq)$	6×10^{-3}
Sn^{2+}	$Sn(H_2O)_6^{2+}(aq)$	4×10^{-4}
Cr^{3+}	$Cr(H_2O)_6^{3+}(aq)$	1×10^{-4}
Al^{3+}	$Al(H_2O)_6^{3+}(aq)$	1×10^{-5}
Cu^{2+}	$Cu(H_2O)_6^{2+}(aq)$	3×10^{-8}
Pb^{2+}	$Pb(H_2O)_6^{2+}(aq)$	3×10^{-8}
Zn^{2+}	$Zn(H_2O)_6^{2+}(aq)$	1×10^{-9}
Co^{2+}	$Co(H_2O)_6^{2+}(aq)$	2×10^{-10}
Ni^{2+}	$Ni(H_2O)_6^{2+}(aq)$	1×10^{-10}

ACID STRENGTH

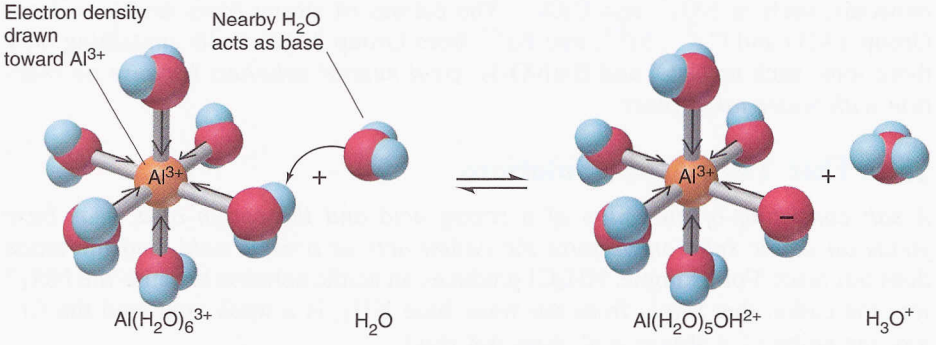

Figure 18.13 The acidic behavior of the hydrated Al^{3+} ion. When a metal ion enters water, it is hydrated as water molecules bond to it. If the ion is small and multiply charged, as is the Al^{3+} ion, it pulls sufficient electron density from the O—H bonds of the attached water molecules to make the bonds more polar, and an H^+ ion is transferred to a nearby water molecule.

SECTION SUMMARY

The strength of an acid depends on the ease with which the ionizable proton is released. For nonmetal hydrides, acid strength increases across a period, with the electronegativity of the nonmetal (E), and down a group, with the length of the E—H bond. For oxoacids with the same number of O atoms, acid strength increases with electronegativity of E; for oxoacids with the same E, acid strength increases with number of O atoms. Small, highly charged metal ions are acidic in water because they withdraw electron density from the O—H bonds of bound H_2O molecules, releasing an H^+ ion to the solution.

18.7 ACID-BASE PROPERTIES OF SALT SOLUTIONS

Up to now you've seen that cations of weak bases (such as NH_4^+) are acidic, anions of weak acids (such as CN^-) are basic, anions of polyprotic acids (such as $H_2PO_4^-$) are often acidic, and small, highly charged metal cations (such as Al^{3+}) are acidic. Therefore, when salts containing these ions dissolve in water, the pH of the solution is affected. You can predict the relative acidity of a salt solution from the relative ability of the cation and/or anion to react with water. Let's examine the ionic makeup of salts that yield neutral, acidic, or basic solutions to see how we make this prediction.

Salts That Yield Neutral Solutions

A salt consisting of the anion of a strong acid and the cation of a strong base yields a neutral solution because the ions do not react with water. In order to see why the ions don't react, let's consider the dissociation of the parent acid and base. When a strong acid such as HNO_3 dissolves, complete dissociation takes place:

$$HNO_3(l) + H_2O(l) \longrightarrow NO_3^-(aq) + H_3O^+(aq)$$

H_2O is a much stronger base than NO_3^-, so the reaction proceeds essentially to completion. The same argument can be made for any strong acid: *the anion of a strong acid is a much weaker base than water.* Therefore, a strong acid anion is hydrated, but nothing further happens.

Now consider the dissociation of a strong base, such as NaOH:

$$NaOH(s) \xrightarrow{H_2O} Na^+(aq) + OH^-(aq)$$

The Na^+ ion has a relatively large size and low charge and therefore does not bond strongly with the water molecules around it. When Na^+ enters water, it becomes hydrated but nothing further happens. *The cations of all strong bases behave this way.*

The anions of strong acids are the halide ions, except F^-, and those of strong oxoacids, such as NO_3^- and ClO_4^-. The cations of strong bases are those from Group 1A(1) and Ca^{2+}, Sr^{2+}, and Ba^{2+} from Group 2A(2). Salts containing only these ions, such as NaCl and $Ba(NO_3)_2$, *yield neutral solutions because no reaction with water takes place.*

Salts That Yield Acidic Solutions

A salt consisting of the anion of a strong acid and the cation of a weak base yields an acidic solution because the cation acts as a weak acid, and the anion does not react. For example, NH_4Cl produces an acidic solution because the NH_4^+ ion, the cation that forms from the weak base NH_3, is a weak acid, and the Cl^- ion, the anion of a strong acid, does not react:

$$NH_4Cl(s) \xrightarrow{H_2O} NH_4^+(aq) + Cl^-(aq) \quad \text{[dissolution and hydration]}$$

$$NH_4^+(aq) + H_2O(l) \rightleftharpoons NH_3(aq) + H_3O^+(aq) \quad \text{[dissociation of weak acid]}$$

As you saw earlier, *small, highly charged metal ions* make up another group of cations that yield H_3O^+ in solution. For example, $Fe(NO_3)_3$ produces an acidic solution because the hydrated Fe^{3+} ion acts as a weak acid, whereas the NO_3^- ion, the anion of a strong acid, does not react:

$$Fe(NO_3)_3(s) + 6H_2O(l) \xrightarrow{H_2O} Fe(H_2O)_6^{3+}(aq) + 3NO_3^-(aq)$$

[dissolution and hydration]

$$Fe(H_2O)_6^{3+}(aq) + H_2O(l) \rightleftharpoons Fe(H_2O)_5OH^{2+}(aq) + H_3O^+(aq)$$

[dissociation of weak acid]

A third group of salts that yield H_3O^+ ions in solutions consists of *cations of strong bases and anions of polyprotic acids that still have one or more ionizable protons*. For example, NaH_2PO_4 yields an acidic solution because Na^+, the cation of a strong base, does not react, while $H_2PO_4^-$, the first anion of the weak polyprotic acid H_3PO_4, is also a weak acid:

$$NaH_2PO_4(s) \xrightarrow{H_2O} Na^+(aq) + H_2PO_4^-(aq) \quad \text{[dissolution and hydration]}$$
$$H_2PO_4^-(aq) + H_2O(l) \rightleftharpoons HPO_4^{2-}(aq) + H_3O^+(aq) \quad \text{[dissociation of weak acid]}$$

Salts That Yield Basic Solutions

A salt consisting of the anion of a weak acid and the cation of a strong base yields a basic solution in water because the anion acts as a weak base, and the cation does not react. The anion of a weak acid accepts a proton from water to yield OH^- ion. Sodium acetate, for example, yields a basic solution because the Na^+ ion, the cation of a strong base, does not react with water, and the CH_3COO^- ion, the anion of the weak acid CH_3COOH, acts as a weak base:

$$CH_3COONa(s) \xrightarrow{H_2O} Na^+(aq) + CH_3COO^-(aq) \quad \text{[dissolution and hydration]}$$
$$CH_3COO^-(aq) + H_2O(l) \rightleftharpoons CH_3COOH(aq) + OH^-(aq) \quad \text{[reaction of weak base]}$$

Table 18.8 displays the acid-base behavior of the various types of salts in water.

Table 18.8 The Behavior of Salts in Water

Salt Solution (Examples)	pH	Nature of Ions	Ion That Reacts with Water	
Neutral [NaCl, KBr, $Ba(NO_3)_2$]	7.0	Cation of strong base Anion of strong acid	None	
Acidic (NH_4Cl, NH_4NO_3, CH_3NH_3Br)	<7.0	Cation of weak base Anion of strong acid	Cation	Acidic [$Al(NO_3)_3$, $CrCl_3$, $FeBr_3$]	<7.0	Small, highly charged cation Anion of strong acid	Cation	
Acidic (NaH_2PO_4, $KHSO_4$, $NaHSO_3$)	<7.0	Cation of strong base First anion of polyprotic acid	Anion	
Basic (CH_3COONa, KF, Na_2CO_3)	>7.0	Cation of strong base Anion of weak acid	Anion	

SAMPLE PROBLEM 18.11 Predicting Relative Acidity of Salt Solutions

Problem Predict whether aqueous solutions of the following are acidic, basic, or neutral, and write an equation for the reaction of any ion with water:

(a) Potassium perchlorate, $KClO_4$ **(b)** Sodium benzoate, C_6H_5COONa

(c) Chromium trichloride, $CrCl_3$ **(d)** Sodium hydrogen sulfate, $NaHSO_4$

Plan We examine the formulas to determine the cations and anions. Depending on the nature of these ions, the solution will be neutral (strong-acid anion and strong-base cation), acidic (weak-base cation and strong-acid anion, highly charged metal cation, or first anion of a polyprotic acid), or basic (weak-acid anion and strong-base cation).

Solution **(a)** Neutral. The ions are K^+ and ClO_4^-. The K^+ ion is from the strong base KOH, and the ClO_4^- anion is from the strong acid $HClO_4$. Neither ion reacts with water.

(b) Basic. The ions are Na^+ and $C_6H_5COO^-$. Na^+ is the cation of the strong base NaOH and does not react with water. The benzoate ion, $C_6H_5COO^-$, is from the weak acid benzoic acid, so it reacts with water to produce OH^- ion:

$$C_6H_5COO^-(aq) + H_2O(l) \rightleftharpoons C_6H_5COOH(aq) + OH^-(aq)$$

(c) Acidic. The ions are Cr^{3+} and Cl^-. Cl^- is the anion of the strong acid HCl, so it does not react with water. Cr^{3+} is a small metal ion with a high positive charge, so the hydrated ion, $Cr(H_2O)_6^{3+}$, reacts with water to produce H_3O^+:

$$Cr(H_2O)_6^{3+}(aq) + H_2O(l) \rightleftharpoons Cr(H_2O)_5OH^{2+}(aq) + H_3O^+(aq)$$

(d) Acidic. The ions are Na^+ and HSO_4^-. Na^+ is the cation of the strong base NaOH, so it does not react with water. HSO_4^- is the first anion of the diprotic acid H_2SO_4, and it reacts with water to produce H_3O^+:

$$HSO_4^-(aq) + H_2O(l) \rightleftharpoons SO_4^{2-}(aq) + H_3O^+(aq)$$

FOLLOW-UP PROBLEM 18.11 Write equations to predict whether solutions of the following salts are acidic, basic, or neutral: **(a)** $KClO_2$; **(b)** $CH_3NH_3NO_3$; **(c)** CsI.

Salts of Weakly Acidic Cations and Weakly Basic Anions

The only salts left to consider are those consisting of a cation that acts as a weak acid *and* an anion that acts as a weak base. In these cases, and there are quite a few, both ions react with water. It makes sense, then, that the overall acidity of the solution will depend on the relative acid strength or base strength of the separated ions, which can be determined by comparing their equilibrium constants.

For example, will an aqueous solution of ammonium hydrogen sulfide, NH_4HS, be acidic or basic? First, we write equations for any reactions that occur between the separated ions and water. Ammonium ion is the conjugate acid of a weak base, so it acts as a weak acid:

$$NH_4^+(aq) + H_2O(l) \rightleftharpoons NH_3(aq) + H_3O^+(aq)$$

Hydrogen sulfide ion is the anion of the weak acid H_2S, so it acts as a weak base:

$$HS^-(aq) + H_2O(l) \rightleftharpoons H_2S(aq) + OH^-(aq)$$

The reaction that goes farther to the right will have the greater influence on the pH of the solution, so we must compare the K_a of NH_4^+ with the K_b of HS^-. Recall that only molecular compounds are listed in K_a and K_b tables, so we have to calculate these values for the ions:

$$K_a \text{ of } NH_4^+ = \frac{K_w}{K_b \text{ of } NH_3} = \frac{1.0\times10^{-14}}{1.76\times10^{-5}} = 5.7\times10^{-10}$$

$$K_b \text{ of } HS^- = \frac{K_w}{K_{a1} \text{ of } H_2S} = \frac{1.0\times10^{-14}}{9\times10^{-8}} = 1\times10^{-7}$$

The difference in magnitude of the equilibrium constants ($K_b \approx 200K_a$) tells us that the acceptance of a proton from H_2O by HS^- proceeds further than the donation of a proton to H_2O by NH_4^+. In other words, because K_b of $HS^- > K_a$ of NH_4^+, the NH_4HS solution is basic.

SAMPLE PROBLEM 18.12 Predicting the Relative Acidity of a Salt Solution from K_a and K_b of the Ions

Problem Determine whether an aqueous solution of zinc formate, $Zn(HCOO)_2$, is acidic, basic, or neutral.

Plan The formula consists of the small, highly charged, and therefore weakly acidic, Zn^{2+} cation and the weakly basic $HCOO^-$ anion of the weak acid HCOOH. To determine the relative acidity of the solution, we write equations that show the reactions of the ions with water, and then find K_a of Zn^{2+} (from Appendix C) and calculate K_b of $HCOO^-$ (from K_a of HCOOH in Appendix C) to see which ion reacts to a greater extent.

Solution Writing the reactions with water:

$$Zn(H_2O)_6^{2+}(aq) + H_2O(l) \rightleftharpoons Zn(H_2O)_5OH^+(aq) + H_3O^+(aq)$$
$$HCOO^-(aq) + H_2O(l) \rightleftharpoons HCOOH(aq) + OH^-(aq)$$

Obtaining K_a and K_b of the ions: The K_a of $Zn(H_2O)_6^{2+}(aq)$ is 1×10^{-9}. We obtain K_a of HCOOH and solve for K_b of $HCOO^-$:

$$K_b \text{ of } HCOO^- = \frac{K_w}{K_a \text{ of HCOOH}} = \frac{1.0\times10^{-14}}{1.8\times10^{-4}} = 5.6\times10^{-11}$$

K_a of $Zn(H_2O)_6^{2+} > K_b$ of $HCOO^-$, so the solution is acidic.

FOLLOW-UP PROBLEM 18.12 Determine whether solutions of the following salts are acidic, basic, or neutral: **(a)** $Cu(CH_3COO)_2$; **(b)** NH_4F.

SECTION SUMMARY

Salts that yield a neutral solution consist of ions that do not react with water. Salts that yield an acidic solution contain an unreactive anion and a cation that releases a proton to water. Salts that yield a basic solution contain an unreactive cation and an anion that accepts a proton from water. If both cation and anion react with water, the ion that reacts to the greater extent (higher *K*) determines the acidity or basicity of the salt solution.

18.8 GENERALIZING THE BRØNSTED-LOWRY CONCEPT: THE LEVELING EFFECT

We conclude our focus on the Brønsted-Lowry concept with an important principle that holds for acid-base behavior in any solvent. Notice that, in H_2O, all Brønsted-Lowry acids yield H_3O^+ and all Brønsted-Lowry bases yield OH^-—the ions that form when the solvent autoionizes. In general, *an acid yields the cation and a base yields the anion of solvent autoionization.*

This idea lets us examine a question you may have been wondering about: why are all strong acids and strong bases *equally* strong in water? The answer is that *in water, the strongest acid possible is H_3O^+ and the strongest base possible is OH^-*. The moment we put some gaseous HCl in water, it reacts with the base H_2O and forms H_3O^+. The same holds for HNO_3, H_2SO_4, and any strong acid. All strong acids are equally strong in water because they dissociate *completely* to form H_3O^+. Given that the strong acid is no longer present, we are actually observing the acid strength of H_3O^+.

Similarly, strong bases, such as $Ba(OH)_2$, dissociate completely in water to yield OH^-. Even those that do not contain hydroxide ions in the solid, such as K_2O, do so. The oxide ion, which is a stronger base than OH^-, immediately takes a proton from water to form OH^-:

$$2K^+(aq) + O^{2-}(aq) + H_2O(l) \longrightarrow 2K^+(aq) + 2OH^-(aq)$$

No matter what species we try, any acid stronger than H_3O^+ simply donates its proton to H_2O, and any base stronger than OH^- accepts a proton from H_2O. Thus, water exerts a **leveling effect** on any strong acid or base by reacting with it to form the products of water's autoionization. Acting as a base, water levels the strength of all strong acids by making them appear equally strong, and acting as an acid, it levels the strength of all strong bases as well.

To rank strong acids in terms of relative strength, we must dissolve them in a solvent that is a *weaker* base than water, one that accepts their protons less readily. For example, you saw in Figure 18.11 that the hydrohalic acids increase in strength as the halogen becomes larger, as a result of the longer, weaker H—X bond. In water, HF is weaker than the other hydrogen halides, but HCl, HBr, and HI appear equally strong because water causes them to dissociate completely. When we dissolve them in pure acetic acid, however, *the acetic acid acts as the base* and accepts a proton from the acids:

$$\begin{aligned}
&\overset{\text{acid}}{HCl}(g) + \overset{\text{base}}{CH_3COOH}(l) \rightleftharpoons \overset{\text{base}}{Cl^-}(acet) + \overset{\text{acid}}{CH_3COOH_2^+}(acet)\\
&HBr(g) + CH_3COOH(l) \rightleftharpoons Br^-(acet) + CH_3COOH_2^+(acet)\\
&HI(g) + CH_3COOH(l) \rightleftharpoons I^-(acet) + CH_3COOH_2^+(acet)
\end{aligned}$$

[The use of (*acet*) instead of (*aq*) indicates solvation by CH_3COOH.] However, because acetic acid is a *weaker base* than water, the three acids protonate it to *different* extents. Measurements show that HI protonates the solvent to a greater extent than HBr, and HBr does so more than HCl; that is, in pure acetic acid, $K_{HI} > K_{HBr} > K_{HCl}$. Therefore, HCl is a weaker acid than HBr, which is weaker than HI. Similarly, the relative strength of strong bases is determined in a solvent that is a weaker acid than H_2O, such as liquid NH_3.

SECTION SUMMARY

Strong acids (or strong bases) dissociate completely to yield H_3O^+ (or OH^-) in water; in effect, water equalizes (levels) their strengths. Acids that are equally strong in water show differences in strength when dissolved in a solvent that is a weaker base than water, such as acetic acid.

18.9 ELECTRON-PAIR DONATION AND THE LEWIS ACID-BASE DEFINITION

The final acid-base concept we consider was developed by Gilbert N. Lewis, whose contribution to understanding the importance of valence electron pairs in molecular bonding we discussed in Chapter 9. Whereas the Brønsted-Lowry concept focuses on the proton in defining a species as an acid or a base, the Lewis concept highlights the role of the *electron pair*. The **Lewis acid-base definition** holds that

- A *base* is any species that *donates* an electron pair.
- An *acid* is any species that *accepts* an electron pair.

The Lewis definition, like the Brønsted-Lowry definition, requires that a base have an electron pair to donate, so it does not expand the classes of bases. However, *it greatly expands the classes of acids*. Many species, such as CO_2 and Cu^{2+}, that do not contain H in their formula (and thus cannot be Brønsted-Lowry acids)

function as Lewis acids by accepting an electron pair in their reactions. Lewis stated his objection to the proton as the defining feature of an acid this way: "To restrict the group of acids to those substances which contain hydrogen interferes as seriously with the systematic understanding of chemistry as would the restriction of the term oxidizing agent to those substances containing oxygen." Moreover, in the Lewis sense, the proton itself functions as an acid because it accepts the electron pair donated by a base:

$$B: + H^+ \rightleftharpoons B{-}H^+$$

Thus, *all Brønsted-Lowry acids donate H^+, a Lewis acid.*

The product of any Lewis acid-base reaction is called an **adduct,** *a single species that contains a* ***new*** *covalent bond:*

$$A + :B \rightleftharpoons A{-}B \text{ (adduct)}$$

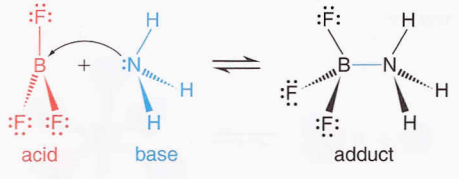
Thus, the Lewis concept radically broadens the idea of acid-base reactions. What to Arrhenius was the formation of H_2O from H^+ and OH^- became, to Brønsted and Lowry, the transfer of a proton from a stronger acid to a stronger base to form a weaker base and weaker acid. To Lewis, the same process became *the donation and acceptance of an electron pair to form a covalent bond in an adduct.*

As we've seen, the key feature of a *Lewis base is a lone pair of electrons to donate.* The key feature of a *Lewis acid is a vacant orbital* (or the ability to rearrange its bonds to form one) to accept that lone pair and form a new bond. There are a variety of neutral molecules and positively charged ions that satisfy this requirement.

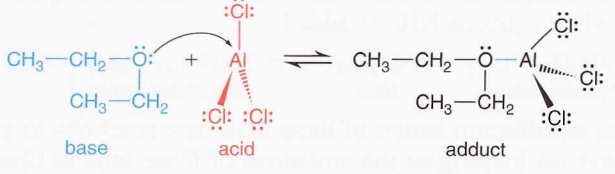
Molecules as Lewis Acids

Many neutral molecules function as Lewis acids. In every case, the atom that accepts the electron pair is low in electron density because of either an electron deficiency or a polar multiple bond.

Lewis Acids with Electron-Deficient Atoms Some molecular Lewis acids contain a central atom that is *electron deficient,* one surrounded by fewer than eight valence electrons. The most important are covalent compounds of the Group 3A(13) elements boron and aluminum. As noted in Chapters 10 and 14, these compounds react vigorously to complete their octet. For example, boron trifluoride accepts an electron pair from ammonia to form a covalent bond in a gaseous Lewis acid-base reaction:



Unexpected solubility behavior is sometimes due to adduct formation. Aluminum chloride, for instance, dissolves freely in relatively nonpolar diethyl ether because of a Lewis acid-base reaction, in which the ether's O atom donates an electron pair to Al to form a covalent bond:



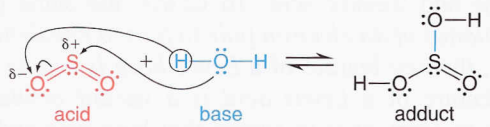
This acidic behavior of boron and aluminum halides is put to use in many organic syntheses. For example, toluene, an important solvent and organic reagent, can be made by the action of CH_3Cl on benzene in the presence of $AlCl_3$. The

Lewis acid $AlCl_3$ abstracts the Lewis base Cl^- from CH_3Cl to form an adduct that has a reactive CH_3^+ group, which attacks the benzene ring:

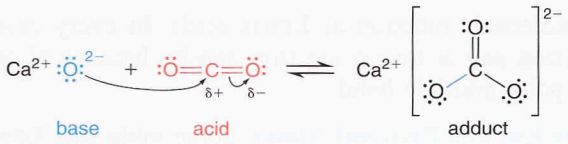
$$\underset{\text{base}}{CH_3Cl} + \underset{\text{acid}}{AlCl_3} \rightleftharpoons \underset{\text{adduct}}{[CH_3]^+[Cl{-}AlCl_3]^-}$$

$$\underset{\text{benzene}}{C_6H_6} + [CH_3]^+[Cl{-}AlCl_3]^- \rightleftharpoons \underset{\text{toluene}}{C_6H_5CH_3} + AlCl_3 + HCl$$

Lewis Acids with Polar Multiple Bonds Molecules that contain a polar double bond also function as Lewis acids. As the electron pair on the Lewis base approaches the partially positive end of the double bond, one of the bonds breaks to form the new bond in the adduct. For example, consider the reaction that occurs when SO_2 dissolves in water. The electronegative O atoms in SO_2 withdraw electron density from the central S, so it is partially positive. The O atom of water donates a lone pair to the S, breaking one of the π bonds and forming an S—O bond, and a proton is transferred from water to that O. The resulting adduct is sulfurous acid, and the overall process is

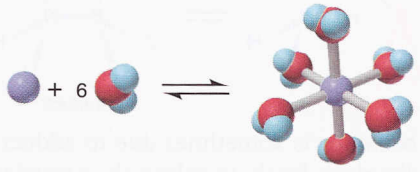


The formation of carbonates from a metal oxide and carbon dioxide is an analogous reaction that occurs in a nonaqueous heterogeneous system. The O^{2-} ion (shown below from CaO) donates an electron pair to the partially positive C in CO_2, a π bond breaks, and the CO_3^{2-} ion forms as the adduct:



Metal Cations as Lewis Acids

Earlier we saw that certain hydrated metal ions act as Brønsted-Lowry acids. In the Lewis sense, the hydration process itself is an acid-base reaction. The hydrated cation is the adduct, as lone electron pairs on the O atoms of water form covalent bonds to the positively charged ion; thus, *any metal ion acts as a Lewis acid when it dissolves in water:*



Ammonia is a stronger Lewis base than water because it displaces H_2O from a hydrated ion when aqueous NH_3 is added:

$$\underset{\text{hydrated adduct}}{Ni(H_2O)_6^{2+}(aq)} + \underset{\text{base}}{6NH_3(aq)} \rightleftharpoons \underset{\text{ammoniated adduct}}{Ni(NH_3)_6^{2+}(aq)} + 6H_2O(l)$$

We discuss the equilibrium nature of these acid-base reactions in greater detail in Chapter 19, and we investigate the structures of these ions in Chapter 23.

Many biomolecules are Lewis adducts with central metal ions. Most often, O and N atoms of organic groups, with their lone pairs, serve as the Lewis bases.

Chlorophyll is a Lewis adduct of a central Mg^{2+} ion and the four N atoms of an organic tetrapyrrole ring system (Figure 18.14). Vitamin B_{12} has a similar structure with a central Co^{3+}, and so does heme, but with a central Fe^{2+}. Several other metal ions, such as Zn^{2+}, Mo^{2+}, and Cu^{2+}, are bound at the active sites of enzymes and function as Lewis acids in the catalytic action.

SAMPLE PROBLEM 18.13 Identifying Lewis Acids and Bases

Problem Identify the Lewis acids and Lewis bases in the following reactions:

(a) $H^+ + OH^- \rightleftharpoons H_2O$

(b) $Cl^- + BCl_3 \rightleftharpoons BCl_4^-$

(c) $K^+ + 6H_2O \rightleftharpoons K(H_2O)_6^+$

Plan We examine the formulas to see which species accepts the electron pair (Lewis acid) and which donates it (Lewis base) in forming the adduct.

Solution **(a)** The H^+ ion accepts an electron pair from the OH^- ion in forming a bond. H^+ is the acid and OH^- is the base.

(b) The Cl^- ion has four lone pairs and uses one to form a new bond to the central B. Therefore, BCl_3 is the acid and Cl^- is the base.

(c) The K^+ ion does not have any valence electrons to provide, so the bond is formed when electron pairs from O atoms of water enter empty orbitals on K^+. Thus, K^+ is the acid and H_2O is the base.

Check The Lewis acids (H^+, BCl_3, and K^+) each have an unfilled valence shell that can accept an electron pair from the Lewis bases (OH^-, Cl^-, and H_2O).

FOLLOW-UP PROBLEM 18.13 Identify the Lewis acids and Lewis bases in the following reactions:

(a) $OH^- + Al(OH)_3 \rightleftharpoons Al(OH)_4^-$

(b) $SO_3 + H_2O \rightleftharpoons H_2SO_4$

(c) $Co^{3+} + 6NH_3 \rightleftharpoons Co(NH_3)_6^{3+}$

An Overview of Acid-Base Definitions

By looking closely at the essential chemical change involved, chemists can see a common theme in reactions as diverse as a standardized base being used to analyze an unknown fatty acid, baking soda being used in breadmaking, and even oxygen binding to hemoglobin in a blood cell. From this wider perspective, the diversity of acid-base reactions takes on more unity. Let's stand back and survey the scope of the three acid-base definitions and see how they fit together.

The *classical (Arrhenius) definition,* which was the first attempt at describing acids and bases on the molecular level, is the most limited and narrow of the three definitions. It applies only to species whose structures include an H atom or an OH group that is released as an ion when the species dissolves in water. Because relatively few species have these prerequisites, Arrhenius acid-base reactions are relatively few in number, and all such reactions result in the formation of H_2O.

The *Brønsted-Lowry definition* is more general, seeing acid-base reactions as proton-transfer processes and eliminating the requirement that they occur in water. Whereas a Brønsted-Lowry acid, like an Arrhenius acid, still must have an H, a Brønsted-Lowry base is defined as any species with an electron pair available to accept a transferred proton. This definition includes a great many more species as bases. Furthermore, it defines the acid-base reaction in terms of conjugate acid-base pairs, with an acid and a base on both sides of the reaction. The system reaches an equilibrium state based on the relative strengths of the acid, the base, and their conjugates.

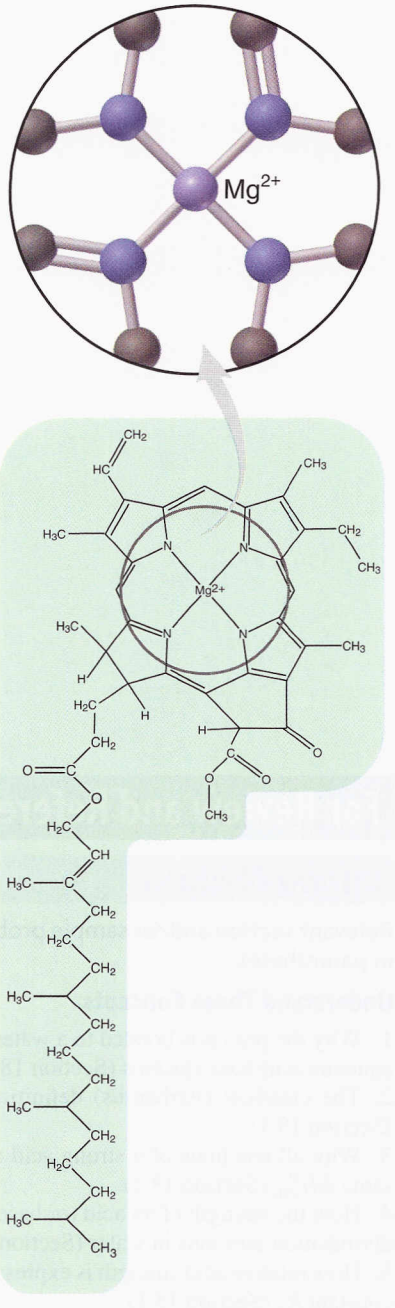


Figure 18.14 The Mg^{2+} ion as a Lewis acid in the chlorophyll molecule. Many biomolecules contain metal ions that act as Lewis acids. In chlorophyll, Mg^{2+} accepts electron pairs from surrounding N atoms that are part of the large organic portion of the molecule.

The *Lewis definition* has the widest scope of the three. The defining event of a Lewis acid-base reaction is the donation and acceptance of an electron pair to form a new covalent bond. Lewis bases still must have an electron pair to donate, but Lewis acids—as electron-pair acceptors—include many species not encompassed by the other two definitions, including molecules with electron-deficient atoms or with polar double bonds, metal ions, and the proton itself.

SECTION SUMMARY

The Lewis acid-base definition focuses on the donation or acceptance of an electron pair to form a new covalent bond in an adduct, the product of an acid-base reaction. Lewis bases donate the electron pair, and Lewis acids accept it. Thus, many species that do not contain H are Lewis acids. Molecules with polar double bonds act as Lewis acids, as do those with electron-deficient atoms. Metal ions act as Lewis acids when they dissolve in water, which acts as a Lewis base, to form the adduct, a hydrated cation. Many metal ions function as Lewis acids in biomolecules.

Chapter Perspective

In this chapter, we extended the principles of equilibrium to acids and bases. We also investigated one direction in which the science of chemistry matured, as narrow definitions of acids and bases progressively widened to encompass different species, physical states, solvent systems, and reaction types. Acids and bases, by whatever definition, are an extremely important group of substances. In Chapter 19, we continue our discussion of acid-base behavior and apply many of the ideas developed here to other aqueous equilibria.

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. Why the proton is bonded to a water molecule, as H_3O^+, in all aqueous acid-base systems (Section 18.1)
2. The classical (Arrhenius) definitions of an acid and a base (Section 18.1)
3. Why all reactions of a strong acid and a strong base have the same ΔH^0_{rxn} (Section 18.1)
4. How the strength of an acid (or base) relates to the extent of its dissociation into ions in water (Section 18.1)
5. How relative acid strength is expressed by the acid-dissociation constant K_a (Section 18.1)
6. Why water is a very weak electrolyte and how its autoionization is expressed by K_w (Section 18.2)
7. Why $[H_3O^+]$ is inversely related to $[OH^-]$ in any aqueous solution (Section 18.2)
8. How the relative magnitudes of $[H_3O^+]$ and $[OH^-]$ define whether a solution is acidic, basic, or neutral (Section 18.2)
9. The Brønsted-Lowry definitions of an acid and a base and how an acid-base reaction can be viewed as a proton-transfer process (Section 18.3)
10. How water acts as a base (or as an acid) when an acid (or a base) dissolves in it (Section 18.3)
11. How a conjugate acid-base pair differs by one proton (Section 18.3)
12. How a Brønsted-Lowry acid-base reaction involves two conjugate acid-base pairs (Section 18.3)
13. Why a stronger acid and base react ($K_c > 1$) to form a weaker base and acid (Section 18.3)
14. How percent dissociation of a weak acid increases as its concentration decreases (Section 18.4)
15. How a polyprotic acid dissociates in two or more steps and why only the first step supplies significant $[H_3O^+]$ (Section 18.4)
16. How weak bases in water accept a proton rather than dissociate; the meaning of K_b and pK_b (Section 18.5)
17. How ammonia, amines, and weak-acid anions act as weak bases in water (Section 18.5)
18. Why relative concentrations of HA and A^- determine the acidity or basicity of their solution (Section 18.5)
19. The relationship of the K_a and K_b of a conjugate acid-base pair to K_w (Section 18.5)
20. The effects of electronegativity, bond polarity, and bond strength on acid strength (Section 18.6)
21. Why aqueous solutions of small, highly charged metal ions are acidic (Section 18.6)
22. The various combinations of cations and anions that lead to acidic, basic, or neutral salt solutions (Section 18.7)
23. Why the strengths of strong acids are leveled in water but differentiated in a less basic solvent (Section 18.8)
24. The Lewis definitions of an acid and a base and how a Lewis acid-base reaction involves the donation and acceptance of an electron pair to form a covalent bond (Section 18.9)
25. How molecules with electron-deficient atoms or polar multiple bonds and metal cations act as Lewis acids (Section 18.9)

Master These Skills

1. Classifying strong and weak acids and bases from their formulas (SP 18.1)
2. Using K_w to calculate $[H_3O^+]$ and $[OH^-]$ in an aqueous solution (SP 18.2)
3. Using p-scales to express $[H_3O^+]$, $[OH^-]$, and K (Section 18.2)
4. Calculating $[H_3O^+]$, pH, $[OH^-]$, and pOH (SP 18.3)
5. Identifying conjugate acid-base pairs (SP 18.4)
6. Using relative acid strengths to predict the net direction of an acid-base reaction (SP 18.5)
7. Calculating K_a of a weak acid from pH (SP 18.6)
8. Calculating $[H_3O^+]$ (and, thus, pH) from K_a and $[HA]_{init}$ (SP 18.7)
9. Applying the quadratic equation to find a concentration (Follow-up Problem 18.7)
10. Calculating the percent dissociation of a weak acid (Section 18.4)
11. Calculating $[H_3O^+]$ and other concentrations for a polyprotic acid (SP 18.8)
12. Calculating pH from K_b and $[B]_{init}$ (SP 18.9)
13. Finding K_b of A^- from K_a of HA and K_w (Section 18.5 and SP 18.10)
14. Calculating pH from K_b of A^- and $[A^-]_{init}$ (SP 18.10)
15. Predicting relative acid strengths of nonmetal hydrides and oxoacids (Section 18.6)
16. Predicting the relative acidity of a salt solution from the nature of the cation and anion (SPs 18.11 and 18.12)
17. Identifying Lewis acids and bases (SP 18.13)

Key Equations and Relationships

18.1 Defining the acid-dissociation constant (770):

$$K_a = \frac{[H_3O^+][A^-]}{[HA]}$$

18.2 Defining the ion-product constant for water (773):

$$K_w = [H_3O^+][OH^-] = 1.0\times10^{-14} \text{ (at 25°C)}$$

18.3 Defining pH (775):

$$pH = -\log [H_3O^+]$$

18.4 Relating pK_w to pH and pOH (776):

$$pK_w = pH + pOH = 14.00 \text{ (at 25°C)}$$

18.5 Finding the percent dissociation of HA (785):

$$\text{Percent HA dissociated} = \frac{[HA]_{dissoc}}{[HA]_{init}} \times 100$$

18.6 Defining the base-dissociation constant (788):

$$K_b = \frac{[BH^+][OH^-]}{[B]}$$

18.7 Expressing the relationship among K_a, K_b, and K_w (792):

$$K_a \times K_b = K_w$$

Highlighted Figures and Tables

Brief Solutions to Follow-up Problems

18.1 (a) $HClO_3$; (b) HCl; (c) NaOH

18.2 $[H_3O^+] = \dfrac{1.0\times10^{-14}}{6.7\times10^{-2}} = 1.5\times10^{-13}\ M$; basic

18.3 pOH = 14.00 − 9.52 = 4.48

$[H_3O^+] = 10^{-9.52} = 3.0\times10^{-10}\ M$

$[OH^-] = \dfrac{1.0\times10^{-14}}{3.0\times10^{-10}} = 3.3\times10^{-5}\ M$

18.4 (a) CH_3COOH/CH_3COO^- and H_3O^+/H_2O

(b) H_2O/OH^- and HF/F^-

18.5 (a) $NH_3(g) + H_2O(l) \rightleftharpoons NH_4^+(aq) + OH^-(aq)$

(b) $NH_3(g) + H_3O^+(aq;\ \text{from HCl}) \longrightarrow NH_4^+(aq) + H_2O(l)$

(c) $NH_4^+(aq) + OH^-(aq;\ \text{from NaOH}) \longrightarrow NH_3(g) + H_2O(l)$

18.6 $NH_4^+(aq) + H_2O(l) \rightleftharpoons NH_3(aq) + H_3O^+(aq)$

$[H_3O^+] = 10^{-\text{pH}} = 10^{-5.0} = 1\times10^{-5}\ M = [NH_3]$

From reaction table, $K_a = \dfrac{[NH_3][H_3O^+]}{[NH_4^+]} = \dfrac{(x)(x)}{0.2 - x}$

$\approx \dfrac{(1\times10^{-5})^2}{0.2} = 5\times10^{-10}$

18.7 $K_a = \dfrac{[H_3O^+][OCN^-]}{[HOCN]} = \dfrac{(x)(x)}{0.10 - x} = 3.5\times10^{-4}$

Since $\dfrac{[HOCN]_{init}}{K_a} = \dfrac{0.10}{3.5\times10^{-4}} = 286 < 400$, you must solve a quadratic equation: $x^2 + (3.5\times10^{-4})x - (3.5\times10^{-5}) = 0$

$x = [H_3O^+] = 5.7\times10^{-3}\ M$; pH = 2.24

18.8 $K_{a1} = \dfrac{[HC_2O_4^-][H_3O^+]}{[H_2C_2O_4]} = \dfrac{x^2}{0.150 - x} = 5.6\times10^{-2}$

Since $\dfrac{[H_2C_2O_4]_{init}}{K_{a1}} < 400$, you must solve a quadratic equation:

$x^2 + (5.6\times10^{-2})x - (8.4\times10^{-3}) = 0$

$x = [H_3O^+] = 0.068\ M$; pH = 1.17

$x = [HC_2O_4^-] = 0.068\ M$; $[H_2C_2O_4] = 0.150\ M - x = 0.082\ M$

$[C_2O_4^{2-}] = \dfrac{(K_{a2})[HC_2O_4^-]}{[H_3O^+]} = \dfrac{(5.4\times10^{-5})(0.068)}{0.068}$

$= 5.4\times10^{-5}\ M$

18.9 $K_b = \dfrac{[C_5H_5NH^+][OH^-]}{[C_5H_5N]} = 10^{-8.77} = 1.7\times10^{-9}$

Assuming $0.10\ M - x \approx 0.10\ M$, $K_b = 1.7\times10^{-9} \approx \dfrac{(x)(x)}{0.10}$;

$x = [OH^-] \approx 1.3\times10^{-5}\ M$; $[H_3O^+] = 7.7\times10^{-10}\ M$;

pH = 9.11

18.10 $K_b \text{ of } ClO^- = \dfrac{K_w}{K_a \text{ of HClO}} = \dfrac{1.0\times10^{-14}}{2.9\times10^{-8}} = 3.4\times10^{-7}$

Assuming $0.20\ M - x \approx 0.20\ M$,

$K_b = 3.4\times10^{-7} = \dfrac{[HClO][OH^-]}{[ClO^-]} \approx \dfrac{x^2}{0.20}$;

$x = [OH^-] \approx 2.6\times10^{-4}\ M$; $[H_3O^+] = 3.8\times10^{-11}\ M$;

pH = 10.42

18.11 (a) Basic:

$ClO_2^-(aq) + H_2O(l) \rightleftharpoons HClO_2(aq) + OH^-(aq)$

K^+ is from strong base KOH.

(b) Acidic:

$CH_3NH_3^+(aq) + H_2O(l) \rightleftharpoons CH_3NH_2(aq) + H_3O^+(aq)$

NO_3^- is from strong acid HNO_3.

(c) Neutral: Cs^+ is from strong base CsOH; I^- is from strong acid HI.

18.12 (a) $K_a \text{ of } Cu(H_2O)_6^{2+} = 3\times10^{-8}$

$K_b \text{ of } CH_3COO^- = \dfrac{K_w}{K_a \text{ of } CH_3COOH} = 5.6\times10^{-10}$

Since $K_a > K_b$, $Cu(CH_3COO)_2(aq)$ is acidic.

(b) $K_a \text{ of } NH_4^+ = \dfrac{K_w}{K_b \text{ of } NH_3} = 5.7\times10^{-10}$

$K_b \text{ of } F^- = \dfrac{K_w}{K_a \text{ of HF}} = 1.5\times10^{-11}$

Since $K_a > K_b$, $NH_4F(aq)$ is acidic.

18.13 (a) OH^- is the Lewis base; $Al(OH)_3$ is the Lewis acid.

(b) H_2O is the Lewis base; SO_3 is the Lewis acid.

(c) NH_3 is the Lewis base; Co^{3+} is the Lewis acid.

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

Note: Unless stated otherwise, all problems refer to aqueous solutions at 298 K (25°C).

Acids and Bases in Water

(Sample Problem 18.1)

Concept Review Questions

18.1 Describe the role of water according to the classical (Arrhenius) acid-base definition.

18.2 What characteristics do all Arrhenius acids have in common? What characteristics do all Arrhenius bases have in common? Explain neutralization in terms of the Arrhenius acid-base definition. What quantitative finding led Arrhenius to propose this idea of neutralization?

18.3 Why is the Arrhenius acid-base definition considered too limited? Give an example of a case in which the Arrhenius definition does not apply.

18.4 What is meant by the words "strong" and "weak" in terms of acids and bases? Weak acids have K_a values that vary over more than 10 orders of magnitude. What do they have in common that classifies them as "weak"?

Skill-Building Exercises *(grouped in similar pairs)*

18.5 Which of the following are Arrhenius acids?

(a) H_2O (b) $Ca(OH)_2$ (c) H_3PO_3 (d) HI

18.6 Which of the following are Arrhenius acids?

(a) $NaHSO_4$ (b) CH_4 (c) NaH (d) H_3N

18.7 Which of the following are Arrhenius bases?

(a) H_3AsO_4 (b) $Ba(OH)_2$ (c) HClO (d) KOH

18.8 Which of the following are Arrhenius bases?
(a) CH_3COOH (b) HOH (c) CH_3OH (d) H_2NNH_2

18.9 Write the K_a expression for each of the following in water:
(a) HCN (b) HCO_3^- (c) HCOOH

18.10 Write the K_a expression for each of the following in water:
(a) $CH_3NH_3^+$ (b) HClO (c) H_2S

18.11 Write the K_a expression for each of the following in water:
(a) HNO_2 (b) CH_3COOH (c) $HBrO_2$

18.12 Write the K_a expression for each of the following in water:
(a) $H_2PO_4^-$ (b) H_3PO_2 (c) HSO_4^-

18.13 Use Appendix C to rank the following in order of *increasing* acid strength: HIO_3, HI, CH_3COOH, HF.

18.14 Use Appendix C to rank the following in order of *decreasing* acid strength: HClO, HCl, HCN, HNO_2.

18.15 Classify each as a strong or weak acid or base:
(a) H_3AsO_4 (b) $Sr(OH)_2$ (c) HIO (d) $HClO_4$

18.16 Classify each as a strong or weak acid or base:
(a) CH_3NH_2 (b) K_2O (c) HI (d) HCOOH

18.17 Classify each as a strong or weak acid or base:
(a) RbOH (b) HBr (c) H_2Te (d) HClO

18.18 Classify each as a strong or weak acid or base:
(a) $HOCH_2CH_2NH_2$ (b) H_2SeO_4 (c) HS^- (d) $B(OH)_3$

Autoionization of Water and the pH Scale

(Sample Problems 18.2 and 18.3)

Concept Review Questions

18.19 What is an autoionization reaction? Write equations for the autoionization reactions of H_2O and of H_2SO_4.

18.20 What is the difference between K_c and K_w for the autoionization of water?

18.21 (a) What is the change in pH when $[OH^-]$ increases by a factor of 10?
(b) What is the change in $[H_3O^+]$ when the pH decreases by 2 units?

18.22 Which solution has the higher pH? Explain.
(a) A 0.1 *M* solution of an acid with $K_a = 1\times10^{-4}$ or one with $K_a = 4\times10^{-5}$
(b) A 0.1 *M* solution of an acid with $pK_a = 3.0$ or one with $pK_a = 3.5$
(c) A 0.1 *M* solution of a weak acid or a 0.01 *M* solution of the same acid
(d) A 0.1 *M* solution of a weak acid or a 0.1 *M* solution of a strong acid
(e) A 0.1 *M* solution of an acid or a 0.1 *M* solution of a base
(f) A solution of pOH 6.0 or one of pOH 8.0

Skill-Building Exercises *(grouped in similar pairs)*

18.23 (a) What is the pH of 0.0111 *M* NaOH? Is the solution neutral, acidic, or basic?
(b) What is the pOH of 1.23×10^{-3} *M* HCl? Is the solution neutral, acidic, or basic?

18.24 (a) What is the pH of 0.0333 *M* HNO_3? Is the solution neutral, acidic, or basic?
(b) What is the pOH of 0.0347 *M* KOH? Is the solution neutral, acidic, or basic?

18.25 (a) What is the pH of 5.04×10^{-3} *M* HI? Is the solution neutral, acidic, or basic?
(b) What is the pOH of 2.55 *M* $Ba(OH)_2$? Is the solution neutral, acidic, or basic?

18.26 (a) What is the pH of 7.52×10^{-4} *M* CsOH? Is the solution neutral, acidic, or basic?
(b) What is the pOH of 1.59×10^{-3} *M* $HClO_4$? Is the solution neutral, acidic, or basic?

18.27 (a) What are $[H_3O^+]$, $[OH^-]$, and pOH in a solution with a pH of 9.78?
(b) What are $[H_3O^+]$, $[OH^-]$, and pH in a solution with a pOH of 10.43?

18.28 (a) What are $[H_3O^+]$, $[OH^-]$, and pOH in a solution with a pH of 3.47?
(b) What are $[H_3O^+]$, $[OH^-]$, and pH in a solution with a pOH of 4.33?

18.29 (a) What are $[H_3O^+]$, $[OH^-]$, and pOH in a solution with a pH of 2.77?
(b) What are $[H_3O^+]$, $[OH^-]$, and pH in a solution with a pOH of 5.18?

18.30 (a) What are $[H_3O^+]$, $[OH^-]$, and pOH in a solution with a pH of 8.97?
(b) What are $[H_3O^+]$, $[OH^-]$, and pH in a solution with a pOH of 11.27?

18.31 How many moles of H_3O^+ or OH^- must you add per liter of HA solution to adjust its pH from 3.25 to 3.65? Assume a negligible volume change.

18.32 How many moles of H_3O^+ or OH^- must you add per liter of HA solution to adjust its pH from 9.33 to 9.07? Assume a negligible volume change.

18.33 How many moles of H_3O^+ or OH^- must you add to 6.5 L of HA solution to adjust its pH from 4.82 to 5.22? Assume a negligible volume change.

18.34 How many moles of H_3O^+ or OH^- must you add to 87.5 mL of HA solution to adjust its pH from 8.92 to 6.33? Assume a negligible volume change.

Problems in Context

18.35 Although the text asserts that water is an extremely weak electrolyte, parents commonly warn their children of the danger of swimming in a pool or lake during a lightning storm. Explain.

18.36 Like any equilibrium constant, K_w changes with temperature.
(a) Given that autoionization is an endothermic process, does K_w increase or decrease with rising temperature? Explain with a reaction that includes heat as reactant or product.
(b) In many medical applications, the value of K_w at 37°C (body temperature) may be more appropriate than the value at 25°C, 1.0×10^{-14}. The pH of pure water at 37°C is 6.80. Calculate K_w, pOH, and $[OH^-]$ at this temperature.

Proton Transfer and the Brønsted-Lowry Acid-Base Definition

(Sample Problems 18.4 and 18.5)

Concept Review Questions

18.37 How do the Arrhenius and Brønsted-Lowry definitions of an acid and a base differ? How are they similar? Name two Brønsted-Lowry bases that are not considered Arrhenius bases. Can you do the same for acids? Explain.

18.38 What is a conjugate acid-base pair? What is the relationship between the two members of the pair?

18.39 A Brønsted-Lowry acid-base reaction proceeds in the net direction in which a stronger acid and stronger base form a weaker acid and weaker base. Explain.

18.40 What is an amphoteric species? Name one and write balanced equations that show why it is amphoteric.

Skill-Building Exercises *(grouped in similar pairs)*

18.41 Write balanced equations and K_a expressions for these Brønsted-Lowry acids in water:
(a) H_3PO_4 (b) C_6H_5COOH (c) HSO_4^-

18.42 Write balanced equations and K_a expressions for these Brønsted-Lowry acids in water:
(a) HCOOH (b) $HClO_3$ (c) $H_2AsO_4^-$

18.43 Give the formula of the conjugate base:
(a) HCl (b) H_2CO_3 (c) H_2O

18.44 Give the formula of the conjugate base:
(a) HPO_4^{2-} (b) NH_4^+ (c) HS^-

18.45 Give the formula of the conjugate acid:
(a) NH_3 (b) NH_2^- (c) nicotine, $C_{10}H_{14}N_2$

18.46 Give the formula of the conjugate acid:
(a) O^{2-} (b) SO_4^{2-} (c) H_2O

18.47 In each equation, label the acids, bases, and conjugate acid-base pairs:
(a) $HCl + H_2O \rightleftharpoons Cl^- + H_3O^+$
(b) $HClO_4 + H_2SO_4 \rightleftharpoons ClO_4^- + H_3SO_4^+$
(c) $HPO_4^{2-} + H_2SO_4 \rightleftharpoons H_2PO_4^- + HSO_4^-$

18.48 In each equation, label the acids, bases, and conjugate acid-base pairs:
(a) $NH_3 + HNO_3 \rightleftharpoons NH_4^+ + NO_3^-$
(b) $O^{2-} + H_2O \rightleftharpoons OH^- + OH^-$
(c) $NH_4^+ + BrO_3^- \rightleftharpoons NH_3 + HBrO_3$

18.49 In each equation, label the acids, bases, and conjugate acid-base pairs:
(a) $NH_3 + H_3PO_4 \rightleftharpoons NH_4^+ + H_2PO_4^-$
(b) $CH_3O^- + NH_3 \rightleftharpoons CH_3OH + NH_2^-$
(c) $HPO_4^{2-} + HSO_4^- \rightleftharpoons H_2PO_4^- + SO_4^{2-}$

18.50 In each equation, label the acids, bases, and conjugate acid-base pairs:
(a) $NH_4^+ + CN^- \rightleftharpoons NH_3 + HCN$
(b) $H_2O + HS^- \rightleftharpoons OH^- + H_2S$
(c) $HSO_3^- + CH_3NH_2 \rightleftharpoons SO_3^{2-} + CH_3NH_3^+$

18.51 Write balanced net ionic equations for the following reactions, and label the conjugate acid-base pairs:
(a) $NaOH(aq) + NaH_2PO_4(aq) \rightleftharpoons H_2O(l) + Na_2HPO_4(aq)$
(b) $KHSO_4(aq) + K_2CO_3(aq) \rightleftharpoons K_2SO_4(aq) + KHCO_3(aq)$

18.52 Write balanced net ionic equations for the following reactions, and label the conjugate acid-base pairs:
(a) $HNO_3(aq) + Li_2CO_3(aq) \rightleftharpoons LiNO_3(aq) + LiHCO_3(aq)$
(b) $2NH_4Cl(aq) + Ba(OH)_2(aq) \rightleftharpoons 2H_2O(l) + BaCl_2(aq) + 2NH_3(aq)$

18.53 The following aqueous species constitute two conjugate acid-base pairs. Use them to write one acid-base reaction with $K_c > 1$ and another with $K_c < 1$: HS^-, Cl^-, HCl, H_2S.

18.54 The following aqueous species constitute two conjugate acid-base pairs. Use them to write one acid-base reaction with $K_c > 1$ and another with $K_c < 1$: NO_3^-, F^-, HF, HNO_3.

18.55 Use Figure 18.9 (p. 781) to determine whether $K_c > 1$ for
(a) $HCl + NH_3 \rightleftharpoons NH_4^+ + Cl^-$
(b) $H_2SO_3 + NH_3 \rightleftharpoons HSO_3^- + NH_4^+$

18.56 Use Figure 18.9 (p. 781) to determine whether $K_c > 1$ for
(a) $OH^- + HS^- \rightleftharpoons H_2O + S^{2-}$
(b) $HCN + HCO_3^- \rightleftharpoons H_2CO_3 + CN^-$

18.57 Use Figure 18.9 (p. 781) to determine whether $K_c < 1$ for
(a) $NH_4^+ + HPO_4^{2-} \rightleftharpoons NH_3 + H_2PO_4^-$
(b) $HSO_3^- + HS^- \rightleftharpoons H_2SO_3 + S^{2-}$

18.58 Use Figure 18.9 (p. 781) to determine whether $K_c < 1$ for
(a) $H_2PO_4^- + F^- \rightleftharpoons HPO_4^{2-} + HF$
(b) $CH_3COO^- + HSO_4^- \rightleftharpoons CH_3COOH + SO_4^{2-}$

Solving Problems Involving Weak-Acid Equilibria

(Sample Problems 18.6 to 18.8)

Concept Review Questions

18.59 In each of the following cases, would you expect the concentration of acid before and after dissociation to be nearly the same or very different? Explain your reasoning.
(a) A concentrated solution of a strong acid
(b) A concentrated solution of a weak acid
(c) A dilute solution of a weak acid
(d) A dilute solution of a strong acid

18.60 A sample of 0.0001 *M* HCl has $[H_3O^+]$ close to that of a sample of 0.1 *M* CH_3COOH. Are acetic acid and hydrochloric acid equally strong in these samples? Explain.

18.61 In which of the following solutions will $[H_3O^+]$ be approximately equal to $[CH_3COO^-]$: (a) 0.1 *M* CH_3COOH; (b) 1×10^{-7} *M* CH_3COOH; (c) a solution containing both 0.1 *M* CH_3COOH and 0.1 *M* CH_3COONa? Explain.

18.62 Why do successive K_a's decrease for all polyprotic acids?

Skill-Building Exercises *(grouped in similar pairs)*

18.63 A 0.15 *M* solution of butanoic acid, $CH_3CH_2CH_2COOH$, contains 1.51×10^{-3} *M* H_3O^+. What is the K_a of butanoic acid?

18.64 A 0.035 *M* solution of a weak acid (HA) has a pH of 4.88. What is the K_a of the acid?

18.65 Nitrous acid, HNO_2, has a K_a of 7.1×10^{-4}. What are $[H_3O^+]$, $[NO_2^-]$, and $[OH^-]$ in 0.50 *M* HNO_2?

18.66 Hydrofluoric acid, HF, has a K_a of 6.8×10^{-4}. What are $[H_3O^+]$, $[F^-]$, and $[OH^-]$ in 0.75 *M* HF?

18.67 Chloroacetic acid, $ClCH_2COOH$, has a pK_a of 2.87. What are $[H_3O^+]$, pH, $[ClCH_2COO^-]$, and $[ClCH_2COOH]$ in 1.05 *M* $ClCH_2COOH$?

18.68 Hypochlorous acid, HClO, has a pK_a of 7.54. What are $[H_3O^+]$, pH, $[ClO^-]$, and [HClO] in 0.115 *M* HClO?

18.69 In a 0.25 *M* solution, a weak acid is 3.0% dissociated.
(a) Calculate the $[H_3O^+]$, pH, $[OH^-]$, and pOH of the solution.
(b) Calculate K_a of the acid.

18.70 In a 0.735 *M* solution, a weak acid is 12.5% dissociated.
(a) Calculate the $[H_3O^+]$, pH, $[OH^-]$, and pOH of the solution.
(b) Calculate K_a of the acid.

18.71 A 0.250-mol sample of HX is dissolved in enough H_2O to form 655 mL of solution. If the pH of the solution is 3.44, what is the K_a of HX?

18.72 A 4.85×10^{-3}-mol sample of HY is dissolved in enough H_2O to form 0.095 L of solution. If the pH of the solution is 2.68, what is the K_a of HY?

18.73 The weak acid HZ has a K_a of 1.55×10^{-4}.
(a) Calculate the pH of 0.075 *M* HZ.
(b) Calculate the pOH of 0.045 *M* HZ.

18.74 The weak acid HQ has a pK_a of 4.89.
(a) Calculate the $[H_3O^+]$ of 3.5×10^{-2} *M* HQ.
(b) Calculate the $[OH^-]$ of 0.65 *M* HQ.

18.75 (a) Calculate the pH of 0.175 *M* HY, if $K_a = 1.00\times10^{-4}$.
(b) Calculate the pOH of 0.175 *M* HX, if $K_a = 1.00\times10^{-2}$.

18.76 (a) Calculate the pH of 0.553 *M* $KHCO_3$; K_a of $HCO_3^- = 4.7\times10^{-11}$.
(b) Calculate the pOH of 0.044 *M* HIO_3; K_a of $HIO_3 = 0.16$.

18.77 Use Appendix C to calculate the percent dissociation of 0.25 *M* benzoic acid, C_6H_5COOH.

18.78 Use Appendix C to calculate the percent dissociation of 0.050 *M* CH_3COOH.

18.79 Use Appendix C to calculate $[H_2S]$, $[HS^-]$, $[S^{2-}]$, $[H_3O^+]$, pH, $[OH^-]$, and pOH in a 0.10 *M* solution of the diprotic acid hydrosulfuric acid.

18.80 Use Appendix C to calculate $[H_2C_2O_4]$, $[HC_2O_4^-]$, $[C_2O_4^{2-}]$, $[H_3O^+]$, pH, $[OH^-]$, and pOH in a 0.200 *M* solution of the diprotic acid oxalic acid.

Problems in Context

18.81 Acetylsalicylic acid (aspirin), $HC_9H_7O_4$, is the most widely used pain reliever and fever reducer. Find the pH of 0.018 *M* aqueous aspirin at body temperature (K_a at 37°C $= 3.6\times10^{-4}$).

18.82 Formic acid, HCOOH, the simplest carboxylic acid, has many uses in the textile and rubber industries. It is an extremely caustic liquid that is secreted as a defense by many species of ants (family Formicidae). Calculate the percent dissociation of 0.50 *M* HCOOH.

Weak Bases and Their Relation to Weak Acids

(Sample Problems 18.9 and 18.10)

Concept Review Questions

18.83 What is the key structural feature of all Brønsted-Lowry bases? How does this feature function in an acid-base reaction?

18.84 Why are most anions basic in H_2O? Give formulas of four anions that are not basic.

18.85 Except for the Na^+ spectator ion, aqueous solutions of CH_3COOH and CH_3COONa contain the same species. (a) What are the species (other than H_2O)? (b) Why is 0.1 *M* CH_3COOH acidic and 0.1 *M* CH_3COONa basic?

Skill-Building Exercises *(grouped in similar pairs)*

18.86 Write balanced equations and K_b expressions for these Brønsted-Lowry bases in water:
(a) Pyridine, C_5H_5N (b) CO_3^{2-}

18.87 Write balanced equations and K_b expressions for these Brønsted-Lowry bases in water:
(a) Benzoate ion, $C_6H_5COO^-$ (b) $(CH_3)_3N$

18.88 Write balanced equations and K_b expressions for these Brønsted-Lowry bases in water:
(a) Hydroxylamine, HO—NH_2 (b) HPO_4^{2-}

18.89 Write balanced equations and K_b expressions for these Brønsted-Lowry bases in water:
(a) Guanidine, $(H_2N)_2C{=}NH$ (double-bonded N is most basic)
(b) Acetylide ion, $HC{\equiv}C^-$

18.90 What is the pH of 0.050 *M* dimethylamine?

18.91 What is the pH of 0.12 *M* diethylamine?

18.92 What is the pH of 0.15 *M* ethanolamine?

18.93 What is the pH of 0.26 *M* aniline?

18.94 (a) What is the K_b of the acetate ion?
(b) What is the K_a of the anilinium ion, $C_6H_5NH_3^+$?

18.95 (a) What is the K_b of the benzoate ion, $C_6H_5COO^-$?
(b) What is the K_a of the 2-hydroxyethylammonium ion, $HOCH_2CH_2NH_3^+$ (pK_b of $HOCH_2CH_2NH_2 = 4.49$)?

18.96 (a) What is the pK_b of ClO_2^-?
(b) What is the pK_a of the dimethylammonium ion, $(CH_3)_2NH_2^+$?

18.97 (a) What is the pK_b of NO_2^-?
(b) What is the pK_a of the hydrazinium ion, $H_2N{-}NH_3^+$ (K_b of hydrazine $= 8.5\times10^{-7}$)?

18.98 (a) What is the pH of 0.050 *M* KCN?
(b) What is the pH of 0.30 *M* triethylammonium chloride, $(CH_3CH_2)_3NHCl$?

18.99 (a) What is the pH of 0.100 *M* sodium phenolate, C_6H_5ONa, the sodium salt of phenol?
(b) What is the pH of 0.15 *M* methylammonium bromide, CH_3NH_3Br (K_b of $CH_3NH_2 = 4.4\times10^{-4}$)?

18.100 (a) What is the pH of 0.53 *M* potassium formate, HCOOK?
(b) What is the pH of 1.22 *M* NH_4Br?

18.101 (a) What is the pH of 0.75 *M* NaF?
(b) What is the pH of 0.88 *M* pyridinium chloride, C_5H_5NHCl?

Problems in Context

18.102 Sodium hypochlorite solution, sold as "chlorine bleach," is recognized as a potentially dangerous household product. The dangers arise from its basicity and from ClO^-, the active bleaching ingredient. What is $[OH^-]$ in an aqueous solution that is 5.0% NaClO by mass? What is the pH of the solution? (Assume *d* of solution = 1.0 g/mL.)

18.103 Codeine ($C_{18}H_{21}NO_3$) is a narcotic pain reliever that forms a salt with HCl. What is the pH of 0.050 *M* codeine hydrochloride (pK_b of codeine = 5.80)?

Molecular Properties and Acid Strength

Concept Review Questions

18.104 Across a period, how does the electronegativity of a nonmetal affect the acidity of its binary hydride?

18.105 How does the atomic size of a nonmetal affect the acidity of its binary hydride?

18.106 A strong acid has a weak bond to its acidic proton, whereas a weak acid has a strong bond to its acidic proton. Explain.

18.107 Perchloric acid, $HClO_4$, is the strongest of the halogen oxoacids, and hypoiodous acid, HIO, is the weakest. What two factors govern this difference in acid strength?

Skill-Building Exercises *(grouped in similar pairs)*

18.108 Choose the *stronger* acid in each of the following pairs:
(a) H_2SeO_3 or H_2SeO_4 (b) H_3PO_4 or H_3AsO_4 (c) H_2S or H_2Te

18.109 Choose the *weaker* acid in each of the following pairs:
(a) HBr or H_2Se (b) $HClO_4$ or H_2SO_4 (c) H_2SO_3 or H_2SO_4

18.110 Choose the *stronger* acid in each of the following pairs:
(a) H_2Se or H_3As (b) $B(OH)_3$ or $Al(OH)_3$ (c) $HBrO_2$ or HBrO

18.111 Choose the *weaker* acid in each of the following pairs:
(a) HI or HBr (b) H_3AsO_4 or H_2SeO_4 (c) HNO_3 or HNO_2

18.112 Use Appendix C to choose the solution with the *lower* pH:
(a) 0.1 *M* $CuSO_4$ or 0.05 *M* $Al_2(SO_4)_3$
(b) 0.1 *M* $ZnCl_2$ or 0.1 *M* $PbCl_2$

18.113 Use Appendix C to choose the solution with the *lower* pH:
(a) 0.1 *M* $FeCl_3$ or 0.1 *M* $AlCl_3$
(b) 0.1 *M* $BeCl_2$ or 0.1 *M* $CaCl_2$

18.114 Use Appendix C to choose the solution with the *higher* pH:
(a) 0.1 *M* $Ni(NO_3)_2$ or 0.1 *M* $Co(NO_3)_2$
(b) 0.1 *M* $Al(NO_3)_3$ or 0.1 *M* $Cr(NO_3)_3$

18.115 Use Appendix C to choose the solution with the *higher* pH:
(a) 0.1 *M* $NiCl_2$ or 0.1 *M* NaCl
(b) 0.1 *M* $Sn(NO_3)_2$ or 0.1 *M* $Co(NO_3)_2$

Acid-Base Properties of Salt Solutions

(Sample Problems 18.11 and 18.12)

Concept Review Questions

18.116 What determines whether an aqueous solution of a salt will be acidic, basic, or neutral? Give an example of each type of salt.

18.117 Why is aqueous NaF basic but aqueous NaCl neutral?

18.118 The NH_4^+ ion forms acidic solutions, and the $C_2H_3O_2^-$ ion forms basic solutions. However, a solution of ammonium acetate is almost neutral. Do all of the ammonium salts of weak acids form neutral solutions? Explain your answer.

Skill-Building Exercises *(grouped in similar pairs)*

18.119 Explain with equations and calculations, when necessary, whether an aqueous solution of each of these salts is acidic, basic, or neutral: (a) KBr; (b)NH_4I; (c) KCN.

18.120 Explain with equations and calculations, when necessary, whether an aqueous solution of each of these salts is acidic, basic, or neutral: (a) $Cr(NO_3)_3$; (b) NaHS; (c) $Zn(CH_3COO)_2$.

18.121 Explain with equations and calculations, when necessary, whether an aqueous solution of each of these salts is acidic, basic, or neutral: (a) Na_2CO_3; (b) $CaCl_2$; (c) $Cu(NO_3)_2$.

18.122 Explain with equations and calculations, when necessary, whether an aqueous solution of each of these salts is acidic, basic, or neutral: (a) CH_3NH_3Cl; (b) $KClO_4$; (c) CoF_2.

18.123 Explain with equations and calculations, when necessary, whether an aqueous solution of each of these salts is acidic, basic, or neutral: (a) $SrBr_2$; (b) $Ba(CH_3COO)_2$; (c) $(CH_3)_2NH_2Br$.

18.124 Explain with equations and calculations, when necessary, whether an aqueous solution of each of these salts is acidic, basic, or neutral: (a) $Fe(HCOO)_3$; (b) $KHCO_3$; (c) K_2S.

18.125 Explain with equations and calculations, when necessary, whether an aqueous solution of each of these salts is acidic, basic, or neutral: (a) $(NH_4)_3PO_4$; (b) Na_2SO_4; (c) LiClO.

18.126 Explain with equations and calculations, when necessary, whether an aqueous solution of each of these salts is acidic, basic, or neutral: (a) $Pb(CH_3COO)_2$; (b) $Cr(NO_2)_3$; (c) CsI.

18.127 Rank the following salts in order of *increasing* pH of their 0.1 *M* aqueous solutions:
(a) KNO_3, K_2SO_3, K_2S, $Fe(NO_3)_2$
(b) NH_4NO_3, $NaHSO_4$, $NaHCO_3$, Na_2CO_3

18.128 Rank the following salts in order of *decreasing* pH of their 0.1 *M* aqueous solutions:
(a) $FeCl_2$, $FeCl_3$, $MgCl_2$, $KClO_2$
(b) NH_4Br, $NaBrO_2$, NaBr, $NaClO_2$

Generalizing the Brønsted-Lowry Concept: The Leveling Effect

Concept Review Questions

18.129 The methoxide ion, CH_3O^-, and amide ion, NH_2^-, are very strong bases that are "leveled" by water. What does this mean? Write the reactions that occur in the leveling process. What species do the two leveled solutions have in common?

18.130 Explain the differing extents of dissociation of H_2SO_4 in CH_3COOH, H_2O, and NH_3.

18.131 In H_2O, HF is weak and the other hydrohalic acids are equally strong. In NH_3, however, all the hydrohalic acids are equally strong. Explain.

Electron-Pair Donation and the Lewis Acid-Base Definition

(Sample Problem 18.13)

Concept Review Questions

18.132 What feature must a molecule or ion have for it to act as a Lewis base? A Lewis acid? Explain the roles of these features.

18.133 How do Lewis acids differ from Brønsted-Lowry acids? How are they similar? Do Lewis bases differ from Brønsted-Lowry bases? Explain.

18.134 (a) Is a weak Brønsted-Lowry base necessarily a weak Lewis base? Explain with an example.
(b) Identify the Lewis bases in the following reaction:

$$Cu(H_2O)_4^{2+}(aq) + 4CN^-(aq) \rightleftharpoons Cu(CN)_4^{2-}(aq) + 4H_2O(l)$$

(c) Given that $K_c > 1$ for the reaction in part (b), which Lewis base is stronger?

18.135 In which of the three concepts of acid-base behavior discussed in the text can water be a product of an acid-base reaction? In which is it the only product?

18.136 (a) Give an example of a *substance* that is a base in two of the three acid-base definitions, but not in the third.
(b) Give an example of a *substance* that is an acid in one of the three acid-base definitions, but not in the other two.

Skill-Building Exercises *(grouped in similar pairs)*

18.137 Which are Lewis acids and which are Lewis bases?
(a) Cu^{2+} (b) Cl^- (c) $SnCl_2$ (d) OF_2

18.138 Which are Lewis acids and which are Lewis bases?
(a) Na^+ (b) NH_3 (c) CN^- (d) BF_3

18.139 Which are Lewis acids and which are Lewis bases?
(a) BF_3 (b) S^{2-} (c) SO_3^{2-} (d) SO_3

18.140 Which are Lewis acids and which are Lewis bases?
(a) Mg^{2+} (b) OH^- (c) SiF_4 (d) $BeCl_2$

18.141 Identify the Lewis acid and Lewis base in each equation:
(a) $Na^+ + 6H_2O \rightleftharpoons Na(H_2O)_6^+$
(b) $CO_2 + H_2O \rightleftharpoons H_2CO_3$
(c) $F^- + BF_3 \rightleftharpoons BF_4^-$

18.142 Identify the Lewis acid and Lewis base in each equation:
(a) $Fe^{3+} + 2H_2O \rightleftharpoons FeOH^{2+} + H_3O^+$
(b) $H_2O + H^- \rightleftharpoons OH^- + H_2$
(c) $4CO + Ni \rightleftharpoons Ni(CO)_4$

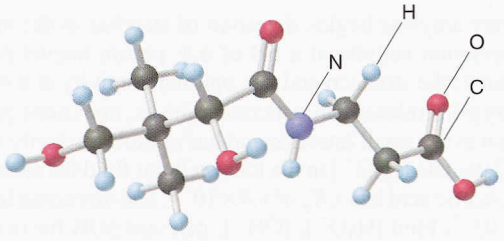
18.143 Classify the following as Arrhenius, Brønsted-Lowry, or Lewis acid-base reactions. A reaction may fit all, two, one, or none of the categories:
(a) $Ag^+ + 2NH_3 \rightleftharpoons Ag(NH_3)_2^+$
(b) $H_2SO_4 + NH_3 \rightleftharpoons HSO_4^- + NH_4^+$

(c) $2HCl \rightleftharpoons H_2 + Cl_2$
(d) $AlCl_3 + Cl^- \rightleftharpoons AlCl_4^-$

18.144 Classify the following as Arrhenius, Brønsted-Lowry, or Lewis acid-base reactions. A reaction may fit all, two, one, or none of the categories:
(a) $Cu^{2+} + 4Cl^- \rightleftharpoons CuCl_4^{2-}$
(b) $Al(OH)_3 + 3HNO_3 \rightleftharpoons Al^{3+} + 3H_2O + 3NO_3^-$
(c) $N_2 + 3H_2 \rightleftharpoons 2NH_3$
(d) $CN^- + H_2O \rightleftharpoons HCN + OH^-$

Comprehensive Problems

18.145 Pantothenic acid ($C_9H_{17}NO_5$; vitamin B_3) is shown below. This biologically active molecule is an optical isomer that behaves like a monoprotic Brønsted-Lowry acid in water.



(a) Use the molecular formula to write the equation for the reaction of pantothenic acid with water and the K_a expression.
(b) Which C atom is the chiral center?

18.146 The pK_a of acetic acid is 4.76 in pure water and 4.53 in seawater. In which solvent is it a stronger acid?

18.147 Bodily processes in humans maintain the pH of blood within a narrow range. In fact, a condition called *acidosis* occurs if the blood pH goes below 7.35, and another called *alkalosis* occurs if the pH goes above 7.45. Given that the pK_w of blood is 13.63 at 37°C (body temperature), what is the normal range of $[H_3O^+]$ and of $[OH^-]$ in blood?

18.148 One use of phenol, C_6H_5OH, is as a disinfectant. In water its pK_a is 10.0, but in methanol it is 14.4. (a) Why are the values different? (b) Use these two values to decide whether methanol is a stronger or weaker base than water. (c) Write the dissociation reaction of phenol in methanol. (d) Write an expression for the autoionization constant of methanol.

18.149 When carbon dioxide dissolves in water, it undergoes a multistep equilibrium process, with $K_{overall} = 4.5\times10^{-7}$, which is simplified to the following:

$$CO_2(g) + H_2O(l) \rightleftharpoons H_2CO_3(aq)$$
$$H_2CO_3(aq) + H_2O(l) \rightleftharpoons HCO_3^-(aq) + H_3O^+(aq)$$

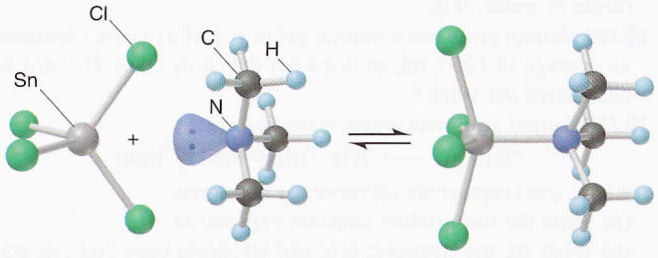
(a) Classify each step as a Lewis or a Brønsted-Lowry reaction.
(b) What is the pH of nonpolluted rainwater in equilibrium with clean air (P_{CO_2} in clean air $= 3.2\times10^{-4}$ atm; Henry's law constant for CO_2 at 25°C is 0.033 mol/L·atm)?
(c) What is $[CO_3^{2-}]$ in rainwater (K_a of $HCO_3^- = 4.7\times10^{-11}$)?
(d) If the partial pressure of CO_2 in clean air doubles in the next few decades, what will the pH of rainwater become?

18.150 Seashells are mostly calcium carbonate, which reacts with H_3O^+ according to the equation

$$CaCO_3(s) + H_3O^+(aq) \rightleftharpoons Ca^{2+}(aq) + HCO_3^-(aq) + H_2O(l)$$

If K_w increases at higher pressure, will seashells dissolve more rapidly near the surface of the ocean or at great depths? Explain.

18.151 Many molecules with central atoms from Period 3 or higher take part in Lewis acid-base reactions in which the central atom expands its valence shell. $SnCl_4$ reacts with $(CH_3)_3N$ as follows:



(a) Identify the Lewis acid and the Lewis base in the reaction.
(b) Give the *nl* designation of the sublevel of the central atom in the acid that accepts the lone pair.

18.152 A chemist makes four successive 1:10 dilutions of 1.0×10^{-5} *M* HCl. Calculate the pH of the original solution and of each diluted solution (through 1.0×10^{-9} *M* HCl).

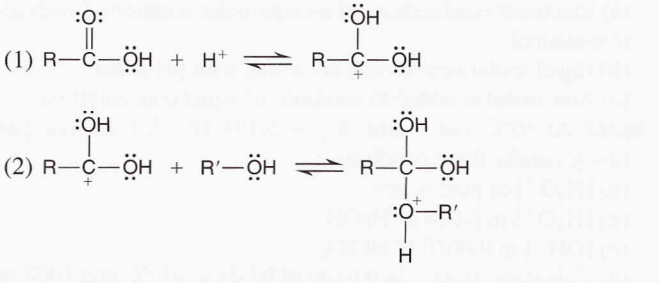
18.153 At 25°C, the pK_w of seawater is 13.22; this value is lower than that for water as a result of the dissolved salts. If the pH of a sample of seawater is 7.54, what is the pOH of the sample?

18.154 Chlorobenzene, C_6H_5Cl, is a key intermediate in the manufacture of many aromatic compounds, including aniline dyes and chlorinated pesticides. It is made by the $FeCl_3$-catalyzed chlorination of benzene in this series of steps:
(1) $Cl_2 + FeCl_3 \rightleftharpoons FeCl_5$ (or $Cl^+FeCl_4^-$)
(2) $C_6H_6 + Cl^+FeCl_4^- \rightleftharpoons C_6H_6Cl^+ + FeCl_4^-$
(3) $C_6H_6Cl^+ \rightleftharpoons C_6H_5Cl + H^+$
(4) $H^+ + FeCl_4^- \rightleftharpoons HCl + FeCl_3$
(a) Which of the step(s) is (are) Lewis acid-base reactions?
(b) Identify the Lewis acids and bases in each of those steps.

18.155 Hydrogen peroxide, H_2O_2 (pK_a = 11.75), is commonly used as a bleaching agent and an antiseptic. The product sold in stores is 3% H_2O_2 by mass and contains 0.001% phosphoric acid by mass to stabilize the solution. Which contributes more H_3O^+ to this commercial solution, the H_2O_2 or the H_3PO_4?

18.156 The strengths of acids and bases are directly related to their strengths as electrolytes (Section 4.4).
(a) Is the electrical conductivity of 0.1 *M* HCl higher, lower, or the same as that of 0.1 *M* CH_3COOH? Explain.
(b) Is the electrical conductivity of 1×10^{-7} *M* HCl higher, lower, or the same as that of 1×10^{-7} *M* CH_3COOH? Explain.

18.157 Esters, RCOOR′, are formed by the reaction of carboxylic acids, RCOOH, and alcohols, R′OH, where R and R′ are hydrocarbon groups. Many esters are responsible for the odors of fruit and, thus, have important uses in the food and cosmetics industries. The first two steps in the mechanism of ester formation are



Identify the Lewis acids and Lewis bases in these two steps.

18.158 Three beakers contain 100. mL of 0.10 *M* acid, either HCl, $HClO_2$, or HClO. (a) Find the pH of each. (b) Describe quantitatively how to make the pH equal in the beakers through the addition of water only.

18.159 Human urine has a normal pH of 6.2. If a person eliminates an average of 1250. mL of urine per day, how many H^+ ions are eliminated per week?

18.160 Liquid ammonia autoionizes like water:

$$2NH_3(l) \longrightarrow NH_4^+(am) + NH_2^-(am)$$

where (*am*) represents solvation by ammonia.
(a) Write the ion-product constant expression, K_{am}.
(b) What are the strongest acid and strongest base that can exist in liquid ammonia?
(c) HNO_3 and HCOOH are leveled in liquid NH_3. Explain with equations.
(d) At the boiling point (−33°C), $K_{am} = 5.1\times10^{-27}$. Calculate $[NH_4^+]$ at this temperature.
(e) Pure sulfuric acid also autoionizes. Write the ion-product constant expression, K_{sulf}, and find the concentration of the conjugate base at 20°C ($K_{sulf} = 2.7\times10^{-4}$ at 20°C).

18.161 Autoionization (see Problem 18.160) occurs in methanol (CH_3OH) and in ethylenediamine ($NH_2CH_2CH_2NH_2$).
(a) The autoionization constant of methanol (K_{met}) is 2×10^{-17}. What is $[CH_3O^-]$ in pure CH_3OH?
(b) The concentration of $NH_2CH_2CH_2NH_3^+$ in pure $NH_2CH_2CH_2NH_2$ is 2×10^{-8} *M*. What is the autoionization constant of ethylenediamine (K_{en})?

18.162 Thiamine hydrochloride ($C_{12}H_{18}ON_4SCl_2$) is a water-soluble form of thiamine (vitamin B_1; $K_a = 3.37\times10^{-7}$). How many grams of the hydrochloride must be dissolved in 10.00 mL of water to give a pH of 3.50?

18.163 Tris(hydroxymethyl)aminomethane, known as TRIS or THAM, is a water-soluble base that is a reactant in the synthesis of surfactants and pharmaceuticals, an emulsifying agent in cosmetic creams and lotions, and a component of various cleaning and polishing mixtures for textiles and leather. In biomedical research, solutions of TRIS are used to maintain nearly constant pH for the study of enzymes and other cellular components. Given that the pK_b is 5.91, calculate the pH of 0.060 *M* TRIS.

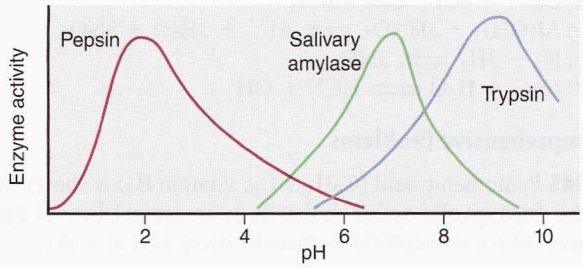
18.164 When Fe^{3+} salts are dissolved in water, the solution becomes acidic due to formation of $Fe(H_2O)_5OH^{2+}$ and H_3O^+. The overall process involves both Lewis and Brønsted-Lowry acid-base reactions. Write the equations for the process.

18.165 Vinegar is a 5.0% (w/v) solution of acetic acid in water. What is the pH of vinegar?

18.166 How would you differentiate between a strong and a weak monoprotic acid from the results of the following procedures?
(a) Electrical conductivity of an equimolar solution of each acid is measured.
(b) Equal molarities of each are tested with pH paper.
(c) Zinc metal is added to solutions of equal concentration.

18.167 At 50°C and 1 atm, $K_w = 5.19\times10^{-14}$. Calculate parts (a)–(c) under these conditions:
(a) $[H_3O^+]$ in pure water
(b) $[H_3O^+]$ in 0.010 *M* NaOH
(c) $[OH^-]$ in 0.0010 *M* $HClO_4$
(d) Calculate $[H_3O^+]$ in 0.0100 *M* KOH at 100°C and 1000 atm pressure ($K_w = 1.10\times10^{-12}$).
(e) Calculate the pH of pure water at 100°C and 1000 atm.

18.168 The catalytic efficiency of an enzyme is called its *activity* and refers to the rate at which it catalyzes the reaction. Most enzymes have optimum activity over a relatively narrow pH range, which is related to the pH of the local cellular fluid. The pH profiles of three digestive enzymes are shown.



Salivary amylase begins digestion of starches in the mouth and has optimum activity at a pH of 6.8; pepsin begins protein digestion in the stomach and has optimum activity at a pH of 2.0; and trypsin, released in pancreatic juices, continues protein digestion in the small intestine and has optimum activity at a pH of 9.5. Calculate $[H_3O^+]$ in the local cellular fluid for each enzyme.

18.169 Acetic acid has a K_a of 1.8×10^{-5}, and ammonia has a K_b of 1.8×10^{-5}. Find $[H_3O^+]$, $[OH^-]$, pH, and pOH for (a) 0.240 *M* acetic acid and (b) 0.240 *M* ammonia.

18.170 Sodium phosphate has industrial uses ranging from clarifying crude sugar to manufacturing paper. Sold as TSP, it is used in solution to remove boiler scale and to wash painted brick and concrete. What is the pH of a solution containing 33 g of Na_3PO_4 per liter? What is $[OH^-]$ of this solution?

18.171 The Group 5A(15) hydrides react with boron trihalides in a reversible Lewis acid-base reaction. When 0.15 mol of $PH_3BCl_3(s)$ is introduced into a 3.0-L container at a certain temperature, 8.4×10^{-3} mol of PH_3 is present at equilibrium: $PH_3BCl_3(s) \rightleftharpoons PH_3(g) + BCl_3(g)$.
(a) Calculate K_c for the reaction at this temperature.
(b) Draw a Lewis structure for the reactant.

18.172 A 1.000 *m* solution of chloroacetic acid ($ClCH_2COOH$) freezes at −1.93°C. Use these data to find the K_a of chloroacetic acid. (Assume the molarities equal the molalities.)

18.173 Sodium stearate ($C_{17}H_{35}COONa$) is a major component of bar soap (see Chapter 13, p. 498). The K_a of the stearic acid is 1.3×10^{-5}. What is the pH of 10.0 mL of a solution containing 0.42 g of sodium stearate?

18.174 Calcium propionate [$Ca(CH_3CH_2COO)_2$; calcium propanoate] is a mold inhibitor used in food, tobacco, and pharmaceuticals. (a) Use balanced equations to show whether aqueous calcium propionate is acidic, basic, or neutral. (b) Use Appendix C to find the pH of a solution made by dissolving 7.05 g of $Ca(CH_3CH_2COO)_2$ in water to give 0.500 L of solution.

18.175 Carbon dioxide is less soluble in dilute HCl than in dilute NaOH. Explain.

18.176 (a) If $K_w = 1.139\times10^{-15}$ at 0°C and 5.474×10^{-14} at 50°C, find $[H_3O^+]$ and pH of water at 0°C and 50°C.
(b) The autoionization constant for heavy water (deuterium oxide, D_2O) is 3.64×10^{-16} at 0°C and 7.89×10^{-15} at 50°C. Find $[D_3O^+]$ and pD of heavy water at 0°C and 50°C.
(c) Suggest a reason for these differences.

18.177 HX ($\mathcal{M}$ = 150. g/mol) and HY ($\mathcal{M}$ = 50.0 g/mol) are weak acids. A solution of 12.0 g/L of HX has the same pH as one containing 6.00 g/L of HY. Which is the stronger acid? Why?

18.178 In his acid-base studies, Arrhenius discovered an important fact involving reactions like the following:

$$KOH(aq) + HNO_3(aq) \longrightarrow ?$$
$$NaOH(aq) + HCl(aq) \longrightarrow ?$$

(a) Complete the reactions and use the data for the individual ions in Appendix B to calculate each ΔH^0_{rxn}.
(b) Explain your results and use them to predict ΔH^0_{rxn} for

$$KOH(aq) + HCl(aq) \longrightarrow ?$$

18.179 Amines have foul odors. Putrescine [$NH_2(CH_2)_4NH_2$], once thought to be found only in rotting animal tissue, is now known to be a component of all cells and essential for normal and abnormal (cancerous) growth. It also plays a key role in formation of GABA, a neurotransmitter. A 0.10 *M* aqueous solution of putrescine has $[OH^-] = 2.1\times10^{-3}$. What is the K_b?

18.180 Nitrogen is discharged from wastewater treatment facilities into rivers and streams, usually as NH_3 and NH_4^+:

$$NH_3(aq) + H_2O(l) \rightleftharpoons NH_4^+(aq) + OH^-(aq) \quad K_b = 1.76\times10^{-5}$$

One strategy for removing it is to raise the pH and "strip" the NH_3 from solution by bubbling air through the water. (a) At pH 7.00, what fraction of the total nitrogen in solution is NH_3, defined as $[NH_3]/([NH_3] + [NH_4^+])$? (b) What is the fraction at pH 10.00? (c) Explain the basis of ammonia stripping.

18.181 Polymers and other large molecules are not very soluble in water, but their solubility increases if they have charged groups.
(a) Casein is a protein in milk that contains many carboxylic acid groups on its side chains. Explain how the solubility of casein in water varies with pH.
(b) Histones are proteins that are essential to the proper function of DNA. They are weakly basic due to the presence of side chains with $-NH_2$ and $=NH$ groups. Explain how the solubility of histones in water varies with pH.

18.182 Hemoglobin (Hb) transports oxygen in the blood:

$$HbH^+(aq) + O_2(aq) + H_2O(l) \longrightarrow H_3O^+(aq) + HbO_2(aq)$$

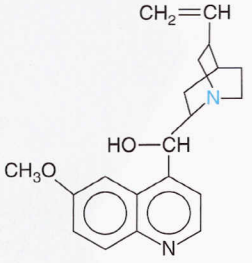
In blood, $[H_3O^+]$ is held nearly constant at 4×10^{-8} *M*.
(a) How does the equilibrium position change in the lungs?
(b) How does it change in O_2-deficient cells?
(c) Excessive vomiting may lead to metabolic *alkalosis*, in which $[H_3O^+]$ in blood *decreases*. How does this condition affect the ability of Hb to transport O_2?
(d) Diabetes mellitus may lead to metabolic *acidosis*, in which $[H_3O^+]$ in blood *increases*. How does this condition affect the ability of Hb to transport O_2?

18.183 Vitamin C (ascorbic acid, $H_2C_6H_6O_6$) is a weak diprotic acid. It is essential for the synthesis of collagen, the major protein in connective tissue. (a) If the pH of a 5.0% (w/v) solution of vitamin C in water is 2.77, calculate the K_{a1} of vitamin C. (b) The vitamin is also taken as its sodium salt. What is the pH of a 10.0 g/L solution of sodium ascorbate (NaAsc)?

18.184 Because of the behavior of their R groups in water, lysine is called a basic amino acid and aspartic acid an acidic amino acid. Write balanced equations that demonstrate this behavior.

18.185 A solution of propanoic acid (CH_3CH_2COOH), made by dissolving 7.500 g in sufficient water to make 100.0 mL, has a freezing point of −1.890°C.
(a) Calculate the molarity of the solution.
(b) Calculate the molarity of the propanoate ion. (Assume the molarity of the solution equals the molality.)
(c) Calculate the percent dissociation of propanoic acid.

18.186 Quinine ($C_{20}H_{24}N_2O_2$; *see below*) is a natural product with antimalarial properties that saved thousands during construction of the Panama Canal. It stands as a classic example of the medicinal wealth of tropical forests. Both N atoms are basic, but the N (colored) of the 3° amine group is far more basic ($pK_b = 5.1$) than the N within the aromatic ring system ($pK_b = 9.7$).



(a) Quinine is not very soluble in water: a saturated solution is only 1.6×10^{-3} *M*. What is the pH of this solution?
(b) Show that the aromatic N contributes negligibly to the pH of the solution.
(c) Because of its low solubility as a free base in water, quinine is given as an amine salt. For instance, quinine hydrochloride ($C_{20}H_{24}N_2O_2\cdot HCl$) is about 120 times more soluble in water than quinine. What is the pH of 0.53 *M* quinine hydrochloride?
(d) An antimalarial concentration in water is 1.5% quinine hydrochloride by mass (d = 1.0 g/mL). What is the pH?

18.187 Drinking water is often disinfected with chlorine gas, which hydrolyzes to form hypochlorous acid (HClO), a weak acid but powerful disinfectant:

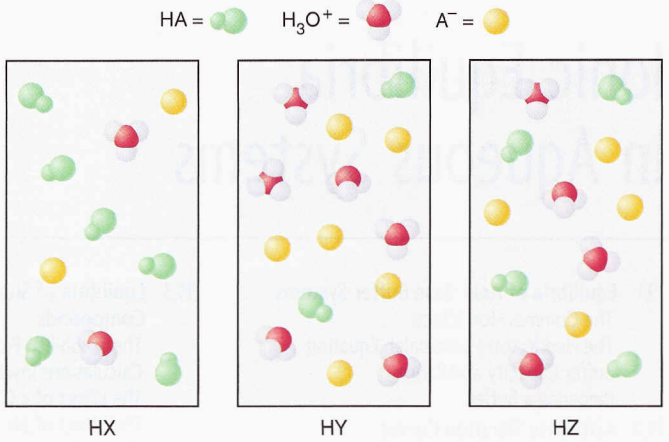
$$Cl_2(aq) + 2H_2O(l) \longrightarrow HClO(aq) + H_3O^+(aq) + Cl^-(aq)$$

The fraction of HOCl in solution is defined as

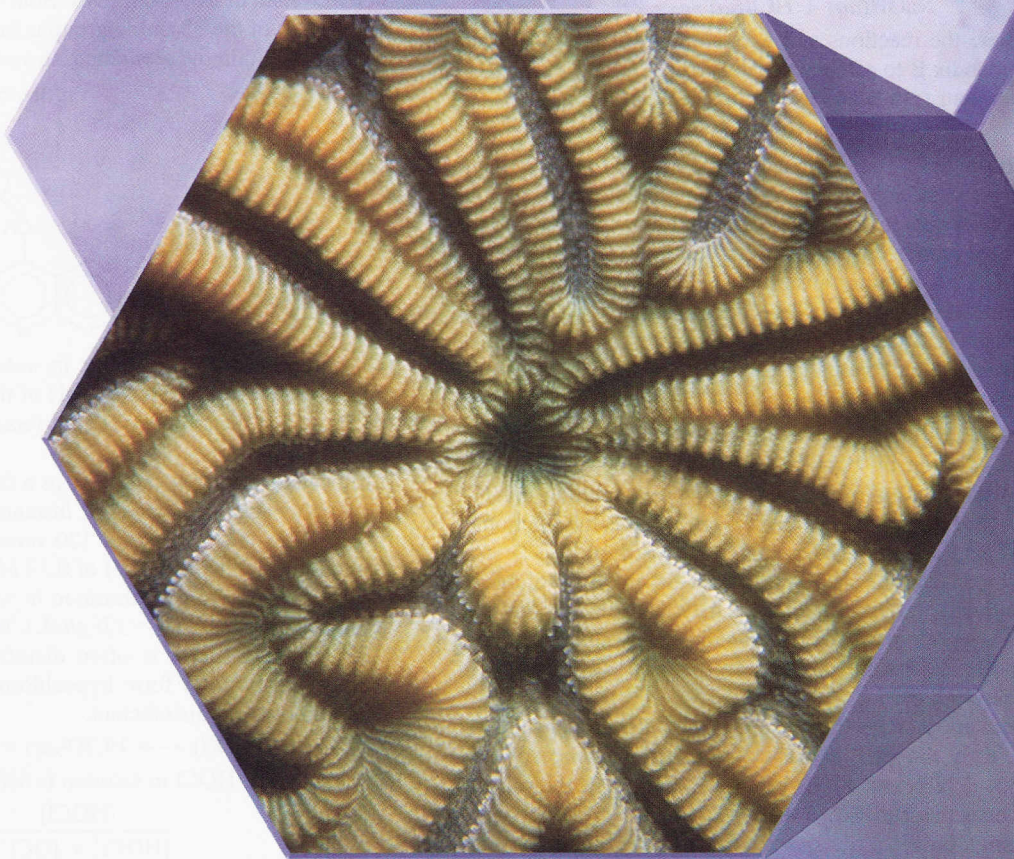
$$\frac{[HOCl]}{[HOCl] + [OCl^-]}$$

(a) What is the fraction of HOCl at pH 7.00 (K_a of HClO = 2.9×10^{-8})? (b) What is the fraction at pH 10.00?

18.188 The following scenes represent three weak acids HA (where A = X, Y, or Z) dissolved in water (H_2O is not shown):



(a) Rank the acids in order of increasing K_a.
(b) Rank the acids in order of increasing pK_a.
(c) Rank the conjugate bases in order of increasing pK_b.
(d) What is the percent dissociation of HX?
(e) If equimolar amounts of the sodium salts of the acids (NaX, NaY, and NaZ) were dissolved in water, which solution would have the highest pOH? The lowest pH?



A living precipitate Each member of a coral reef is the product of equilibria involving solid calcium carbonate, dissolved CO_2, and, primarily, calcium and bicarbonate ions. In this chapter, we investigate this system and two other types of aqueous ionic equilibria, all of which have great industrial, biological, and environmental importance.

- Selective Precipitation
- Qualitative Analysis

Europa, one of Jupiter's moons, has an icy surface with hints of vast oceans of liquid water beneath. Is there life on Europa? Perhaps some Europan astronomer viewing Earth is asking a similar question, because liquid water is essential for the aqueous systems that maintain life. Every astronaut has felt awe at seeing our "beautiful blue orb" from space. A biologist peering at the fabulous watery world of a living cell probably feels the same way. A chemist is awed by the principles of equilibrium and their universal application to aqueous solutions wherever they occur.

Consider just a few cases of aqueous equilibria. The magnificent formations in limestone caves and the vast expanses of oceanic coral reefs result from subtle shifts in carbonate solubility equilibria. Carbonates also influence soil pH and prevent acidification of lakes by acid rain. Equilibria involving carbon dioxide and phosphates help organisms maintain cellular pH within narrow limits. Equilibria involving clays in soils control the availability of ionic nutrients for plants. The principles of ionic equilibrium also govern how water is softened, how substances are purified by precipitation of unwanted ions, and even how the weak acids in wine and vinegar influence the delicate taste of a fine French sauce.

IN THIS CHAPTER . . . We explore three aqueous ionic equilibrium systems: acid-base buffers, slightly soluble salts, and complex ions. Our discussion of buffers introduces the common-ion effect, an important phenomenon in many ionic equilibria. We discuss why buffers are important, how they work, and how to prepare them, and we then examine the various types of acid-base titrations and how buffered solutions are involved in them. Slightly soluble salts have major roles in the laboratory and in nature, and we'll see how conditions influence their solubility equilibria. Next, we investigate how complex ions form and change from one type to another. Finally, we see how various aqueous equilibria are employed in chemical analysis.

Concepts & Skills to Review

before you study this chapter

- solubility rules for ionic compounds (Section 4.3)
- effect of concentration on equilibrium position (Section 17.6)
- conjugate acid-base pairs (Section 18.3)
- calculations for weak-acid and weak-base equilibria (Sections 18.4 and 18.5)
- acid-base properties of salt solutions (Section 18.7)
- Lewis acids and bases (Section 18.9)

19.1 EQUILIBRIA OF ACID-BASE BUFFER SYSTEMS

Why do some lakes become acidic when showered by acid rain, while others remain unaffected? How does blood maintain a constant pH in contact with countless cellular acid-base reactions? How can a chemist sustain a nearly constant $[H_3O^+]$ in reactions that consume or produce H_3O^+ or OH^-? The answer in each case depends on the action of a buffer.

In everyday language, a buffer is something that lessens the impact of an external force. An **acid-base buffer** is a solution that *lessens the impact on pH from the addition of acid or base*. Figure 19.1 shows that a small amount of H_3O^+ or OH^- added to an unbuffered solution (or just water) changes the pH by several units. Indeed, because of the logarithmic nature of pH, *this change is several orders of magnitude larger* than the change that results from the same addition

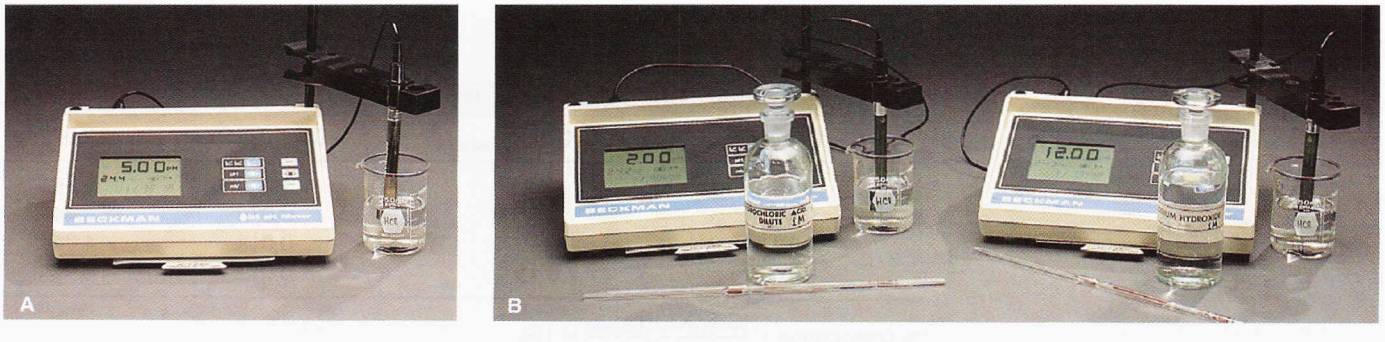

Figure 19.1 The effect of addition of acid or base to an unbuffered solution. **A,** A 100-mL sample of dilute HCl is adjusted to pH 5.00. **B,** After the addition of 1 mL of 1 *M* HCl (*left*) or of 1 *M* NaOH (*right*), the pH changes by several units.

Figure 19.2 The effect of addition of acid or base to a buffered solution.
A, A 100-mL sample of a buffered solution, made by mixing 1 *M* CH_3COOH with 1 *M* CH_3COONa, is adjusted to pH 5.00. **B,** After the addition of 1 mL of 1 *M* HCl (*left*) or of 1 *M* NaOH (*right*), the pH change is negligibly small. Compare these changes with those in Figure 19.1.

to a buffered solution, shown in Figure 19.2. To withstand the addition of strong acid or strong base without significantly changing its pH, a buffer must contain an acidic component that can react with the added OH^- ion *and* a basic component that can react with added H_3O^+ ion. However, these buffer components cannot be just any acid and base because they would neutralize each other. Most commonly, *the components of a buffer are the conjugate acid-base pair of a weak acid.* The buffer used in Figure 19.2, for example, is a mixture of acetic acid (CH_3COOH) and acetate ion (CH_3COO^-).

How a Buffer Works: The Common-Ion Effect

Buffers work through a phenomenon known as the **common-ion effect.** An example of this effect occurs when acetic acid dissociates in water and some sodium acetate is added. As you know, acetic acid dissociates only slightly in water:

$$CH_3COOH(aq) + H_2O(l) \rightleftharpoons H_3O^+(aq) + CH_3COO^-(aq)$$

From Le Châtelier's principle (Section 17.6), we know that if some CH_3COO^- ion is added (from the soluble sodium acetate), the equilibrium position shifts to the left; thus, $[H_3O^+]$ decreases, in effect lowering the extent of acid dissociation:

$$CH_3COOH(aq) + H_2O(l) \rightleftharpoons H_3O^+(aq) + CH_3COO^-(aq; \text{added})$$

Similarly, if we dissolve acetic acid in a sodium acetate solution, acetate ion and H_3O^+ ion from the acid enter the solution. The acetate ion already present combines with some of the H_3O^+, which lowers the $[H_3O^+]$. The effect again is to lower the acid dissociation. Acetate ion is called *the common ion* in this case because it is "common" to both the acetic acid and sodium acetate solutions; that is, acetate ion from the acid enters a solution in which it is already present. *The common-ion effect occurs when a reactant containing a given ion is added to an equilibrium mixture that already contains that ion, and the position of equilibrium shifts away from forming more of it.*

Table 19.1 shows the percent dissociation and the pH of an acetic acid solution containing various concentrations of acetate ion (supplied from solid sodium

Table 19.1 The Effect of Added Acetate Ion on the Dissociation of Acetic Acid

$[CH_3COOH]_{init}$	$[CH_3COO^-]_{added}$	% Dissociation*	pH
0.10	0.00	1.3	2.89
0.10	0.050	0.036	4.44
0.10	0.10	0.018	4.74
0.10	0.15	0.012	4.92

*% Dissociation $= \dfrac{[CH_3COOH]_{dissoc}}{[CH_3COOH]_{init}} \times 100$

acetate). Note that the *common ion, CH_3COO^-, suppresses the dissociation of CH_3COOH,* which makes the solution less acidic (higher pH).

The Essential Feature of a Buffer In the previous case, we prepared a buffer by mixing a weak acid (CH_3COOH) and its conjugate base (CH_3COO^-). *How* does this solution resist pH changes when H_3O^+ or OH^- is added? The essential feature of a buffer is that *it consists of high concentrations of the acidic (HA) and basic (A^-) components.* When small amounts of H_3O^+ or OH^- ions are added to the buffer, they cause *a small amount of one buffer component to convert into the other,* which changes the relative concentrations of the two components. As long as the amount of H_3O^+ or OH^- added is much smaller than the amounts of HA and A^- present originally, *the added ions have little effect on the pH because they are consumed by one or the other buffer component:* the A^- consumes added H_3O^+, and the HA consumes added OH^-.

Consider what happens to a solution containing high $[CH_3COOH]$ and $[CH_3COO^-]$ when we add small amounts of strong acid or base. The expression for HA dissociation at equilibrium is

$$K_a = \frac{[CH_3COO^-][H_3O^+]}{[CH_3COOH]}$$

Solving for $[H_3O^+]$ gives

$$[H_3O^+] = K_a \times \frac{[CH_3COOH]}{[CH_3COO^-]}$$

Note that because K_a is constant, *the $[H_3O^+]$ of the solution depends directly on the buffer-component concentration ratio,* $\frac{[CH_3COOH]}{[CH_3COO^-]}$:

- If the ratio $[HA]/[A^-]$ goes up, $[H_3O^+]$ goes up.
- If the ratio $[HA]/[A^-]$ goes down, $[H_3O^+]$ goes down.

When we add a small amount of strong acid, the increased amount of H_3O^+ ion reacts with a nearly *stoichiometric amount* of acetate ion from the buffer to form more acetic acid:

$$H_3O^+(aq;\ \text{added}) + CH_3COO^-(aq;\ \text{from buffer}) \longrightarrow CH_3COOH(aq) + H_2O(l)$$

As a result, $[CH_3COO^-]$ goes down by that amount and $[CH_3COOH]$ goes up by that amount, which increases the buffer-component concentration ratio, as you can see in Figure 19.3. The $[H_3O^+]$ also increases but only very slightly.

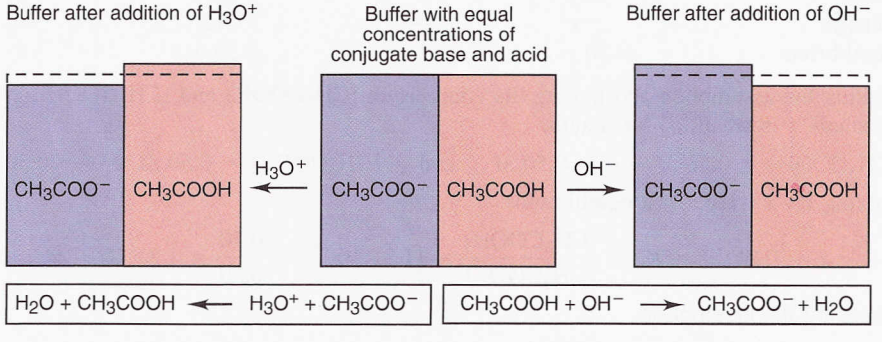

Figure 19.3 How a buffer works. A buffer consists of high concentrations of a conjugate acid-base pair, in this case, acetic acid (CH_3COOH) and acetate ion (CH_3COO^-). When a small amount of H_3O^+ is added (*left*), that same amount of CH_3COO^- combines with it, which increases the amount of CH_3COOH slightly. Similarly, when a small amount of OH^- is added (*right*), that amount of CH_3COOH combines with it, which increases the amount of CH_3COO^- slightly. In both cases, the relative changes in amounts of the buffer components are small, so their concentration ratio, and therefore the pH, changes very little.

Adding a small amount of strong base produces the opposite result. It supplies OH^- ions, which react with a nearly *stoichiometric amount* of CH_3COOH from the buffer, forming that much more CH_3COO^-:

$$CH_3COOH(aq;\text{ from buffer}) + OH^-(aq;\text{ added}) \longrightarrow CH_3COO^-(aq) + H_2O(l)$$

The buffer-component concentration ratio decreases, which decreases $[H_3O^+]$, but once again, the change is very slight.

Thus, the buffer components consume virtually all the added H_3O^+ or OH^-. To reiterate, as long as the amount of added H_3O^+ or OH^- is small compared with the amounts of the buffer components, *the conversion of one component into the other produces a small change in the buffer-component concentration ratio and, consequently, a small change in* $[H_3O^+]$ *and in pH.* Sample Problem 19.1 demonstrates how small these pH changes typically are. Note that the latter two parts of the problem combine a stoichiometry portion, like the problems in Chapter 3, and a weak-acid dissociation portion, like those in Chapter 18.

SAMPLE PROBLEM 19.1 Calculating the Effect of Added H_3O^+ or OH^- on Buffer pH

Problem Calculate the pH:
(a) Of a buffer solution consisting of 0.50 *M* CH_3COOH and 0.50 *M* CH_3COONa
(b) After adding 0.020 mol of solid NaOH to 1.0 L of the buffer solution in part (a)
(c) After adding 0.020 mol of HCl to 1.0 L of the buffer solution in part (a)
K_a of $CH_3COOH = 1.8\times10^{-5}$. (Assume the additions cause negligible volume changes.)

Plan In each case, we know, or can find, $[CH_3COOH]_{init}$ and $[CH_3COO^-]_{init}$ and the K_a of CH_3COOH (1.8×10^{-5}), and we need to find $[H_3O^+]$ at equilibrium and convert it to pH. In **(a),** we use the given concentrations of buffer components (each 0.50 *M*) as the initial values. As in earlier problems, we assume that x, the $[CH_3COOH]$ that dissociates, which equals $[H_3O^+]$, is so small relative to $[CH_3COOH]_{init}$ that it can be neglected. We set up a reaction table, solve for x, and check the assumption. In **(b)** and **(c),** we assume that the added OH^- or H_3O^+ reacts completely with the buffer components to yield new $[CH_3COOH]_{init}$ and $[CH_3COO^-]_{init}$, which then dissociate to an unknown extent. We set up two reaction tables. The first summarizes the stoichiometry of adding strong base (0.020 mol) or acid (0.020 mol). The second summarizes the dissociation of the new HA concentrations, so we proceed as in part (a) to find the new $[H_3O^+]$.

Solution **(a)** The original pH: $[H_3O^+]$ in the original buffer.
Setting up a reaction table with $x = [CH_3COOH]_{dissoc} = [H_3O^+]$ (as in Chapter 18, we assume that $[H_3O^+]$ from H_2O is negligible and disregard it):

Concentration (*M*)	$CH_3COOH(aq)$	+	$H_2O(l)$	$\rightleftharpoons$	$CH_3COO^-(aq)$	+	$H_3O^+(aq)$
Initial	0.50		—		0.50		0
Change	$-x$		—		$+x$		$+x$
Equilibrium	$0.50 - x$		—		$0.50 + x$		x

Making the assumption and finding the equilibrium $[CH_3COOH]$ and $[CH_3COO^-]$: With K_a small, x is small, so we assume

$$[CH_3COOH] = 0.50\ M - x \approx 0.50\ M \quad \text{and} \quad [CH_3COO^-] = 0.50\ M + x \approx 0.50\ M$$

Solving for x ($[H_3O^+]$ at equilibrium):

$$x = [H_3O^+] = K_a \times \frac{[CH_3COOH]}{[CH_3COO^-]} \approx (1.8\times10^{-5}) \times \frac{0.50}{0.50} = 1.8\times10^{-5}\ M$$

Checking the assumption:

$$\frac{1.8\times10^{-5}\ M}{0.50\ M} \times 100 = 3.6\times10^{-3}\% < 5\%$$

The assumption is justified, and we will use the same assumption in parts (b) and (c).
Calculating pH:

$$pH = -\log [H_3O^+] = -\log (1.8\times10^{-5}) = 4.74$$

(b) The pH after adding base (0.020 mol of NaOH to 1.0 L of buffer). Finding $[OH^-]_{added}$:

$$[OH^-]_{added} = \frac{0.020 \text{ mol } OH^-}{1.0 \text{ L soln}} = 0.020\ M\ OH^-$$

Setting up a reaction table for the *stoichiometry* of adding OH^- to CH_3COOH:

Concentration (M)	$CH_3COOH(aq)$	+	$OH^-(aq)$	⟶	$CH_3COO^-(aq)$	+	$H_2O(aq)$
Before addition	0.50		—		0.50		—
Addition	—		0.020		—		—
After addition	0.48		0		0.52		—

Setting up a reaction table for the *acid dissociation*, using these new initial concentrations. As in part (a), $x = [CH_3COOH]_{dissoc} = [H_3O^+]$:

Concentration (M)	$CH_3COOH(aq)$	+	$H_2O(l)$	⇌	$CH_3COO^-(aq)$	+	$H_3O^+(aq)$
Initial	0.48		—		0.52		0
Change	$-x$		—		$+x$		$+x$
Equilibrium	$0.48 - x$		—		$0.52 + x$		x

Making the assumption that x is small, and solving for x:

$$[CH_3COOH] = 0.48\ M - x \approx 0.48\ M \quad \text{and} \quad [CH_3COO^-] = 0.52\ M + x \approx 0.52\ M$$

$$x = [H_3O^+] = K_a \times \frac{[CH_3COOH]}{[CH_3COO^-]} \approx (1.8\times10^{-5}) \times \frac{0.48}{0.52} = 1.7\times10^{-5}\ M$$

Calculating the pH:

$$pH = -\log [H_3O^+] = -\log (1.7\times10^{-5}) = 4.77$$

The addition of strong base increased the concentration of the basic buffer component at the expense of the acidic buffer component. Note especially that the pH *increased only slightly*, from 4.74 to 4.77.

(c) The pH after adding acid (0.020 mol of HCl to 1.0 L of buffer). Finding $[H_3O^+]_{added}$:

$$[H_3O^+]_{added} = \frac{0.020 \text{ mol } H_3O^+}{1.0 \text{ L soln}} = 0.020\ M\ H_3O^+$$

Now we proceed as in part (b), by first setting up a reaction table for the *stoichiometry* of adding H_3O^+ to CH_3COO^-:

Concentration (M)	$CH_3COO^-(aq)$	+	$H_3O^+(aq)$	⟶	$CH_3COOH(aq)$	+	$H_2O(l)$
Before addition	0.50		—		0.50		—
Addition	—		0.020		—		—
After addition	0.48		0		0.52		—

The reaction table for the acid dissociation, with $x = [CH_3COOH]_{dissoc} = [H_3O^+]$ is

Concentration (M)	$CH_3COOH(aq)$	+	$H_2O(l)$	⇌	$CH_3COO^-(aq)$	+	$H_3O^+(aq)$
Initial	0.52		—		0.48		0
Change	$-x$		—		$+x$		$+x$
Equilibrium	$0.52 - x$		—		$0.48 + x$		x

Making the assumption that x is small, and solving for x:

$$[CH_3COOH] = 0.52\ M - x \approx 0.52\ M \quad \text{and} \quad [CH_3COO^-] = 0.48\ M + x \approx 0.48\ M$$

$$x = [H_3O^+] = K_a \times \frac{[CH_3COOH]}{[CH_3COO^-]} \approx (1.8\times10^{-5}) \times \frac{0.52}{0.48} = 2.0\times10^{-5}\ M$$

Calculating the pH:

$$pH = -\log [H_3O^+] = -\log (2.0\times10^{-5}) = 4.70$$

The addition of strong acid increased the concentration of the acidic buffer component at the expense of the basic buffer component and *lowered* the pH only slightly, from 4.74 to 4.70.

Check The changes in $[CH_3COOH]$ and $[CH_3COO^-]$ occur in opposite directions in parts (b) and (c), which makes sense. The additions were of equal amounts, so the pH increase in (b) should equal the pH decrease in (c), within rounding.

Comment In part (a), we justified our assumption that x can be neglected. Therefore, in parts (b) and (c), we could have used the "After addition" values from the last line of the stoichiometry tables directly for the ratio of buffer components; that would have allowed us to dispense with a reaction table for the dissociation. In subsequent problems in this chapter, we will follow this simplified approach.

FOLLOW-UP PROBLEM 19.1 Calculate the pH of a buffer consisting of 0.50 *M* HF and 0.45 *M* F^- (**a**) before and (**b**) after addition of 0.40 g of NaOH to 1.0 L of the buffer (K_a of HF = 6.8×10^{-4}).

The Henderson-Hasselbalch Equation

For any weak acid, HA, the equation and K_a expression for the acid dissociation at equilibrium are

$$HA + H_2O \rightleftharpoons H_3O^+ + A^-$$

$$K_a = \frac{[H_3O^+][A^-]}{[HA]}$$

A simple mathematical rearrangement turns this expression into a more useful form for buffer calculations. Remember that the key variable that determines $[H_3O^+]$ is the concentration *ratio* of acid species to base species. Isolating $[H_3O^+]$ gives

$$[H_3O^+] = K_a \times \frac{[HA]}{[A^-]}$$

Taking the negative common logarithm (base 10) of both sides gives

$$-\log [H_3O^+] = -\log K_a - \log \left(\frac{[HA]}{[A^-]}\right)$$

from which we obtain

$$pH = pK_a + \log \left(\frac{[A^-]}{[HA]}\right)$$

(Note the inversion of the buffer-component concentration ratio when the sign of the logarithm is changed.) A key point we'll emphasize again later is that when $[A^-] = [HA]$, their ratio becomes 1; the log term then becomes 0, and thus $pH = pK_a$.

Generalizing the previous equation for any conjugate acid-base pair gives the **Henderson-Hasselbalch equation:**

$$pH = pK_a + \log \left(\frac{[base]}{[acid]}\right) \qquad (19.1)$$

This relationship allows us to solve directly for pH instead of having to calculate $[H_3O^+]$ first. For instance, by applying the Henderson-Hasselbalch equation in part (b) of Sample Problem 19.1, we could have found the pH of the buffer after the addition of NaOH as follows:

$$pH = pK_a + \log \left(\frac{[CH_3COO^-]}{[CH_3COOH]}\right)$$

$$= 4.74 + \log \left(\frac{0.52}{0.48}\right) = 4.77$$

(We just derived the Henderson-Hasselbalch equation from fundamental definitions and simple algebra. It's always a good idea to derive simple relationships this way rather than having to memorize them.)

Buffer Capacity and Buffer Range

As you've seen, a buffer resists a pH change as long as the concentrations of buffer components are *large* compared with the amount of strong acid or base added. **Buffer capacity** is a measure of this ability to resist pH change and depends on both the absolute and relative component concentrations.

In absolute terms, *the more concentrated the components of a buffer, the greater the buffer capacity.* In other words, you must add more H_3O^+ or OH^- to a high-capacity (concentrated) buffer than to a low-capacity (dilute) buffer to obtain the same pH change. Conversely, adding the same amount of H_3O^+ or OH^- to buffers of different capacities produces a smaller pH change in the higher capacity buffer (Figure 19.4). It's important to realize that *the pH of a buffer is distinct from its buffer capacity.* A buffer made of equal volumes of 1.0 *M* CH_3COOH and 1.0 *M* CH_3COO^- has the same pH (4.74) as a buffer made of equal volumes of 0.10 *M* CH_3COOH and 0.10 *M* CH_3COO^-, but the more concentrated buffer has a much larger capacity for resisting a pH change.

Buffer capacity is also affected by the *relative* concentrations of the buffer components. As a buffer functions, the concentration of one component increases relative to the other. Because the ratio of these concentrations determines the pH, the less the ratio changes, the less the pH changes. *For a given addition of acid or base, the concentration ratio changes less when the buffer-component concentrations are similar than when they are different.* Suppose that a buffer has $[HA] = [A^-] = 1.000\ M$. When we add 0.010 mol of OH^- to 1.00 L of buffer, $[A^-]$ becomes 1.010 *M* and [HA] becomes 0.990 *M*:

$$\frac{[A^-]_{init}}{[HA]_{init}} = \frac{1.000\ M}{1.000\ M} = 1.000 \qquad \frac{[A^-]_{final}}{[HA]_{final}} = \frac{1.010\ M}{0.990\ M} = 1.02$$

$$\text{Percent change} = \frac{1.02 - 1.000}{1.000} \times 100 = 2\%$$

Now suppose that the buffer-component concentrations are $[HA] = 0.250\ M$ and $[A^-] = 1.750\ M$. The same addition of 0.010 mol of OH^- to 1.00 L of buffer gives $[HA] = 0.240\ M$ and $[A^-] = 1.760\ M$, so the ratios are

$$\frac{[A^-]_{init}}{[HA]_{init}} = \frac{1.750\ M}{0.250\ M} = 7.00 \qquad \frac{[A^-]_{final}}{[HA]_{final}} = \frac{1.760\ M}{0.240\ M} = 7.33$$

$$\text{Percent change} = \frac{7.33 - 7.00}{7.00} \times 100 = 4.7\%$$

As you can see, the change in the buffer-component concentration ratio is much larger when the initial concentrations of the components are very different.

It follows that *a buffer has the highest capacity when the component concentrations are equal,* that is, when $[A^-]/[HA] = 1$:

$$pH = pK_a + \log\left(\frac{[A^-]}{[HA]}\right) = pK_a + \log 1 = pK_a + 0 = pK_a$$

Note this important result: for a given concentration, *a buffer whose pH is equal to or near the pK_a of its acid component has the highest buffer capacity.*

The **buffer range** is the pH range over which the buffer acts effectively, and it is related to the relative component concentrations. The further the buffer-component concentration ratio is from 1, the less effective the buffering action (that is, the lower the buffer capacity). In practice, if the $[A^-]/[HA]$ ratio is greater than 10 or less than 0.1—that is, if one component concentration is more than 10 times the other—buffering action is poor. Recalling that $\log 10 = +1$ and $\log 0.1 = -1$, we find that *buffers have a usable range within ±1 pH unit of the pK_a of the acid component:*

$$pH = pK_a + \log\left(\frac{10}{1}\right) = pK_a + 1 \qquad \text{and} \qquad pH = pK_a + \log\left(\frac{1}{10}\right) = pK_a - 1$$

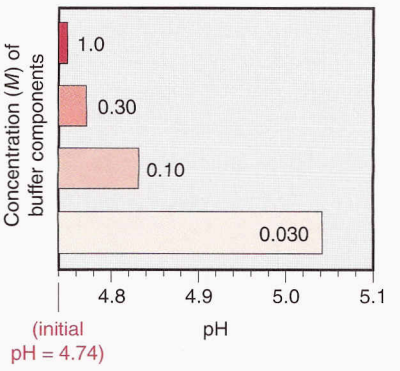

Figure 19.4 The relation between buffer capacity and pH change. The four bars in the graph represent CH_3COOH-CH_3COO^- buffers with the same initial pH (4.74) but different component concentrations (labeled on or near each bar). When a given amount of strong base is added to each buffer, the pH increases. The length of the bar corresponds to the pH increase. Note that the more concentrated the buffer, the greater its capacity, and the smaller the pH change.

Preparing a Buffer

Any large chemical supply-house catalog lists many common buffers in a variety of pH values and concentrations. So, you might ask, why learn how to prepare a buffer? In many cases, a common buffer is simply not available with the desired pH or concentration, and you have to make it yourself. In many environmental or biomedical research applications, a buffer of unusual composition may be required to simulate an ecosystem or stabilize a fragile biological macromolecule. Even the most sophisticated, automated laboratory frequently relies on personnel with a good knowledge of basic chemistry to prepare a buffer. Several steps are required to prepare a buffer of a desired pH:

1. *Choose the conjugate acid-base pair.* First, decide on the chemical composition of the buffer, that is, the conjugate acid-base pair. This choice is determined to a large extent by the desired pH. Remember that a buffer is most effective when the ratio of its component concentrations is close to 1, in which case the pH $\approx$ pK_a of the acid.

Suppose that you need a buffer whose pH is 3.90: the pK_a of the acid component should be as close to 3.90 as possible; or $K_a = 10^{-3.90} = 1.3\times10^{-4}$. Scanning a table of acid-dissociation constants (see Appendix C) shows that lactic acid (pK_a = 3.86), glycolic acid (pK_a = 3.83), and formic acid (pK_a = 3.74) are good choices. To avoid adding common biological species, let's use formic acid. Therefore, the buffer components will be formic acid, HCOOH, and formate ion, $HCOO^-$, supplied by a soluble salt, such as sodium formate, HCOONa.

2. *Calculate the ratio of buffer component concentrations.* Next, find the ratio of $[A^-]/[HA]$ that gives the desired pH. With the Henderson-Hasselbalch equation, we have

$$\text{pH} = \text{p}K_a + \log\left(\frac{[A^-]}{[HA]}\right) \qquad \text{or} \qquad 3.90 = 3.74 + \log\left(\frac{[HCOO^-]}{[HCOOH]}\right)$$

$$\log\left(\frac{[HCOO^-]}{[HCOOH]}\right) = 0.16 \qquad \text{so} \qquad \left(\frac{[HCOO^-]}{[HCOOH]}\right) = 10^{0.16} = 1.4$$

Thus, for every 1.0 mol of HCOOH in a given volume of solution, you need 1.4 mol of HCOONa.

3. *Determine the buffer concentration.* Next, decide how concentrated the buffer should be. Remember that the higher the concentrations of components, the greater the buffer capacity. For most laboratory-scale applications, concentrations of about 0.50 *M* are suitable, but the decision is often based on availability of stock solutions.

Suppose you have a large stock of 0.40 *M* HCOOH and you need approximately 1.0 L of final buffer. First, find the moles of sodium formate that will give the needed 1.4:1.0 ratio, and then convert to grams:

$$\text{Moles of HCOOH} = 1.0\text{ L soln} \times \frac{0.40\text{ mol HCOOH}}{1.0\text{ L soln}} = 0.40\text{ mol HCOOH}$$

$$\text{Moles of HCOONa} = 0.40\text{ mol HCOOH} \times \frac{1.4\text{ mol HCOONa}}{1.0\text{ mol HCOOH}} = 0.56\text{ mol HCOONa}$$

$$\text{Mass (g) of HCOONa} = 0.56\text{ mol HCOONa} \times \frac{68.01\text{ g HCOONa}}{1\text{ mol HCOONa}} = 38\text{ g HCOONa}$$

4. *Mix the solution and adjust the pH.* Thoroughly dissolve 38 g of solid sodium formate in 0.40 *M* HCOOH to a total volume of 1.0 L. Finally, note that because of the behavior of nonideal solutions (Section 13.6), a buffer prepared in this way may vary from the desired pH by a few tenths of a pH unit. Therefore, after making up the solution, *adjust the buffer pH* to the desired value by adding strong acid or strong base, while monitoring the solution with a pH meter. (The following sample problem does not refer to the Henderson-Hasselbalch equation.)

SAMPLE PROBLEM 19.2 Preparing a Buffer

Problem An environmental chemist needs a carbonate buffer of pH 10.00 to study the effects of the acid rain on limestone-rich soils. How many grams of Na_2CO_3 must she add to 1.5 L of freshly prepared 0.20 *M* $NaHCO_3$ to make the buffer? K_a of HCO_3^- is 4.7×10^{-11}.

Plan The conjugate pair is already chosen, HCO_3^- (acid) and CO_3^{2-} (base), as are the volume (1.5 L) and concentration (0.20 *M*) of HCO_3^-, so we must find the buffer-component concentration ratio that gives pH 10.00 and the mass of Na_2CO_3 to dissolve. We first convert pH to $[H_3O^+]$ and use the K_a expression from the equation to solve for the required $[CO_3^{2-}]$. Multiplying by the volume of solution gives the amount (mol) of CO_3^{2-} required, and then we use the molar mass to find the mass (g) of Na_2CO_3.

Solution Calculating $[H_3O^+]$: $[H_3O^+] = 10^{-pH} = 10^{-10.00} = 1.0\times10^{-10}\ M$

Solving for $[CO_3^{2-}]$ in the concentration ratio:

$$HCO_3^-(aq) + H_2O(l) \rightleftharpoons H_3O^+(aq) + CO_3^{2-}(aq) \qquad K_a = \frac{[H_3O^+][CO_3^{2-}]}{[HCO_3^-]}$$

So
$$[CO_3^{2-}] = K_a\frac{[HCO_3^-]}{[H_3O^+]} = \frac{(4.7\times10^{-11})(0.20)}{1.0\times10^{-10}} = 0.094\ M$$

Calculating the amount (mol) of CO_3^{2-} needed for the given volume:

$$\text{Moles of } CO_3^{2-} = 1.5\text{ L soln} \times \frac{0.094\text{ mol } CO_3^{2-}}{1\text{ L soln}} = 0.14\text{ mol } CO_3^{2-}$$

Calculating the mass (g) of Na_2CO_3 needed:

$$\text{Mass (g) of } Na_2CO_3 = 0.14\text{ mol } Na_2CO_3 \times \frac{105.99\text{ g } Na_2CO_3}{1\text{ mol } Na_2CO_3} = 15\text{ g } Na_2CO_3$$

We dissolve 15 g of Na_2CO_3 into 1.3 L of 0.20 *M* $NaHCO_3$ and add 0.20 *M* $NaHCO_3$ to make 1.5 L. Using a pH meter, we adjust the pH to 10.00 with strong acid or base.

Check For a useful buffer range, the concentration of the acidic component, $[HCO_3^-]$, must be within a factor of 10 of the concentration of the basic component, $[CO_3^{2-}]$. We have (1.5 L)(0.20 *M* HCO_3^-), or 0.30 mol of HCO_3^-, and 0.14 mol of CO_3^{2-}; 0.30:0.14 = 2.1, which seems fine. Make sure the relative amounts of components seem reasonable: since we want a pH lower than the pK_a of HCO_3^- (10.33), it makes sense that we have more of the acidic than the basic species.

FOLLOW-UP PROBLEM 19.2 How would you prepare a benzoic acid–benzoate buffer with pH = 4.25, starting with 5.0 L of 0.050 *M* sodium benzoate (C_6H_5COONa) solution and adding the acidic component? K_a of benzoic acid (C_6H_5COOH) is 6.3×10^{-5}.

Another way to prepare a buffer is to form one of the components during the final mixing step by *partial neutralization* of the other component. For example, you can prepare an HCOOH-$HCOO^-$ buffer by mixing appropriate amounts of HCOOH solution and NaOH solution. As the OH^- ions react with the HCOOH molecules, neutralization of part of the total HCOOH present produces the $HCOO^-$ needed:

$$\text{HCOOH (HA total)} + OH^-\text{ (amt added)} \longrightarrow$$
$$\text{HCOOH (HA total} - OH^-\text{ amt added)} + HCOO^-\text{ (}OH^-\text{ amt added)} + H_2O$$

This method is based on the same chemical process that occurs when a weak acid is titrated with a strong base, as you'll see in the next section.

SECTION SUMMARY

A buffered solution exhibits a much smaller change in pH when H_3O^+ or OH^- is added than does an unbuffered solution. A buffer consists of relatively high concentrations of the components of a conjugate weak acid–base pair. The buffer-component concentration ratio determines the pH, and the ratio and pH are related by the Henderson-Hasselbalch equation. As H_3O^+ or OH^- is added, one buffer component

reacts with it and is converted into the other component; therefore, the buffer-component concentration ratio, and consequently the free $[H_3O^+]$ (and pH), changes only slightly. A concentrated buffer undergoes smaller changes in pH than a dilute buffer. When the buffer pH equals the pK_a of the acid component, the buffer has its highest capacity. A buffer has an effective range of $pK_a \pm 1$ pH unit. To prepare a buffer, you choose the conjugate acid-base pair, calculate the ratio of buffer components, determine buffer concentration, and adjust the final solution to the desired pH.

19.2 ACID-BASE TITRATION CURVES

In Chapter 4, we discussed the acid-base titration as an analytical method. Let's re-examine it, this time tracking the change in pH with an **acid-base titration curve,** a plot of pH vs. volume of titrant added. The behavior of an acid-base indicator and its role in the titration are described first. To better understand the titration process, we apply the principles of the acid-base behavior of salt solutions (Section 18.7) and, later in the section, the principles of buffer action.

Monitoring pH with Acid-Base Indicators

The two common devices for measuring pH in the laboratory are pH meters and acid-base indicators. (We discuss the operation of pH meters in Chapter 21.) An *acid-base indicator* is a weak organic acid (denoted as HIn) that has a different color than its conjugate base (In^-), with the color change occurring over a specific and relatively narrow pH range. Typically, one or both of the forms are intensely colored, so only a tiny amount of indicator is needed, far too little to affect the pH of the solution being studied.

Indicators are used for estimating the pH of a solution and for monitoring the pH in acid-base titrations and in reactions. Figure 19.5 shows the color changes and their pH ranges for some common acid-base indicators. Selecting an indicator requires that you know the approximate pH of the titration end point, which in turn requires that you know which ionic species are present. You'll see how to identify those in our discussion of acid-base titration curves.

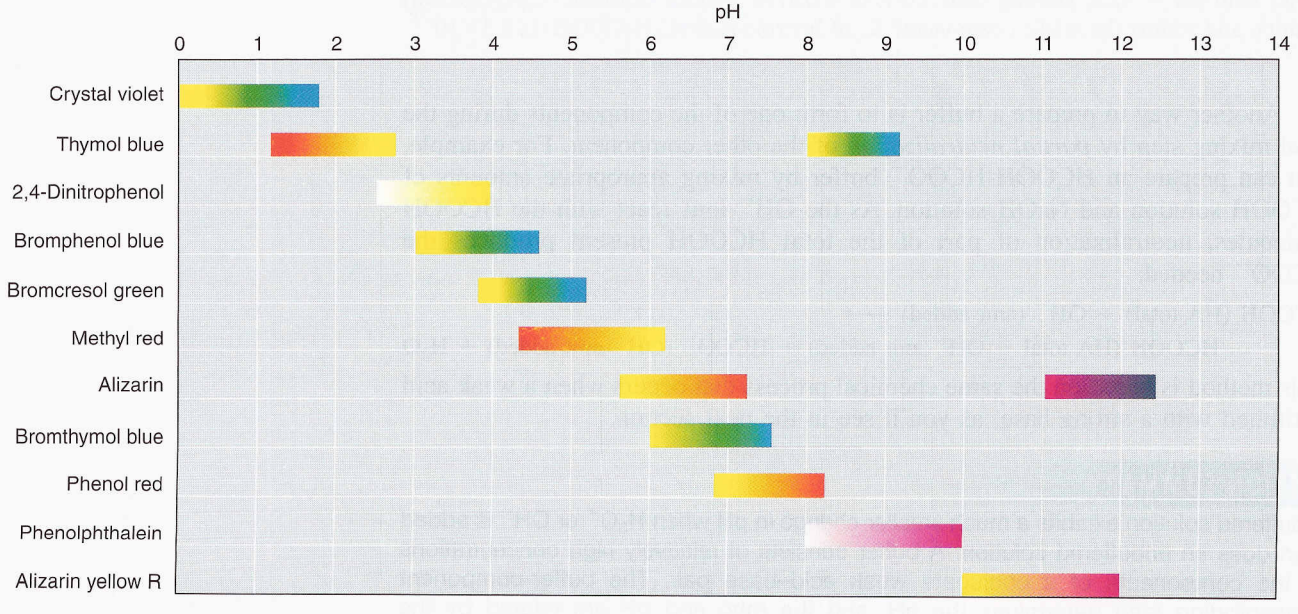

Figure 19.5 Colors and approximate pH range of some common acid-base indicators. Most have a range of about 2 pH units, in keeping with the useful buffer range of 2 pH units ($pK_a \pm 1$). (pH range depends to some extent on the solvent used to prepare the indicator.)

Because the indicator molecule is a weak acid, the ratio of the two forms is governed by the $[H_3O^+]$ of the test solution:

$$HIn(aq) + H_2O(l) \rightleftharpoons H_3O^+(aq) + In^-(aq) \qquad K_a \text{ of HIn} = \frac{[H_3O^+][In^-]}{[HIn]}$$

Therefore,

$$\frac{[HIn]}{[In^-]} = \frac{[H_3O^+]}{K_a}$$

How we perceive colors has a major influence on the use of indicators. Typically, the experimenter will see the HIn color if the $[HIn]/[In^-]$ ratio is 10:1 or greater and the In^- color if the $[HIn]/[In^-]$ ratio is 1:10 or less. Between these extremes, the colors of the two forms merge into an intermediate hue. Therefore, an indicator has a *color range* that reflects a 100-fold range in the [HIn]/[In] ratio, which means that an *indicator changes color over a range of about 2 pH units.* For example, as you can see in Figure 19.5, bromthymol blue has a pH range of about 6.0 to 7.6 and, as Figure 19.6 shows, it is yellow below that range, blue above it, and greenish in between.

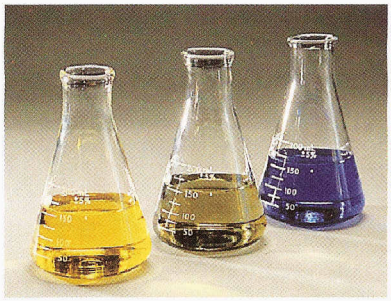

Figure 19.6 The color change of the indicator bromthymol blue. The acidic form of bromthymol blue is yellow (*left*) and the basic form is blue (*right*). Over the pH range in which the indicator is changing, both forms are present, so the mixture appears greenish (*center*).

Strong Acid–Strong Base Titration Curves

A typical curve for the titration of a strong acid with a strong base appears in Figure 19.7, along with the data used to construct it.

Features of the Curve There are three distinct regions of the curve, which correspond to three major changes in slope:

1. The pH starts out low, reflecting the high $[H_3O^+]$ of the strong acid, and increases slowly as acid is gradually neutralized by the added base.
2. Suddenly, the pH rises steeply. This rise begins when the moles of OH^- that have been added nearly equal the moles of H_3O^+ originally present in the acid. An additional drop or two of base neutralizes the final tiny excess of acid and introduces a tiny excess of base, so the pH jumps 6 to 8 units.
3. Beyond this steep portion, the pH increases slowly as more base is added.

The **equivalence point,** which occurs within the nearly vertical portion of the curve, is the point at which the *number of moles of added OH^- equals the number of moles of H_3O^+* originally present. At the equivalence point of a strong

A

Volume of NaOH added (mL)	pH
00.00	1.00
10.00	1.22
20.00	1.48
30.00	1.85
35.00	2.18
39.00	2.89
39.50	3.20
39.75	3.50
39.90	3.90
39.95	4.20
39.99	4.90

70.00	12.43
80.00	12.52

B

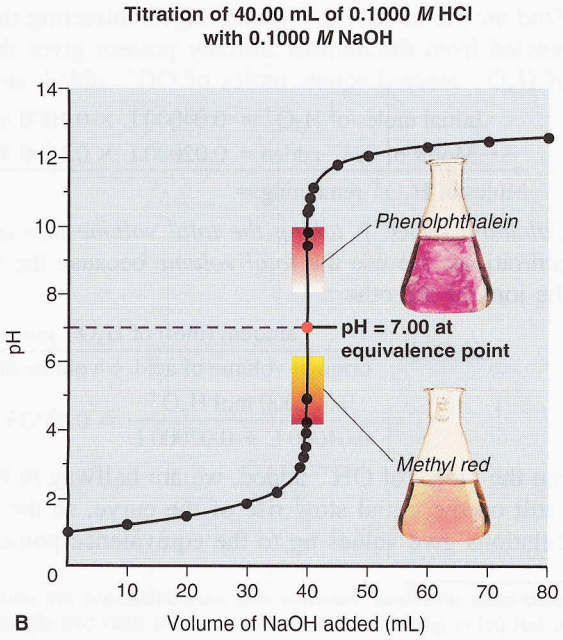

Figure 19.7 Curve for a strong acid–strong base titration. A, Data obtained from the titration of 40.00 mL of 0.1000 *M* HCl with 0.1000 *M* NaOH. **B,** Acid-base titration curve from data in part A. The pH increases gradually at first. When the amount (mol) of OH^- added is slightly less than the amount (mol) of H_3O^+ originally present, a large pH change accompanies a small addition of OH^-. The equivalence point occurs when amount (mol) of OH^- added = amount (mol) of H_3O^+ originally present. Note that, for a strong acid–strong base titration, pH = 7.00 at the equivalence point. Added before the titration begins, either methyl red or phenolphthalein is a suitable indicator in this case because each changes color on the steep portion of the curve, as shown by the color strips. Photos showing the color changes from 1–2 drops of indicator appear nearby. Beyond this point, added OH^- causes a gradual pH increase again.

Animation: Acid-Base Titration
Online Learning Center

acid–strong base titration, *the solution consists of the anion of the strong acid and the cation of the strong base*. Recall from Chapter 18 that *these ions do not react with water, so the solution is neutral: pH = 7.00*. The volume and concentration of base needed to reach the equivalence point allow us to calculate the amount of acid originally present (see Sample Problem 4.5, p. 147).

Before the titration begins, we add a few drops of an appropriate indicator to the acid solution to signal when we reach the equivalence point. The **end point** of the titration occurs when the indicator changes color. *We choose an indicator with an end point close to the equivalence point,* one that changes color in the pH range on the steep vertical portion of the curve. Figure 19.7 shows the color changes for two indicators that are suitable for a strong acid–strong base titration. Methyl red changes from red at pH 4.2 to yellow at pH 6.3, whereas phenolphthalein changes from colorless at pH 8.3 to pink at pH 10.0. Even though neither color change occurs *at* the equivalence point (pH 7.00), both occur on the vertical portion of the curve, where a single drop of base causes a large pH change: when methyl red turns yellow, or when phenolphthalein turns pink, we know we are within a fraction of a drop from the equivalence point. For example, in going from 39.90 to 39.99 mL, one to two drops, the pH changes one whole unit. For all practical purposes, then, the *visible* change in color of the indicator (end point) signals the *invisible* point at which moles of added base equal the original moles of acid (equivalence point).

Calculating the pH By knowing the chemical species present during the titration, we can calculate the pH at various points along the way:

1. *Original solution of strong HA*. In Figure 19.7, 40.00 mL of 0.1000 *M* HCl is titrated with 0.1000 *M* NaOH. Because a strong acid is completely dissociated, $[HCl] = [H_3O^+] = 0.1000\ M$. Therefore, the initial pH is*

$$pH = -\log [H_3O^+] = -\log (0.1000) = 1.00$$

2. *Before the equivalence point*. As soon as we start adding base, two changes occur that affect the pH calculations: (1) some acid is neutralized, and (2) the volume of solution increases. To find the pH at various points up to the equivalence point, we find the initial *amount (mol)* of H_3O^+ present, subtract the amount reacted, *which equals the amount (mol) of* OH^- *added*, and then use the change in volume to calculate the *concentration*, $[H_3O^+]$, and convert to pH. For example, after adding 20.00 mL of 0.1000 *M* NaOH:

- *Find the moles of* H_3O^+ *remaining*. Subtracting the number of moles of H_3O^+ reacted from the number initially present gives the number remaining. Moles of H_3O^+ reacted equals moles of OH^- added, so

$$\begin{array}{rl} \text{Initial moles of } H_3O^+ = & 0.04000\ \text{L} \times 0.1000\ M = 0.004000\ \text{mol } H_3O^+ \\ -\text{Moles of } OH^- \text{ added} = & 0.02000\ \text{L} \times 0.1000\ M = 0.002000\ \text{mol } OH^- \\ \hline \text{Moles of } H_3O^+ \text{ remaining} = & \qquad\qquad 0.002000\ \text{mol } H_3O^+ \end{array}$$

- *Calculate* $[H_3O^+]$*, taking the total volume into account*. To find the ion concentrations, we use the *total volume* because the water of one solution dilutes the ions of the other:

$$[H_3O^+] = \frac{\text{amount (mol) of } H_3O^+ \text{ remaining}}{\text{original volume of acid} + \text{volume of added base}}$$

$$= \frac{0.002000\ \text{mol } H_3O^+}{0.04000\ \text{L} + 0.02000\ \text{L}} = 0.03333\ M \qquad pH = 1.48$$

Given the moles of OH^- added, we are halfway to the equivalence point; but we are still on the initial slow rise of the curve, so the pH is still very low. Similar calculations give values up to the equivalence point.

*In acid-base titrations, volumes and concentrations are usually known to four significant figures, but pH is generally reported to no more than two digits to the right of the decimal point.

3. *At the equivalence point.* After 40.00 mL of 0.1000 *M* NaOH has been added, the equivalence point is reached. All the H_3O^+ from the acid has been neutralized, and the solution contains Na^+ and Cl^-, neither of which reacts with water. Because of the autoionization of water, however,

$$[H_3O^+] = 1.0\times10^{-7}\ M \qquad pH = 7.00$$

In this example, 0.004000 mol of OH^- reacted with 0.004000 mol of H_3O^+ to reach the equivalence point.

4. *After the equivalence point.* From the equivalence point on, the pH calculation is based on the moles of *excess* OH^- present. For example, after adding 50.00 mL of NaOH, we have

$$\begin{aligned}&\text{Total moles of } OH^- \text{ added} = 0.05000\ \text{L} \times 0.1000\ M = 0.005000\ \text{mol } OH^-\\ &-\text{Moles of } H_3O^+ \text{ consumed} = 0.04000\ \text{L} \times 0.1000\ M = 0.004000\ \text{mol } H_3O^+\\ &\text{Moles of excess } OH^- = \qquad\qquad 0.001000\ \text{mol } OH^-\end{aligned}$$

$$[OH^-] = \frac{0.001000\ \text{mol } OH^-}{0.04000\ \text{L} + 0.05000\ \text{L}} = 0.01111\ M \qquad pOH = 1.95$$

$$pH = pK_w - pOH = 14.00 - 1.95 = 12.05$$

Weak Acid–Strong Base Titration Curves

Now let's turn to the titration of a weak acid with a strong base. Figure 19.8 shows the curve obtained when we use 0.1000 *M* NaOH to titrate 40.00 mL of 0.1000 *M* propanoic acid, a weak organic acid (CH_3CH_2COOH; $K_a = 1.3\times10^{-5}$). (We abbreviate the acid as HPr and the conjugate base, $CH_3CH_2COO^-$, as Pr^-.)

Features of the Curve When we compare this weak acid–strong base titration curve with the strong acid–strong base titration curve (dotted curve portion in Figure 19.8 corresponds to bottom half of curve in Figure 19.7), four key regions appear, and the first three differ from the strong acid case:

1. *The initial pH is higher.* Because the weak acid (HPr) dissociates slightly, less H_3O^+ is present than with the strong acid.
2. *A gradually rising portion of the curve, called the buffer region, appears before the steep rise to the equivalence point.* As HPr reacts with the strong base, more and more conjugate base (Pr^-) forms, which creates an HPr-Pr^- buffer. At the midpoint of the buffer region, *half the original HPr has reacted,* so [HPr] = [Pr^-], or [Pr^-]/[HPr] = 1. Therefore, *the pH equals the* pK_a:

$$pH = pK_a + \log\left(\frac{[Pr^-]}{[HPr]}\right) = pK_a + \log 1 = pK_a + 0 = pK_a$$

   Observing the pH at the midpoint of the buffer region is a common method for estimating the pK_a of an unknown acid.
3. *The pH at the equivalence point is greater than 7.00.* The solution contains the strong-base cation Na^+, which does not react with water, and the weak-acid anion Pr^-, which acts as a weak base to accept a proton from H_2O and yield OH^-.
4. Beyond the equivalence point, the pH increases slowly as *excess* OH^- is added.

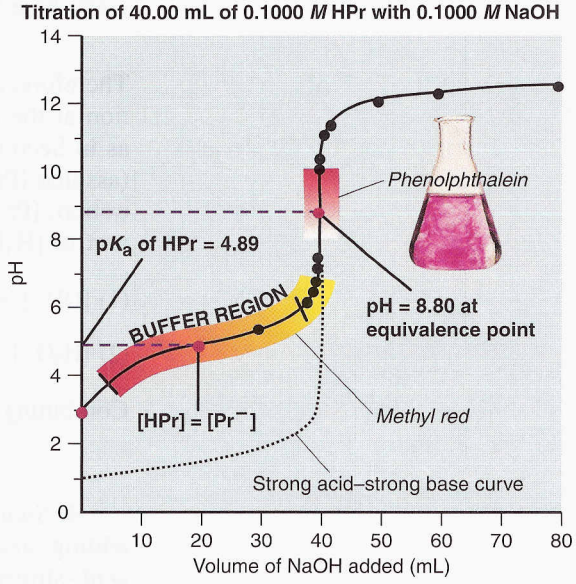

Figure 19.8 Curve for a weak acid–strong base titration. The curve for the titration of 40.00 mL of 0.1000 *M* CH_3CH_2COOH (HPr) with 0.1000 *M* NaOH is compared with that for the strong acid HCl (*dotted curve portion*). Phenolphthalein (*photo*) is a suitable indicator here.

Our choice of indicator is more limited here than for a strong acid–strong base titration because the steep rise occurs over a smaller pH range. Phenolphthalein is suitable because its color change lies within this range (Figure 19.8). However, the figure shows that methyl red, our other choice for the strong acid–strong base titration, changes color earlier and slowly over a large volume (~10 mL) of titrant, thereby giving a vague and false indication of the equivalence point.

Calculating the pH The calculation procedure for the weak acid–strong base titration is different from the previous case because we have to consider the partial dissociation of the weak acid and the reaction of the conjugate base with water. There are four key regions of the titration curve, each of which requires a different type of calculation to find $[H_3O^+]$:

1. *Solution of HA.* Before base is added, the $[H_3O^+]$ is that of a weak-acid solution, so we find $[H_3O^+]$ as in Section 18.4: we set up a reaction table with $x = [HPr]_{dissoc}$, assume $[H_3O^+] = [HPr]_{dissoc} << [HPr]_{init}$, and solve for x:

$$K_a = \frac{[H_3O^+][Pr^-]}{[HPr]} \approx \frac{x^2}{[HPr]_{init}} \qquad \text{therefore,} \qquad x = [H_3O^+] \approx \sqrt{K_a \times [HPr]_{init}}$$

2. *Solution of HA and added base.* As soon as we add NaOH, it reacts with HPr to form Pr^-. This means that up to the equivalence point, we have a mixture of acid and conjugate base, and an HPr-Pr^- buffer solution exists over much of that interval. Therefore, we find $[H_3O^+]$ from the relationship

$$[H_3O^+] = K_a \times \frac{[HPr]}{[Pr^-]}$$

(Of course, we can find pH directly with the Henderson-Hasselbalch equation, which is just an alternative form of this relationship.) Note that in this calculation we do *not* have to consider the new total volume because *the volumes cancel in the ratio of concentrations*. That is, $[HPr]/[Pr^-]$ = moles of HPr/moles of Pr^-, so we need not calculate concentrations.

3. *Equivalent amounts of HA and added base.* At the equivalence point, the original amount of HPr has reacted, so the flask contains a solution of Pr^-, a weak base that reacts with water to form OH^-:

$$Pr^-(aq) + H_2O(l) \rightleftharpoons HPr(aq) + OH^-(aq)$$

Therefore, as mentioned previously, in a weak acid–strong base titration, the solution at the equivalence point is slightly basic, pH > 7.00. We calculate $[H_3O^+]$ as in Section 18.5: we first find K_b of Pr^- from K_a of HPr, set up a reaction table (assume $[Pr^-] >> [Pr^-]_{reacting}$), and solve for $[OH^-]$. We need a single concentration, $[Pr^-]$, to solve for $[OH^-]$, so we *do* need the total volume. Then, we convert to $[H_3O^+]$. These two steps are

$$(1)\ [OH^-] \approx \sqrt{K_b \times [Pr^-]}, \quad \text{where } K_b = \frac{K_w}{K_a} \quad \text{and} \quad [Pr^-] = \frac{\text{moles of } HPr_{init}}{\text{total volume}}$$

$$(2)\ [H_3O^+] = \frac{K_w}{[OH^-]}$$

Combining them into one step gives

$$[H_3O^+] \approx \frac{K_w}{\sqrt{K_b \times [Pr^-]}}$$

4. *Solution of excess added base.* Beyond the equivalence point, we are just adding excess OH^- ion, so the calculation is the same as for the strong acid–strong base titration:

$$[H_3O^+] = \frac{K_w}{[OH^-]}, \qquad \text{where } [OH^-] = \frac{\text{moles of excess } OH^-}{\text{total volume}}$$

Sample Problem 19.3 shows the overall approach.

SAMPLE PROBLEM 19.3 Finding the pH During a Weak Acid–Strong Base Titration

Problem Calculate the pH during the titration of 40.00 mL of 0.1000 *M* propanoic acid (HPr; $K_a = 1.3\times10^{-5}$) after adding the following volumes of 0.1000 *M* NaOH:
(a) 0.00 mL **(b)** 30.00 mL **(c)** 40.00 mL **(d)** 50.00 mL

Plan **(a)** 0.00 mL: No base has been added yet, so this is a weak-acid solution. Thus, we calculate the pH as we did in Section 18.4. **(b)** 30.00 mL: A mixture of Pr^- and HPr is

present. We find the amount (mol) of each, substitute into the K_a expression to solve for $[H_3O^+]$, and convert to pH. **(c)** 40.00 mL: The amount (mol) of NaOH added equals the initial amount (mol) of HPr, so a solution of Na^+ and the weak base Pr^- exists. We calculate the pH as we did in Section 18.5, except that we need *total* volume to find $[Pr^-]$. **(d)** 50.00 mL: Excess NaOH is added, so we calculate the amount (mol) of excess OH^- in the total volume and convert to $[H_3O^+]$ and then pH.

Solution **(a)** 0.00 mL of 0.1000 *M* NaOH added. Following the approach used in Sample Problem 18.7 and just described in the text, we obtain

$$[H_3O^+] \approx \sqrt{K_a \times [HPr]_{init}} = \sqrt{(1.3\times10^{-5})(0.1000)} = 1.1\times10^{-3}\ M$$

$$pH = 2.96$$

(b) 30.00 mL of 0.1000 *M* NaOH added. Calculating the ratio of moles of HPr to Pr^-:

$$\text{Original moles of HPr} = 0.04000\ \text{L} \times 0.1000\ M = 0.004000\ \text{mol HPr}$$

$$\text{Moles of NaOH added} = 0.03000\ \text{L} \times 0.1000\ M = 0.003000\ \text{mol } OH^-$$

For 1 mol of NaOH that reacts, 1 mol of Pr^- forms, so we construct the following reaction table for the stoichiometry:

Amount (mol)	$HPr(aq)$	+	$OH^-(aq)$	⟶	$Pr^-(aq)$	+	$H_2O(l)$
Before addition	0.004000		—		0		—
Addition	—		0.003000		—		—
After addition	0.001000		0		0.003000		—

The last line of this table shows the new initial amounts of HPr and Pr^- that will react to attain a new equilibrium. However, with x very small, we assume that the $[HPr]/[Pr^-]$ ratio at equilibrium is essentially equal to the ratio of these new initial amounts (see Comment in Sample Problem 19.1). Thus,

$$\frac{[HPr]}{[Pr^-]} = \frac{0.001000\ \text{mol}}{0.003000\ \text{mol}} = 0.3333$$

Solving for $[H_3O^+]$:

$$[H_3O^+] = K_a \times \frac{[HPr]}{[Pr^-]} = (1.3\times10^{-5})(0.3333) = 4.3\times10^{-6}\ M$$

$$pH = 5.37$$

(c) 40.00 mL of 0.1000 *M* NaOH added. Calculating $[Pr^-]$ after all HPr has reacted:

$$[Pr^-] = \frac{0.004000\ \text{mol}}{0.04000\ \text{L} + 0.04000\ \text{L}} = 0.05000\ M$$

Calculating K_b:

$$K_b = \frac{K_w}{K_a} = \frac{1.0\times10^{-14}}{1.3\times10^{-5}} = 7.7\times10^{-10}$$

Solving for $[H_3O^+]$ as described in the text:

$$[H_3O^+] \approx \frac{K_w}{\sqrt{K_b \times [Pr^-]}} = \frac{1.0\times10^{-14}}{\sqrt{(7.7\times10^{-10})(0.05000)}} = 1.6\times10^{-9}\ M$$

$$pH = 8.80$$

(d) 50.00 mL of 0.1000 *M* NaOH added.

$$\text{Moles of excess } OH^- = (0.1000\ M)(0.05000\ \text{L} - 0.04000\ \text{L}) = 0.001000\ \text{mol}$$

$$[OH^-] = \frac{\text{moles of excess } OH^-}{\text{total volume}} = \frac{0.001000\ \text{mol}}{0.09000\ \text{L}} = 0.01111\ M$$

$$[H_3O^+] = \frac{K_w}{[OH^-]} = \frac{1.0\times10^{-14}}{0.01111} = 9.0\times10^{-13}\ M$$

$$pH = 12.05$$

Check As expected from the continuous addition of base, the pH increases through the four stages. Be sure to round off and check the arithmetic along the way.

FOLLOW-UP PROBLEM 19.3 A chemist titrates 20.00 mL of 0.2000 *M* HBrO ($K_a = 2.3\times10^{-9}$) with 0.1000 *M* NaOH. What is the pH **(a)** before any base is added; **(b)** when $[HBrO] = [BrO^-]$; **(c)** at the equivalence point; **(d)** when the moles of OH^- added are twice the moles of HBrO originally present? **(e)** Sketch the titration curve.

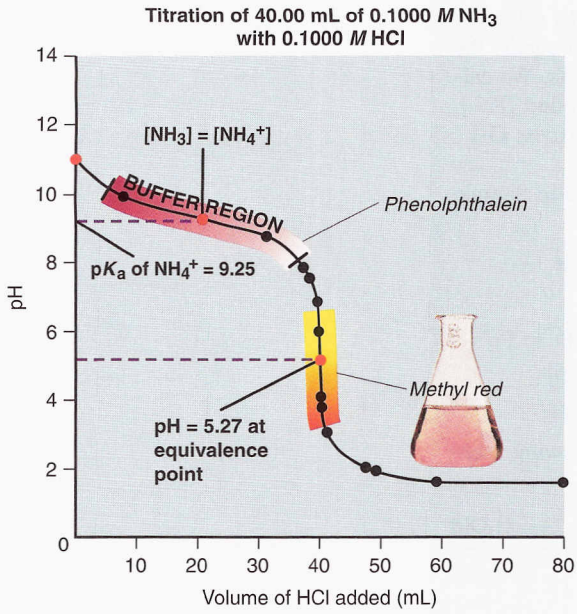

Figure 19.9 Curve for a weak base–strong acid titration. Titrating 40.00 mL of 0.1000 *M* NH_3 with a solution of 0.1000 *M* HCl leads to a curve whose shape is the same as that of the weak acid–strong base curve in Figure 19.8 but inverted. The midpoint of the buffer region occurs when $[NH_3] = [NH_4^+]$; the pH at this point equals the pK_a of NH_4^+. Methyl red (*photo*) is a suitable indicator here.

Weak Base–Strong Acid Titration Curves

In the previous case, we titrated a weak acid with a strong base. The opposite process is the titration of a weak base (NH_3) with a strong acid (HCl), shown in Figure 19.9. Note that *the curve has the same shape as the weak acid–strong base curve* (Figure 19.8, p. 827), *but it is inverted.* Thus, the regions of the curve have the same features, but *the pH decreases* throughout the process:

1. The initial solution is that of a weak base, so *the pH starts out above 7.00.*
2. The pH decreases gradually in the buffer region, where significant amounts of base (NH_3) and conjugate acid (NH_4^+) are present. At the midpoint of the buffer region, *the pH equals the* pK_a of the ammonium ion.
3. After the buffer region, the curve drops vertically to the equivalence point, at which all the NH_3 has reacted and the solution contains only NH_4^+ and Cl^-. Note that *the pH at the equivalence point is below 7.00* because Cl^- does not react with water and NH_4^+ is acidic:

$$NH_4^+(aq) + H_2O(l) \rightleftharpoons NH_3(aq) + H_3O^+(aq)$$

4. Beyond the equivalence point, the pH decreases slowly as *excess* H_3O^+ is added.

For this titration also, we must be more careful in choosing the indicator than for a strong acid–strong base titration. Phenolphthalein changes color too soon and too slowly to indicate the equivalence point; but methyl red lies on the steep portion of the curve and straddles the equivalence point, so it is a perfect choice.

Titration Curves for Polyprotic Acids

As we discussed in Section 18.4, polyprotic acids have more than one ionizable proton. Except for sulfuric acid, the common polyprotic acids are all weak. The successive K_a values for a polyprotic acid differ by several orders of magnitude, which means that the first H^+ is lost much more easily than subsequent ones, as these values for sulfurous acid show:

$$H_2SO_3(aq) + H_2O(l) \rightleftharpoons HSO_3^-(aq) + H_3O^+(aq)$$
$$K_{a1} = 1.4\times10^{-2} \quad \text{and} \quad pK_{a1} = 1.85$$

$$HSO_3^-(aq) + H_2O(l) \rightleftharpoons SO_3^{2-}(aq) + H_3O^+(aq)$$
$$K_{a2} = 6.5\times10^{-8} \quad \text{and} \quad pK_{a2} = 7.19$$

In a titration of a diprotic acid such as H_2SO_3, two OH^- ions are required to completely remove both H^+ ions from each molecule of acid. Figure 19.10 shows the titration curve for sulfurous acid with strong base. Because of the large difference in K_a values, we assume that each mole of H^+ is titrated separately; that is, all H_2SO_3 molecules lose one H^+ before any HSO_3^- ions lose one:

$$H_2SO_3 \xrightarrow{1\text{ mol }OH^-} HSO_3^- \xrightarrow{1\text{ mol }OH^-} SO_3^{2-}$$

As you can see from the curve in Figure 19.10, the loss of each mole of H^+ shows up as a separate equivalence point and buffer region. As on the curve for a weak monoprotic acid (Figure 19.8, p. 827), the pH at the midpoint of the buffer region is equal to the pK_a of that acidic species. Note also that the same volume of added base (in this case, 40.00 mL of 0.1000 *M* OH^-) is required to remove each mole of H^+.

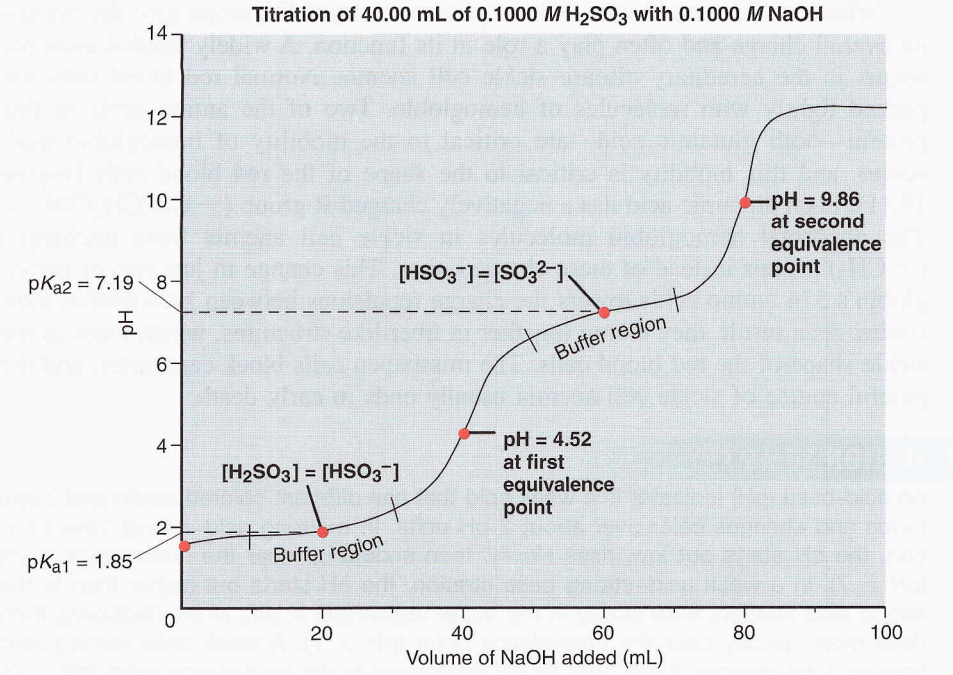

Figure 19.10 Curve for the titration of a weak polyprotic acid. Titrating 40.00 mL of 0.1000 *M* H_2SO_3 with 0.1000 *M* NaOH leads to a curve with two buffer regions and two equivalence points. Because the K_a values are separated by several orders of magnitude, the titration curve looks like two weak acid–strong base curves joined end to end. The pH of the first equivalence point is below 7.00 because the solution contains HSO_3^-, which is a stronger acid than it is a base (K_a of HSO_3^- = 6.5×10^{-8}; K_b of HSO_3^- = 7.1×10^{-13}).

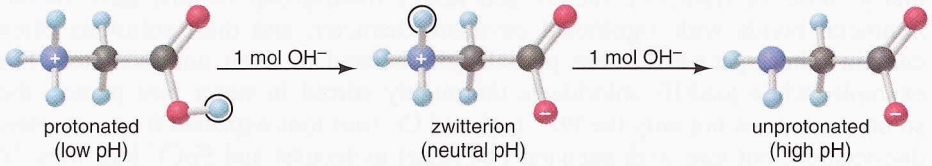
Amino Acids as Biological Polyprotic Acids

Amino acids, the molecules that link together to form proteins (Sections 13.2 and 15.6), have the general formula $NH_2—CH(R)—COOH$, where R can be one of about 20 different groups. At low pH, both the amino group ($—NH_2$) and the acid group (—COOH) are protonated: $^+NH_3—CH(R)—COOH$. Thus, in this form the amino acid behaves like a polyprotic acid. In the case of glycine (R = H), the simplest amino acid, the dissociation reactions and pK_a values are

$$^+NH_3CH_2COOH(aq) + H_2O(l) \rightleftharpoons {}^+NH_3CH_2COO^-(aq) + H_3O^+(aq) \quad pK_{a1} = 2.35$$
$$^+NH_3CH_2COO^-(aq) + H_2O(l) \rightleftharpoons NH_2CH_2COO^-(aq) + H_3O^+(aq) \quad pK_{a2} = 9.78$$

The pK_a values show that the —COOH group is much more acidic than the $—NH_3^+$ group. As we saw with H_2SO_3, the protons are titrated separately, so virtually all the —COOH protons are removed before any $—NH_3^+$ protons are:



Thus, at physiological pH (~7), *glycine exists predominantly as a zwitterion* (German *zwitter,* "double"), a species with opposite charges on the same molecule: $^+NH_3CH_2COO^-$. Among the 20 different R groups of amino acids in proteins, several have *additional* $—COO^-$ or $—NH_3^+$ groups at pH 7 (see Figure 15.28, p. 655).

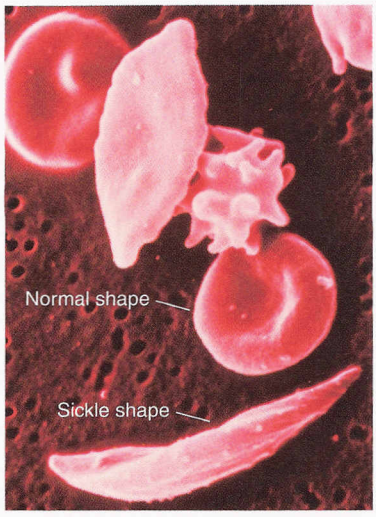


Figure 19.11 Sickle shape of red blood cells in sickle cell anemia.

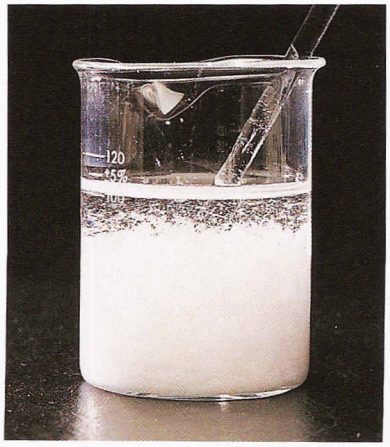
When amino acids link to form a protein, charged R groups give the protein its overall charge and often play a role in its function. A widely studied example occurs in the hereditary disease sickle cell anemia. Normal red blood cells are packed tightly with molecules of hemoglobin. Two of the amino acids in this protein—both glutamic acid—are critical to the mobility of hemoglobin molecules, and this mobility is critical to the shape of the red blood cells (Figure 19.11). Each glutamic acid has a negatively charged R group ($—CH_2CH_2COO^-$). The abnormal hemoglobin molecules in sickle cell anemia have uncharged ($—CH_3$) groups instead of these charged ones. This change in just two of hemoglobin's 574 amino acids lowers the charge repulsions between hemoglobin molecules. As a result, they clump together in fiber-like structures, which leads to the sickle shape of the red blood cells. The misshapen cells block capillaries, and the painful course of sickle cell anemia usually ends in early death.

SECTION SUMMARY

An acid-base (pH) indicator is a weak acid that has different colored acidic and basic forms and changes color over about 2 pH units. In a strong acid–strong base titration, the pH starts out low, rises slowly, then shoots up near the equivalence point (pH = 7). In a weak acid–strong base titration, the pH starts out higher than in the strong acid titration, rises slowly in the buffer region (pH = pK_a at the midpoint), then rises more quickly near the equivalence point (pH > 7). A weak base–strong acid titration is the inverse of this, with its pH decreasing to the equivalence point (pH < 7). Polyprotic acids have two or more acidic protons, each with its own K_a value. Because the K_a's differ by several orders of magnitude, each proton is titrated separately. Amino acids exist in different charged forms that depend on the pH of the solution.

19.3 EQUILIBRIA OF SLIGHTLY SOLUBLE IONIC COMPOUNDS

In this section, we explore the aqueous equilibria of slightly soluble ionic compounds, which up to now we've called "insoluble." In Chapter 13, we found that most solutes, even those called "soluble," have a limited solubility in a particular solvent. Add more than this amount, and some solute remains undissolved. In a saturated solution at a particular temperature, equilibrium exists between the undissolved and dissolved solute. Slightly soluble ionic compounds have a relatively low solubility, so they reach equilibrium with relatively little solute dissolved. At this point, it would be a good idea for you to review the solubility rules listed in Table 4.1 (p. 143).



$PbCl_2$, a slightly soluble ionic compound.

When a soluble ionic compound dissolves in water, it dissociates completely into ions. In this discussion, we will assume that the small amount of a slightly soluble ionic compound that dissolves in water also dissociates completely into ions. In reality, however, this is not the case. Many slightly soluble salts, particularly those of transition metals and heavy main-group metals, have metal-nonmetal bonds with significant covalent character, and their solutions often contain other species that are partially dissociated or even undissociated. For example, when lead(II) chloride is thoroughly stirred in water (see photo), the solution contains not only the $Pb^{2+}(aq)$ and $Cl^-(aq)$ ions expected from complete dissociation, but also undissociated $PbCl_2(aq)$ molecules and $PbCl^+(aq)$ ions. In solutions of some other salts, such as $CaSO_4$, there are no molecules, but pairs of ions exist, such as $Ca^{2+}SO_4^{2-}(aq)$. These species increase the solubility above what we calculate assuming complete dissociation. More advanced courses address these complexities, but we will only hint at some of them in the Comments of several sample problems. For these reasons, it is best to treat our calculations here as first approximations.

The Ion-Product Expression (Q_{sp}) and the Solubility-Product Constant (K_{sp})

If we make the assumption that there is complete dissociation of a slightly soluble ionic compound into its component ions, then *equilibrium exists between solid solute and aqueous ions*. Thus, for example, for a saturated solution of lead(II) sulfate in water, we have

$$PbSO_4(s) \rightleftharpoons Pb^{2+}(aq) + SO_4^{2-}(aq)$$

As with all the other equilibrium systems we've looked at, this one can be expressed by a reaction quotient:

$$Q_c = \frac{[Pb^{2+}][SO_4^{2-}]}{[PbSO_4]}$$

As in previous cases, we combine the constant concentration of the solid, $[PbSO_4]$, with the value of Q_c and eliminate it. This gives the *ion-product expression*, Q_{sp}:

$$Q_{sp} = Q_c[PbSO_4] = [Pb^{2+}][SO_4^{2-}]$$

And, when solid $PbSO_4$ attains equilibrium with Pb^{2+} and SO_4^{2-} ions, that is, when the solution reaches saturation, the numerical value of Q_{sp} attains a constant value. This new equilibrium constant is called the **solubility-product constant, K_{sp}.** The K_{sp} for $PbSO_4$ at 25°C, for example, is 1.6×10^{-8}.

As we've seen with other equilibrium constants, a given K_{sp} value depends only on the temperature, not on the individual ion concentrations. Suppose, for example, you add some lead(II) nitrate, a soluble lead salt, to increase the solution's $[Pb^{2+}]$. The equilibrium position shifts to the left, and $[SO_4^{2-}]$ goes down as more $PbSO_4$ precipitates; so the K_{sp} value is maintained.

The form of Q_{sp} is identical to that of the other reaction quotients we have written: each ion concentration is raised to an exponent equal to the coefficient in the balanced equation, which in this case also *equals the subscript of each ion in the compound's formula*. Thus, in general, for a saturated solution of a slightly soluble ionic compound, M_pX_q, composed of the ions M^{n+} and X^{z-}, the equilibrium condition is

$$Q_{sp} = [M^{n+}]^p[X^{z-}]^q = K_{sp} \qquad (19.2)$$

Of course, at saturation, the concentration terms represent equilibrium concentrations, so from here on, we write the ion-product expression directly with the symbol K_{sp}. For example, the equation and ion-product expression that describe a saturated solution of $Cu(OH)_2$ are

$$Cu(OH)_2(s) \rightleftharpoons Cu^{2+}(aq) + 2OH^-(aq) \qquad K_{sp} = [Cu^{2+}][OH^-]^2$$

Insoluble metal sulfides present a slightly different case. The sulfide ion, S^{2-}, is so basic that it is not stable in water and reacts completely to form the hydrogen sulfide ion (HS^-) and the hydroxide ion (OH^-):

$$S^{2-}(aq) + H_2O(l) \longrightarrow HS^-(aq) + OH^-(aq)$$

For instance, when manganese(II) sulfide is shaken with water, the solution contains Mn^{2+}, HS^-, and OH^- ions. Although the sulfide ion does not exist as such in water, you can imagine the dissolution process as the sum of two steps, with S^{2-} occurring as an intermediate that is consumed immediately:

$$\begin{aligned} MnS(s) &\rightleftharpoons Mn^{2+}(aq) + \cancel{S^{2-}(aq)} \\ \cancel{S^{2-}(aq)} + H_2O(l) &\longrightarrow HS^-(aq) + OH^-(aq) \\ \hline MnS(s) + H_2O(l) &\rightleftharpoons Mn^{2+}(aq) + HS^-(aq) + OH^-(aq) \end{aligned}$$

Therefore, the ion-product expression is

$$K_{sp} = [Mn^{2+}][HS^-][OH^-]$$

SAMPLE PROBLEM 19.4 Writing Ion-Product Expressions for Slightly Soluble Ionic Compounds

Problem Write the ion-product expression for each of the following compounds:
(a) Magnesium carbonate
(b) Iron(II) hydroxide
(c) Calcium phosphate
(d) Silver sulfide

Plan We write an equation that describes a saturated solution and then write the ion-product expression, K_{sp}, according to Equation 19.2, noting the sulfide in part (d).

Solution **(a)** Magnesium carbonate:

$$MgCO_3(s) \rightleftharpoons Mg^{2+}(aq) + CO_3^{2-}(aq) \qquad K_{sp} = [Mg^{2+}][CO_3^{2-}]$$

(b) Iron(II) hydroxide:

$$Fe(OH)_2(s) \rightleftharpoons Fe^{2+}(aq) + 2OH^-(aq) \qquad K_{sp} = [Fe^{2+}][OH^-]^2$$

(c) Calcium phosphate:

$$Ca_3(PO_4)_2(s) \rightleftharpoons 3Ca^{2+}(aq) + 2PO_4^{3-}(aq) \qquad K_{sp} = [Ca^{2+}]^3[PO_4^{3-}]^2$$

(d) Silver sulfide:

$$Ag_2S(s) \rightleftharpoons 2Ag^+(aq) + \cancel{S^{2-}(aq)}$$
$$\cancel{S^{2-}(aq)} + H_2O(l) \longrightarrow HS^-(aq) + OH^-(aq)$$
$$Ag_2S(s) + H_2O(l) \rightleftharpoons 2Ag^+(aq) + HS^-(aq) + OH^-(aq) \qquad K_{sp} = [Ag^+]^2[HS^-][OH^-]$$

Check Except for part (d), you can check by reversing the process to see if you obtain the formula of the compound from K_{sp}.

Comment In part (d), we include H_2O as reactant to obtain a balanced equation.

FOLLOW-UP PROBLEM 19.4 Write the ion-product expression for each of the following compounds:
(a) Calcium sulfate
(b) Chromium(III) carbonate
(c) Magnesium hydroxide
(d) Arsenic(III) sulfide

Table 19.2 Solubility-Product Constants (K_{sp}) of Selected Ionic Compounds at 25°C

Name, Formula	K_{sp}
Aluminum hydroxide, $Al(OH)_3$	3×10^{-34}
Cobalt(II) carbonate, $CoCO_3$	1.0×10^{-10}
Iron(II) hydroxide, $Fe(OH)_2$	4.1×10^{-15}
Lead(II) fluoride, PbF_2	3.6×10^{-8}
Lead(II) sulfate, $PbSO_4$	1.6×10^{-8}
Mercury(I) iodide, Hg_2I_2	4.7×10^{-29}
Silver sulfide, Ag_2S	8×10^{-48}
Zinc iodate, $Zn(IO_3)_2$	3.9×10^{-6}

The magnitude of the solubility-product constant, K_{sp}, is a measure of how far to the right the dissolution proceeds at equilibrium (saturation). We'll use K_{sp} values later to compare solubilities. Table 19.2 presents some representative K_{sp} values of slightly soluble ionic compounds. (Appendix C includes a much more extensive list.) Note that, even though the values are all quite low, they range over many orders of magnitude.

Calculations Involving the Solubility-Product Constant

In Chapters 17 and 18, we described two types of equilibrium problems. In one type, we use concentrations to find K, and in the other, we use K to find concentrations. Here we encounter the same two types.

Determining K_{sp} from Solubility The solubilities of ionic compounds are determined experimentally, and several chemical handbooks tabulate them. Most solubility values are given in units of grams of solute dissolved in 100 grams of H_2O. Because the mass of compound in solution is small, a negligible error is introduced if we assume that "100 g of water" is equal to "100 mL of solution." We then convert the solubility from grams of solute per 100 mL of solution to **molar solubility,** the amount (mol) of solute dissolved per liter of solution (that is, the molarity of the solute). Next, we use the equation showing the dissolution of the solute to find the molarity of each ion and substitute into the ion-product expression to find the value of K_{sp}.

SAMPLE PROBLEM 19.5 Determining K_{sp} from Solubility

Problem **(a)** Lead(II) sulfate ($PbSO_4$) is a key component in lead-acid car batteries. Its solubility in water at 25°C is 4.25×10^{-3} g/100 mL solution. What is the K_{sp} of $PbSO_4$? **(b)** When lead(II) fluoride (PbF_2) is shaken with pure water at 25°C, the solubility is found to be 0.64 g/L. Calculate the K_{sp} of PbF_2.

Plan We are given the solubilities in various units and must find K_{sp}. For each compound, we write an equation for its dissolution to see the number of moles of each ion, and then write the ion-product expression. We convert the solubility to molar solubility, find the molarity of each ion, and substitute into the ion-product expression to calculate K_{sp}.

Solution **(a)** For $PbSO_4$. Writing the equation and ion-product (K_{sp}) expression:

$$PbSO_4(s) \rightleftharpoons Pb^{2+}(aq) + SO_4^{2-}(aq) \qquad K_{sp} = [Pb^{2+}][SO_4^{2-}]$$

Converting solubility to molar solubility:

$$\text{Molar solubility of } PbSO_4 = \frac{0.00425 \text{ g } PbSO_4}{100 \text{ mL soln}} \times \frac{1000 \text{ mL}}{1 \text{ L}} \times \frac{1 \text{ mol } PbSO_4}{303.3 \text{ g } PbSO_4}$$
$$= 1.40\times10^{-4}\ M\ PbSO_4$$

Determining molarities of the ions: Because 1 mol of Pb^{2+} and 1 mol of SO_4^{2-} form when 1 mol of $PbSO_4$ dissolves, $[Pb^{2+}] = [SO_4^{2-}] = 1.40\times10^{-4}\ M$.

Calculating K_{sp}:

$$K_{sp} = [Pb^{2+}][SO_4^{2-}] = (1.40\times10^{-4})^2$$
$$= 1.96\times10^{-8}$$

(b) For PbF_2. Writing the equation and K_{sp} expression:

$$PbF_2(s) \rightleftharpoons Pb^{2+}(aq) + 2F^-(aq) \qquad K_{sp} = [Pb^{2+}][F^-]^2$$

Converting solubility to molar solubility:

$$\text{Molar solubility of } PbF_2 = \frac{0.64 \text{ g } PbF_2}{1 \text{ L soln}} \times \frac{1 \text{ mol } PbF_2}{245.2 \text{ g } PbF_2} = 2.6\times10^{-3}\ M\ PbF_2$$

Determining molarities of the ions: Since 1 mol of Pb^{2+} and 2 mol of F^- form when 1 mol of PbF_2 dissolves,

$$[Pb^{2+}] = 2.6\times10^{-3}\ M \qquad \text{and} \qquad [F^-] = 2(2.6\times10^{-3}\ M) = 5.2\times10^{-3}\ M$$

Calculating K_{sp}:

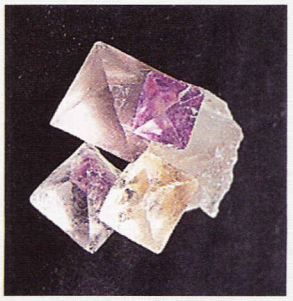
$$K_{sp} = [Pb^{2+}][F^-]^2 = (2.6\times10^{-3})(5.2\times10^{-3})^2$$
$$= 7.0\times10^{-8}$$

Check The low solubilities are consistent with K_{sp} values being small. In **(a)**, the molar solubility seems about right: $\sim \frac{4\times10^{-2} \text{ g/L}}{3\times10^{2} \text{ g/mol}} \approx 1.3\times10^{-4}\ M$. Squaring this number gives 1.7×10^{-8}, close to the calculated K_{sp}. In **(b)**, we check the final step: $\sim(3\times10^{-3})(5\times10^{-3})^2 = 7.5\times10^{-8}$, close to the calculated K_{sp}.

Comment **1.** In part (b), the formula PbF_2 means that $[F^-]$ is twice $[Pb^{2+}]$. Then we square this value of $[F^-]$. Always follow the ion-product expression explicitly.

2. The tabulated K_{sp} values for these compounds (Table 19.2) are lower than our calculated values. For PbF_2, for instance, the tabulated value is 3.6×10^{-8}, but we calculated 7.0×10^{-8} from solubility data. The discrepancy arises because we assumed that the PbF_2 in solution dissociates completely to Pb^{2+} and F^-. Here is an example of the complexity pointed out at the beginning of this section. Actually, about a third of the PbF_2 dissolves as $PbF^+(aq)$ and a small amount as undissociated $PbF_2(aq)$. The solubility (0.64 g/L) is determined experimentally and includes these other species, which we did not include in our simple calculation. This is why we treat such calculated K_{sp} values as approximations.

FOLLOW-UP PROBLEM 19.5 When powdered fluorite (CaF_2; see photo) is shaken with pure water at 18°C, 1.5×10^{-4} g dissolves for every 10.0 mL of solution. Calculate the K_{sp} of CaF_2 at 18°C.



Fluorite

Determining Solubility from K_{sp} The reverse of the previous type of problem involves finding the solubility of a compound based on its formula and K_{sp} value. An approach similar to the one we used for weak acids in Sample Problem 18.7 is to define the unknown amount dissolved—molar solubility—as S. Then we define the ion concentrations in terms of this unknown in a reaction table, and solve for S.

SAMPLE PROBLEM 19.6 Determining Solubility from K_{sp}

Problem Calcium hydroxide (slaked lime) is a major component of mortar, plaster, and cement, and solutions of $Ca(OH)_2$ are used in industry as a cheap, strong base. Calculate the solubility of $Ca(OH)_2$ in water if the K_{sp} is 6.5×10^{-6}.

Plan We write the dissolution equation and the ion-product expression. We know K_{sp} (6.5×10^{-6}); to find molar solubility (S), we set up a reaction table that expresses $[Ca^{2+}]$ and $[OH^-]$ in terms of S, substitute into the ion-product expression, and solve for S.

Solution Writing the equation and ion-product expression:

$$Ca(OH)_2(s) \rightleftharpoons Ca^{2+}(aq) + 2OH^-(aq) \qquad K_{sp} = [Ca^{2+}][OH^-]^2 = 6.5\times10^{-6}$$

Setting up a reaction table, with S = molar solubility:

Concentration (M)	$Ca(OH)_2(s)$	$\rightleftharpoons$	$Ca^{2+}(aq)$	+	$2OH^-(aq)$
Initial	—		0		0
Change	—		$+S$		$+2S$
Equilibrium	—		S		$2S$

Substituting into the ion-product expression and solving for S:

$$K_{sp} = [Ca^{2+}][OH^-]^2 = (S)(2S)^2 = (S)(4S^2) = 4S^3$$
$$= 6.5\times10^{-6}$$
$$S = \sqrt[3]{\frac{6.5\times10^{-6}}{4}}$$
$$= 1.2\times10^{-2}\ M$$

Check We expect a low solubility from a slightly soluble salt. If we reverse the calculation, we should obtain the given K_{sp}: $4(1.2\times10^{-2})^3 = 6.9\times10^{-6}$, close to 6.5×10^{-6}.

Comment **1.** Note that we did not double and *then* square $[OH^-]$. $2S$ *is* the $[OH^-]$, so we just squared it, as the ion-product expression required.

2. Once again, we assumed that the solid dissociates completely. Actually, the solubility is increased to about $2.0\times10^{-2}\ M$ by the presence of $CaOH^+(aq)$ formed in the reaction $Ca(OH)_2(s) \rightleftharpoons CaOH^+(aq) + OH^-(aq)$. Our calculated answer is only approximate because we did not take this other species into account.

FOLLOW-UP PROBLEM 19.6 A suspension of $Mg(OH)_2$ in water is marketed as "milk of magnesia," which alleviates minor symptoms of indigestion by neutralizing stomach acid. The $[OH^-]$ is too low to harm the mouth and throat, but the suspension dissolves in the acidic stomach juices. What is the molar solubility of $Mg(OH)_2$ ($K_{sp} = 6.3\times10^{-10}$) in pure water?

Using K_{sp} Values to Compare Solubilities The K_{sp} values provide a guide to *relative* solubility, as long as we compare compounds whose formulas contain the *same total number of ions*. In such cases, *the higher the K_{sp}, the greater the solubility.* Table 19.3 shows this point for several compounds. Note that for compounds that form three ions, the relationship holds whether the cation:anion ratio is 1:2 or 2:1, because the mathematical expression containing S is the same ($4S^3$) in the calculation (see Sample Problem 19.6).

Table 19.3 Relationship Between K_{sp} and Solubility at 25°C

No. of Ions	Formula	Cation:Anion	K_{sp}	Solubility (M)
2	$MgCO_3$	1:1	3.5×10^{-8}	1.9×10^{-4}
2	$PbSO_4$	1:1	1.6×10^{-8}	1.3×10^{-4}
2	$BaCrO_4$	1:1	2.1×10^{-10}	1.4×10^{-5}
3	$Ca(OH)_2$	1:2	6.5×10^{-6}	1.2×10^{-2}
3	BaF_2	1:2	1.5×10^{-6}	7.2×10^{-3}
3	CaF_2	1:2	3.2×10^{-11}	2.0×10^{-4}
3	Ag_2CrO_4	2:1	2.6×10^{-12}	8.7×10^{-5}

The Effect of a Common Ion on Solubility

The presence of a common ion decreases the solubility of a slightly soluble ionic compound. As we saw in the case of acid-base systems, Le Châtelier's principle helps explain this effect. Let's examine the equilibrium condition for a saturated solution of lead(II) chromate:

$$PbCrO_4(s) \rightleftharpoons Pb^{2+}(aq) + CrO_4^{2-}(aq) \qquad K_{sp} = [Pb^{2+}][CrO_4^{2-}] = 2.3\times10^{-13}$$

At a given temperature, K_{sp} depends only on the product of the ion concentrations. If the concentration of either ion goes up, the other must go down to maintain the constant K_{sp}. Suppose we add Na_2CrO_4, a very soluble salt, to the saturated $PbCrO_4$ solution. The concentration of the common ion, CrO_4^{2-}, increases, and some of it combines with Pb^{2+} ion to form more solid $PbCrO_4$ (Figure 19.12). The overall effect is a shift in the position of equilibrium to the left:

$$PbCrO_4(s) \leftarrow\!\rightleftharpoons Pb^{2+}(aq) + CrO_4^{2-}(aq;\ \text{added})$$

After the addition, $[CrO_4^{2-}]$ is higher, but $[Pb^{2+}]$ is lower. In this case, $[Pb^{2+}]$ represents the amount of $PbCrO_4$ dissolved; thus, in effect, the solubility of $PbCrO_4$ has decreased. The same result is obtained if we dissolve $PbCrO_4$ in a Na_2CrO_4 solution. We also obtain this result by adding a soluble lead(II) salt, such as $Pb(NO_3)_2$. The added Pb^{2+} ion combines with some $CrO_4^{2-}(aq)$, thereby lowering the amount of dissolved $PbCrO_4$.

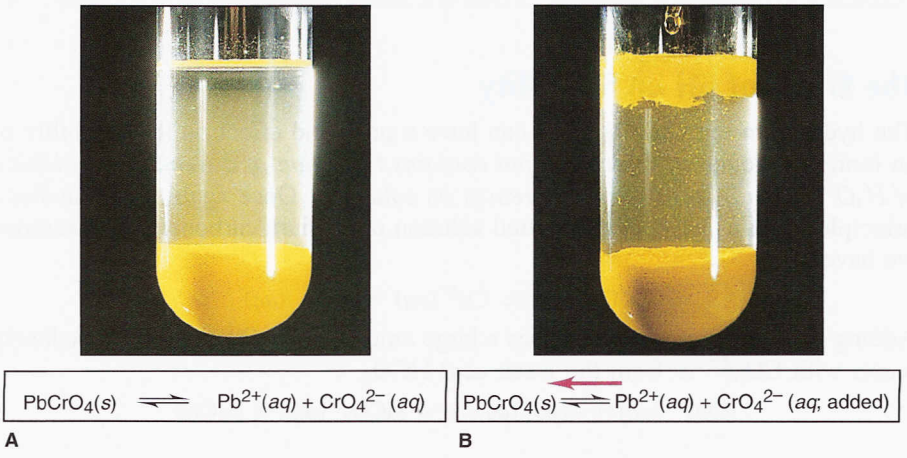


Figure 19.12 The effect of a common ion on solubility. When a common ion is added to a saturated solution of an ionic compound, the solubility is lowered and more of the compound precipitates. **A,** Lead(II) chromate, a slightly soluble salt, forms a saturated aqueous solution. **B,** When Na_2CrO_4 solution is added, the amount of $PbCrO_4(s)$ increases. Thus, $PbCrO_4$ is less soluble in the presence of the common ion CrO_4^{2-}.

SAMPLE PROBLEM 19.7 Calculating the Effect of a Common Ion on Solubility

Problem In Sample Problem 19.6, we calculated the solubility of $Ca(OH)_2$ in water. What is its solubility in 0.10 *M* $Ca(NO_3)_2$? K_{sp} of $Ca(OH)_2$ is 6.5×10^{-6}.

Plan From the equation and the ion-product expression for $Ca(OH)_2$, we predict that the addition of Ca^{2+}, the common ion, will lower the solubility. We set up a reaction table with $[Ca^{2+}]_{init}$ coming from $Ca(NO_3)_2$ and S equal to $[Ca^{2+}]_{from\ Ca(OH)_2}$. To simplify the math, we assume that, because K_{sp} is low, S is so small relative to $[Ca^{2+}]_{init}$ that it can be neglected. Then we solve for S and check the assumption.

Solution Writing the equation and ion-product expression:

$$Ca(OH)_2(s) \rightleftharpoons Ca^{2+}(aq) + 2OH^-(aq) \qquad K_{sp} = [Ca^{2+}][OH^-]^2 = 6.5\times10^{-6}$$

Setting up the reaction table, with $S = [Ca^{2+}]_{from\ Ca(OH)_2}$:

Concentration (*M*)	$Ca(OH)_2(s)$	$\rightleftharpoons$	$Ca^{2+}(aq)$	+	$2OH^-(aq)$
Initial	—		0.10		0
Change	—		$+S$		$+2S$
Equilibrium	—		$0.10 + S$		$2S$

Making the assumption: K_{sp} is small, so $S << 0.10\ M$; thus, $0.10\ M + S \approx 0.10\ M$. Substituting into the ion-product expression and solving for S:

$$K_{sp} = [Ca^{2+}][OH^-]^2 = 6.5\times10^{-6} \approx (0.10)(2S)^2$$

Therefore,
$$4S^2 \approx \frac{6.5\times10^{-6}}{0.10}$$

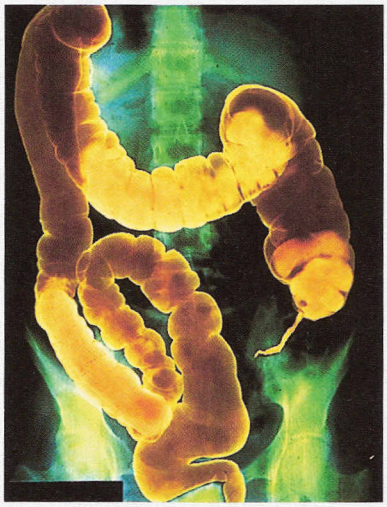
so
$$S \approx \sqrt{\frac{6.5\times10^{-5}}{4}} = 4.0\times10^{-3}\ M$$

Checking the assumption:

$$\frac{4.0\times10^{-3}\ M}{0.10\ M} \times 100 = 4.0\% < 5\%$$

Check In Sample Problem 19.6, the solubility of $Ca(OH)_2$ was 0.012 *M*, but here, it is 0.0040 *M*, so the solubility *decreased* in the presence of added Ca^{2+}, the common ion, as we predicted.

FOLLOW-UP PROBLEM 19.7 To improve the quality of x-ray images used in the diagnosis of intestinal disorders, the patient drinks an aqueous suspension of $BaSO_4$ before the x-ray procedure (see photo). The Ba^{2+} in the suspension is opaque to x-rays, but it is also toxic; thus, the Ba^{2+} concentration is lowered by the addition of dilute Na_2SO_4. What is the solubility of $BaSO_4$ ($K_{sp} = 1.1\times10^{-10}$) in **(a)** pure water and in **(b)** 0.10 *M* Na_2SO_4?



$BaSO_4$ imaging of a human large intestine.

The Effect of pH on Solubility

The hydronium ion concentration can have a profound effect on the solubility of an ionic compound. *If the compound contains the anion of a weak acid, addition of H_3O^+ (from a strong acid) increases its solubility.* Once again, Le Châtelier's principle explains why. In a saturated solution of calcium carbonate, for example, we have

$$CaCO_3(s) \rightleftharpoons Ca^{2+}(aq) + CO_3^{2-}(aq)$$

Adding some strong acid introduces a large amount of H_3O^+, which immediately reacts with CO_3^{2-} to form the weak acid HCO_3^-:

$$CO_3^{2-}(aq) + H_3O^+(aq) \longrightarrow HCO_3^-(aq) + H_2O(l)$$

If enough H_3O^+ is added, further reaction occurs to form carbonic acid, which decomposes immediately to H_2O and CO_2, which escapes the container:

$$HCO_3^-(aq) + H_3O^+(aq) \longrightarrow H_2CO_3(aq) + H_2O(l) \longrightarrow CO_2(g) + 2H_2O(l)$$

Thus, the net effect of added H_3O^+ is a shift in the equilibrium position to the right, and more $CaCO_3$ dissolves:

$$CaCO_3(s) \rightleftharpoons Ca^{2+} + CO_3^{2-} \xrightarrow{H_3O^+} HCO_3^- \xrightarrow{H_3O^+} H_2CO_3 \longrightarrow CO_2(g) + H_2O + Ca^{2+}$$

This particular case illustrates a qualitative field test for carbonate minerals because the CO_2 bubbles vigorously (Figure 19.13).

In contrast, adding H_3O^+ to a saturated solution of a compound with a strong-acid anion, such as silver chloride, has no effect on the equilibrium position:

$$AgCl(s) \rightleftharpoons Ag^+(aq) + Cl^-(aq)$$

Because Cl^- ion is the conjugate base of a strong acid (HCl), it can coexist in solution with high $[H_3O^+]$. The Cl^- does not leave the system, so the equilibrium position is not affected.

Figure 19.13 Test for the presence of a carbonate. When a mineral that contains carbonate ion is treated with strong acid, the added H_3O^+ shifts the equilibrium position of the carbonate solubility. More carbonate dissolves, and the carbonic acid that is formed breaks down to water and gaseous CO_2.

SAMPLE PROBLEM 19.8 Predicting the Effect on Solubility of Adding Strong Acid

Problem Write balanced equations to explain whether addition of H_3O^+ from a strong acid affects the solubility of these ionic compounds:
(a) Lead(II) bromide
(b) Copper(II) hydroxide
(c) Iron(II) sulfide

Plan We write the balanced dissolution equation and note the anion: Weak-acid anions react with H_3O^+ and shift the equilibrium position toward more dissolution. Strong-acid anions do not react, so added H_3O^+ has no effect.

Solution **(a)** $PbBr_2(s) \rightleftharpoons Pb^{2+}(aq) + 2Br^-(aq)$

No effect. Br^- is the anion of HBr, a strong acid, so it does not react with H_3O^+.

(b) $Cu(OH)_2(s) \rightleftharpoons Cu^{2+}(aq) + 2OH^-(aq)$

Increases solubility. OH^- is the anion of H_2O, a very weak acid, so it reacts with the added H_3O^+:

$$OH^-(aq) + H_3O^+(aq) \longrightarrow 2H_2O(l)$$

(c) $FeS(s) + H_2O(l) \rightleftharpoons Fe^{2+}(aq) + HS^-(aq) + OH^-(aq)$

Increases solubility. We noted earlier that the S^{2-} ion reacts immediately with water to form HS^-. The added H_3O^+ reacts with both weak-acid anions, HS^- and OH^-:

$$HS^-(aq) + H_3O^+(aq) \longrightarrow H_2S(aq) + H_2O(l)$$
$$OH^-(aq) + H_3O^+(aq) \longrightarrow 2H_2O(l)$$

FOLLOW-UP PROBLEM 19.8 Write balanced equations to show how addition of $HNO_3(aq)$ affects the solubility of these ionic compounds:
(a) Calcium fluoride
(b) Zinc sulfide
(c) Silver iodide

Many principles of ionic equilibria are manifested in natural formations. The upcoming Chemical Connections essay illustrates the fascinating carbonate equilibria that give rise to limestone caves.

Creation of a Limestone Cave

Limestone caves and the intricate structures within them provide striking evidence of the workings of aqueous ionic equilibria (Figure B19.1). The spires and vaults of these natural cathedrals are the products of reactions between carbonate rocks and the water that has run through them for millennia. Limestone is predominantly calcium carbonate ($CaCO_3$), a slightly soluble ionic compound with a K_{sp} of 3.3×10^{-9}. This rocky material began accumulating in the Earth over 400 million years ago, and a relatively young cave, such as Howe Caverns in eastern New York State, began forming about 800,000 years ago.

Two key facts help us understand how limestone caves form:

1. Gaseous CO_2 is in equilibrium with aqueous CO_2 in natural waters:

$$CO_2(g) \overset{H_2O(l)}{\rightleftharpoons} CO_2(aq) \qquad \textbf{(equation 1)}$$

The concentration of CO_2 in the water is proportional to the partial pressure of $CO_2(g)$ in contact with the water (Henry's law; Section 13.4):

$$[CO_2(aq)] \propto P_{CO_2}$$

Because of the continual release of CO_2 from within the Earth (outgassing), the P_{CO_2} in soil-trapped air is *higher* than the P_{CO_2} in the atmosphere.

2. As discussed in the text, the presence of $H_3O^+(aq)$ increases the solubility of ionic compounds that contain the anion of a weak acid. The reaction of CO_2 with water produces H_3O^+:

$$CO_2(aq) + 2H_2O(l) \rightleftharpoons H_3O^+(aq) + HCO_3^-(aq)$$

Thus, the presence of $CO_2(aq)$ leads to the formation of H_3O^+, which increases the solubility of $CaCO_3$:

$$CaCO_3(s) + CO_2(aq) + H_2O(l) \rightleftharpoons Ca^{2+}(aq) + 2HCO_3^-(aq) \qquad \textbf{(equation 2)}$$

Here is an overview of the principal cave-forming process in most limestone caves: As surface water trickles through cracks in the ground, it meets soil-trapped air with its high P_{CO_2}. As a result, $[CO_2(aq)]$ increases (equation 1 shifts to the right), and the solution becomes more acidic. When this CO_2-rich water contacts limestone, more $CaCO_3$ dissolves (equation 2 shifts to the right). As a result, more rock is carved out, more water flows in, and so on. Centuries pass and a cave slowly begins to form.

Eating its way through underground tunnels, some of the aqueous solution, largely dilute $Ca(HCO_3)_2$, passes through the ceiling of the growing cave. As it drips, it meets air, which has a lower P_{CO_2} than the soil, so some $CO_2(aq)$ comes out of solution (equation 1 shifts to the left). This causes some $CaCO_3$ to precipitate on the ceiling and on the floor below, where the drops land (equation 2 shifts to the left). Decades pass, and the ceiling bears an "icicle" of $CaCO_3$, called a *stalactite,* while a spike of $CaCO_3$, called a *stalagmite,* grows upward from the cave floor. With time, they meet to form a column of precipitated limestone.

The same chemical process can lead to different shapes. Standing pools of $Ca(HCO_3)_2$ solution form limestone "lily pads" or "corals." Cascades of solution form delicate limestone "draperies" on a cave wall, with fabulous colors arising from trace metal ions, such as iron (reddish brown) or copper (bluish green).

Recently, vast, spectacularly shaped deposits of gypsum ($CaSO_4\cdot2H_2O$; Figure B19.2) found in some limestone caves in Mexico point strongly to another process of cave formation. Certain bacteria found in abundance in these caves can survive at very low pH and consume hydrogen sulfide (H_2S), which leaks into the cave from oil deposits deep below it. The evidence shows that these *acidophilic* microbes use O_2 to oxidize the H_2S to sulfuric acid (H_2SO_4), a strong acid:

$$H_2S(g) + 2O_2(g) + H_2O(l) \xrightarrow{\text{bacteria}} H_3O^+(aq) + HSO_4^-(aq)$$

The sulfuric acid contributes greatly to the formation of the cave.

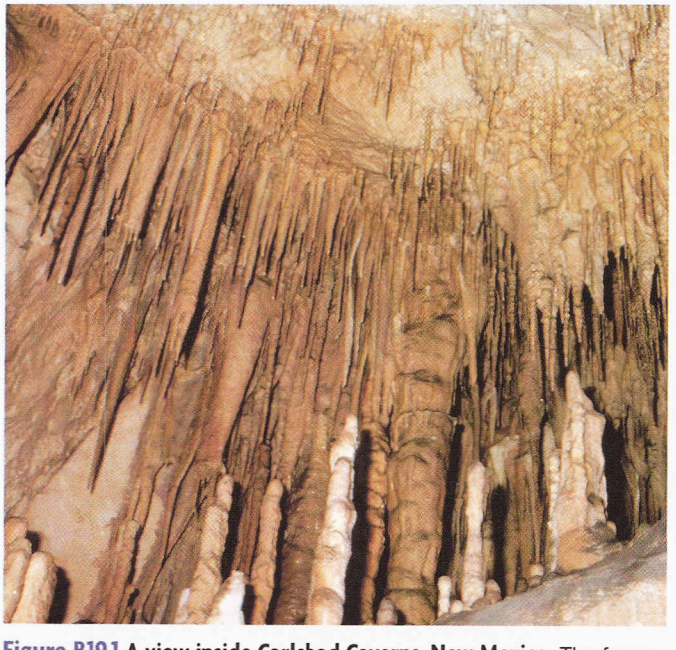


Figure B19.1 A view inside Carlsbad Caverns, New Mexico. The formations within this limestone cave result from subtle shifts in carbonate equilibria acting over millions of years.

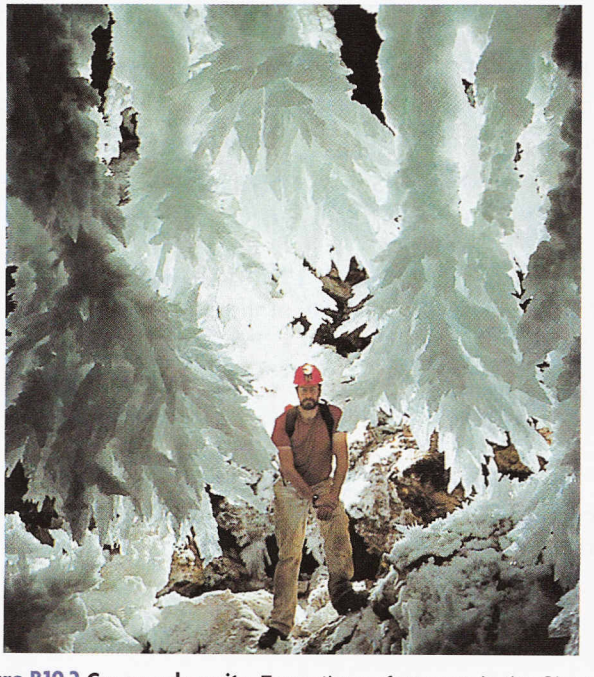

Figure B19.2 Gypsum deposits. Formations of gypsum in the Chandelier Ballroom of Lechuguilla Cave in Mexico.

Predicting the Formation of a Precipitate: Q_{sp} vs. K_{sp}

In Chapter 17, we compared the values of Q and K to see if a reaction had reached equilibrium and, if not, in which net direction it would move until it did. In this discussion, we use the same approach to see if a precipitation reaction has reached equilibrium, that is, whether a precipitate will form and, if not, what changes in the concentrations of the component ions will cause it to do so.

As you know, $Q_{sp} = K_{sp}$ when the solution is saturated. If Q_{sp} is greater than K_{sp}, the solution is momentarily supersaturated, and some solid precipitates until the remaining solution becomes saturated ($Q_{sp} = K_{sp}$). If Q_{sp} is less than K_{sp}, the solution is unsaturated, and no precipitate forms at that temperature (more solid can dissolve). To summarize,

- $Q_{sp} = K_{sp}$: solution is saturated and no change occurs.
- $Q_{sp} > K_{sp}$: precipitate forms until solution is saturated.
- $Q_{sp} < K_{sp}$: solution is unsaturated and no precipitate forms.

SAMPLE PROBLEM 19.9 Predicting Whether a Precipitate Will Form

Problem A common laboratory method for preparing a precipitate is to mix solutions containing the component ions. Does a precipitate form when 0.100 L of 0.30 M $Ca(NO_3)_2$ is mixed with 0.200 L of 0.060 M NaF?

Plan First, we must decide which slightly soluble salt could form and look up its K_{sp} value in Appendix C. To see whether mixing these solutions will form the precipitate, we find the initial ion concentrations by calculating the amount (mol) of each ion from its concentration and volume, and then dividing by the *total* volume, since one solution dilutes the other. Finally, we write the ion-product expression, calculate Q_{sp}, and compare Q_{sp} with K_{sp}.

Solution The ions present are Ca^{2+}, Na^+, F^-, and NO_3^-. All sodium and all nitrate salts are soluble (Table 4.1, p.143), so the only possibility is CaF_2 ($K_{sp} = 3.2\times10^{-11}$). Calculating the ion concentrations:

$$\text{Moles of } Ca^{2+} = 0.30\ M\ Ca^{2+} \times 0.100\ \text{L} = 0.030\ \text{mol}\ Ca^{2+}$$

$$[Ca^{2+}]_{init} = \frac{0.030\ \text{mol}\ Ca^{2+}}{0.100\ \text{L} + 0.200\ \text{L}} = 0.10\ M\ Ca^{2+}$$

$$\text{Moles of } F^- = 0.060\ M\ F^- \times 0.200\ \text{L} = 0.012\ \text{mol}\ F^-$$

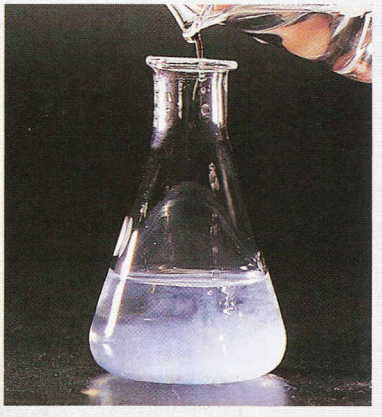
$$[F^-]_{init} = \frac{0.012\ \text{mol}\ F^-}{0.100\ \text{L} + 0.200\ \text{L}} = 0.040\ M\ F^-$$

Substituting into the ion-product expression and comparing Q_{sp} with K_{sp}:

$$Q_{sp} = [Ca^{2+}]_{init}[F^-]^2_{init} = (0.10)(0.040)^2 = 1.6\times10^{-4}$$

Because $Q_{sp} > K_{sp}$, CaF_2 will precipitate until $Q_{sp} = 3.2\times10^{-11}$.

Check Make sure you remember to round off and quickly check the math. For example, $Q_{sp} = (1\times10^{-1})(4\times10^{-2})^2 = 1.6\times10^{-4}$. With K_{sp} so low, CaF_2 must have a low solubility, and given the sizable concentrations being mixed, we would expect CaF_2 to precipitate.



Precipitation of CaF_2.

FOLLOW-UP PROBLEM 19.9 As a result of mineral erosion and biological activity, phosphate ion is common in natural waters, where it often precipitates as insoluble salts, such as $Ca_3(PO_4)_2$. If $[Ca^{2+}]_{init} = [PO_4^{3-}]_{init} = 1.0\times10^{-9}\ M$ in a given river, will $Ca_3(PO_4)_2$ precipitate? K_{sp} of $Ca_3(PO_4)_2$ is 1.2×10^{-29}.

As the upcoming Chemical Connections essay demonstrates, the principles of ionic equilibria often help us understand the chemical basis of complex environmental problems and may provide ways to solve them.

The Acid-Rain Problem

The conflict between industrial society and the environment is very clear in the problem of *acid rain,* acids resulting from human activity that occur as wet deposition in rain, snow, or fog, and as dry deposition on solid particles. Acidic precipitation has been recorded in all parts of the United States, in Canada, Mexico, the Amazon basin, throughout Europe, Russia, and many parts of Asia, and even at the North and South Poles. We've addressed several aspects of this problem earlier; now, let's examine some effects of acidic precipitation on biological and mineral systems and see how to prevent them. Several chemical culprits are

1. *Sulfurous acid.* Sulfur dioxide (SO_2) formed primarily by the burning of high-sulfur coal, forms sulfurous acid (H_2SO_3) in contact with water. Oxidants, such as hydrogen peroxide and ozone, that are present as pollutants in the atmosphere also dissolve in water and oxidize the sulfurous acid to sulfuric acid:

$$H_2O_2(aq) + H_2SO_3(aq) \longrightarrow H_2SO_4(aq) + H_2O(l)$$

2. *Sulfuric acid.* Sulfur trioxide forms through the atmospheric oxidation of SO_2. It forms sulfuric acid (H_2SO_4) on contact with water, including that in the atmosphere.

3. *Nitric acid.* Nitrogen oxides (collectively known as NO_x) form in the reaction of N_2 and O_2. NO is formed during combustion, primarily in car engines and electric power plants, and it forms NO_2 and HNO_3 in air in the process that creates smog (p. 588). At night, NO_x is converted to N_2O_5, which hydrolyzes to HNO_3 in the presence of water. The strong acids H_2SO_4 and HNO_3 cause the greatest concern (Figure B19.3).

How does the pH of acidic precipitation compare with that of natural waters? Normal rainwater is weakly acidic because it contains dissolved CO_2 from the air:

$$CO_2(g) + 2\,H_2O(l) \rightleftharpoons H_3O^+(aq) + HCO_3^-(aq)$$

Based on the volume percent of CO_2 in air, the solubility of CO_2 in water, and the K_{a1} of H_2CO_3, the pH of normal rainwater is about 5.6 (see Problem 19.148 at the end of the chapter). In stark contrast, the average pH of rainfall in many parts of the United States was 4.2 as recently as 1984, representing 25 times as much H_3O^+. Worldwide, rain in Sweden and Pennsylvania shared second prize with a pH of 2.7, about the same as vinegar. Rain in Wheeling, West Virginia, won first prize with a pH of 1.8, between that of lemon juice and stomach acid! Acidic fog in California sometimes has a pH of 1.6 because evaporation of water from the particles concentrates the acid.

These 10- to 10,000-fold excesses of $[H_3O^+]$ are very destructive to living things. Some fish and shellfish die at pH values between 4.5 and 5.0. The young of most species are generally most sensitive. At pH 5, most fish eggs cannot hatch. With tens of thousands of rivers and lakes around the world becoming acidified, the loss of fish became a major concern long ago. In addition, acres of forest have been harmed by the acid, which removes nutrients and releases toxic substances from the soil. Even if the soil is buffered, acidic fog and clouds can remove essential nutrients from leaf surfaces (Figure B19.4).

Many principles of aqueous equilibria bear directly on the effects of acid rain. The aluminosilicates that make up most soils are extremely insoluble in water. In these materials, the Al^{3+} ion is bonded to OH^- and O^{2-} ions in complex structures (see the Gallery in Chapter 14, p. 580). Continual contact with the H_3O^+ in acid rain causes these ions to react, and some of the bound Al^{3+}, which is toxic to fish, dissolves. Along with dissolved Al^{3+} ions, the acid rain carries away ions that serve as nutrients for plants and animals.

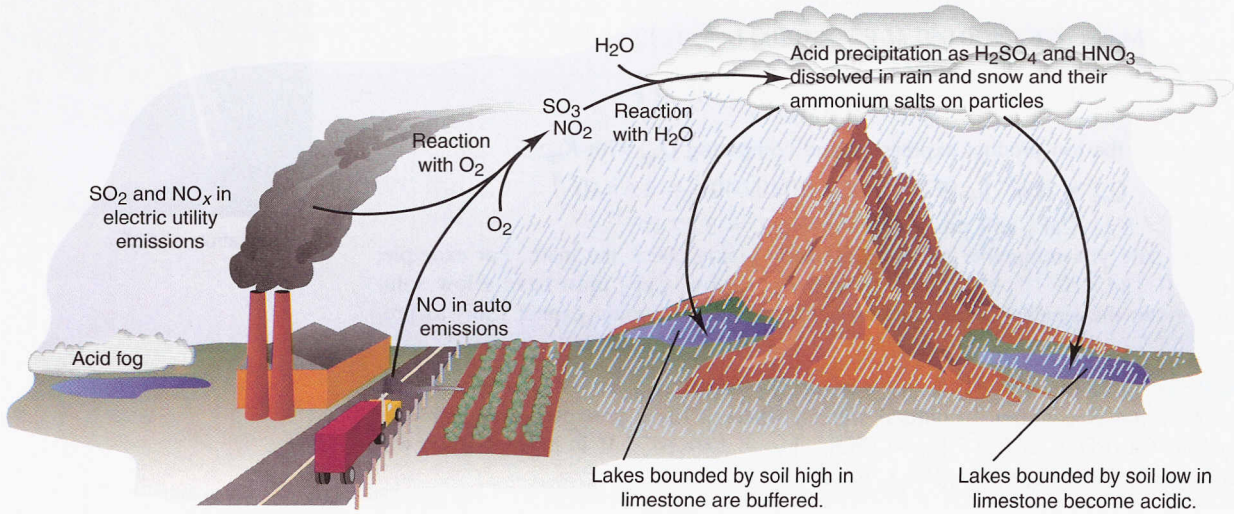


Figure B19.3 Formation of acidic precipitation. A complex interplay of human activities, atmospheric chemistry, and environmental distribution leads to acidic precipitation and its harmful effects. Car exhaust and electrical utility waste gases contain lower oxides of nitrogen and sulfur. These are oxidized in the atmosphere by O_2 (or O_3, not shown) to higher oxides (NO_2, SO_3), which react with moisture to form acidic rain, snow, and fog. In contact with acidic precipitation, many lakes become acidified, whereas limestone-bounded lakes form a carbonate buffer that prevents acidification.

Figure B19.4 A forest damaged by acid rain.

Acid rain also dissolves the calcium carbonate in the marble and limestone of buildings and monuments (Figure B19.5). Ironically, the same chemical process that destroys these structures is responsible for saving those lakes that lie on or are bounded by limestone-rich soil. As acid rain falls, the H_3O^+ reacts with dissolved carbonate ion in the lake to form bicarbonate:

$$CO_3^{2-}(aq) + H_3O^+(aq) \rightleftharpoons HCO_3^-(aq) + H_2O(l)$$

In essence, limestone-bounded lakes function as enormous HCO_3^--CO_3^{2-} buffer solutions, absorbing the additional H_3O^+ and maintaining a relatively stable pH. In fact, lakes, rivers, and groundwater in limestone-rich soils actually remain mildly basic.

For lakes and rivers in contact with limestone-poor soils, expensive remediation methods are needed. A direct attack on the symptoms is carried out by *liming* (treating with limestone) lakes and rivers. Sweden spent tens of millions of dollars during the 1990s to neutralize slightly more than 3000 lakes by adding limestone. This approach is, at best, only a stopgap because the lakes are acidic again within several years.

As we pointed out earlier (see Chemical Connections, Chapter 6, p. 245), the principal means of controlling sulfur dioxide is by "scrubbing" the emissions from power plants with limestone. Both dry and wet scrubbers are used. Another method reduces some of the SO_2 with methane or coal to H_2S, and the mixture is catalytically converted to sulfur, which is sold:

$$16H_2S(g) + 8SO_2(g) \longrightarrow 3S_8(s) + 16H_2O(l)$$

Burning low-sulfur coal to reduce SO_2 formation is sometimes an option, but such coal deposits are rare and expensive to mine. Coal can also be converted into gaseous and liquid low-sulfur fuels (see Chemical Connections, p. 245). The sulfur is removed (as H_2S) in an acid-gas scrubber after gasification.

1944 1994

Figure B19.5 The effect of acid rain on marble statuary. Calcium carbonate, which is the major component of marble, decomposes slowly when exposed to acid rain. These photos of the same statue of George Washington in Washington Square, New York City, were taken 50 years apart.

Through the use of a catalytic converter in an auto exhaust system, NO_x species are reduced to N_2 and NH_3. In power plants, the amount of NO_x is decreased by adjusting combustion conditions, but it also can be removed from the hot stack gases by treatment with ammonia:

$$4NO(g) + 4NH_3(g) + O_2(g) \longrightarrow 4N_2(g) + 6H_2O(g)$$

Several 1990 amendments to the Clean Air Act led to large reductions in SO_2 emissions from coal-burning utilities. Emissions of NO_x must be curbed substantially in the eastern United States under new rules designed to help states meet ozone standards, and HNO_3 will be reduced in the process.

SECTION SUMMARY

As a first approximation, the dissolved portion of a slightly soluble salt dissociates completely into ions. In a saturated solution, the ions are in equilibrium with the solid, and the product of the ion concentrations, each raised to the power of its subscript in the compound's formula, has a constant value ($Q_{sp} = K_{sp}$). The value of K_{sp} can be obtained from the solubility, and vice versa. Adding a common ion lowers an ionic compound's solubility. Adding H_3O^+ (lowering the pH) increases a compound's solubility if the anion of the compound is that of a weak acid. If $Q_{sp} > K_{sp}$ for an ionic compound, a precipitate forms when two solutions, each containing one of the compound's ions, are mixed. Limestone caves result from shifts in the $CaCO_3$-CO_2 equilibrium system. Lakes bounded by limestone-rich soils form buffer systems that prevent harmful acidification.

19.4 EQUILIBRIA INVOLVING COMPLEX IONS

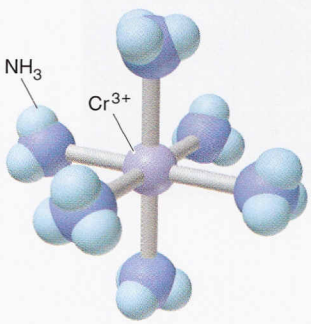

Figure 19.14 $Cr(NH_3)_6^{3+}$, a typical complex ion. A complex ion consists of a central metal ion, such as Cr^{3+}, covalently bonded to a specific number of ligands, such as NH_3.

The final type of aqueous ionic equilibrium we consider involves a different kind of ion than we've examined up to now. Simple ions, such as Na^+ or SO_4^{2-}, consist of one or a few bound atoms, with an excess or deficit of electrons. A **complex ion** consists of a central metal ion covalently bonded to two or more anions or molecules, called **ligands.** Hydroxide, chloride, and cyanide ions are some ionic ligands; water, carbon monoxide, and ammonia are some molecular ligands. In the complex ion $Cr(NH_3)_6^{3+}$, for example, Cr^{3+} is the central metal ion and six NH_3 molecules are the ligands, giving an overall 3+ charge (Figure 19.14).

As we discussed in Section 18.9, *all complex ions are Lewis adducts*. The metal ion acts as a Lewis acid (accepts an electron pair) and the ligand acts as a Lewis base (donates an electron pair). The acidic hydrated metal ions that we discussed in Section 18.6 are complex ions with water molecules as ligands. In Chapter 23, we discuss the transition metals and the structures and properties of the numerous complex ions they form. Our focus here is on equilibria of hydrated ions with ligands other than water.

Formation of Complex Ions

Whenever a metal ion enters water, a complex ion forms, with water as the ligand. In many cases, when we treat this hydrated cation with a solution of another ligand, the bound water molecules exchange for the other ligand. For example, a hydrated M^{2+} ion, $M(H_2O)_4^{2+}$, forms the complex ion $M(NH_3)_4^{2+}$ in aqueous NH_3:

$$M(H_2O)_4^{2+}(aq) + 4NH_3(aq) \rightleftharpoons M(NH_3)_4^{2+}(aq) + 4H_2O(l)$$

At equilibrium, this system is expressed by a ratio of concentration terms whose form follows that of any other equilibrium expression:

$$K_c = \frac{[M(NH_3)_4^{2+}][H_2O]^4}{[M(H_2O)_4^{2+}][NH_3]^4}$$

Once again, because the concentration of water is essentially constant in aqueous reactions, we incorporate it into K_c and obtain the expression for a new equilibrium constant, the **formation constant, K_f:**

$$K_f = \frac{K_c}{[H_2O]^4} = \frac{[M(NH_3)_4^{2+}]}{[M(H_2O)_4^{2+}][NH_3]^4}$$

At the molecular level, the actual process is stepwise, with ammonia molecules replacing water molecules one at a time to give a series of intermediate species, each with its own formation constant:

$$M(H_2O)_4^{2+}(aq) + NH_3(aq) \rightleftharpoons M(H_2O)_3(NH_3)^{2+}(aq) + H_2O(l)$$

$$K_{f1} = \frac{[M(H_2O)_3(NH_3)^{2+}]}{[M(H_2O)_4^{2+}][NH_3]}$$

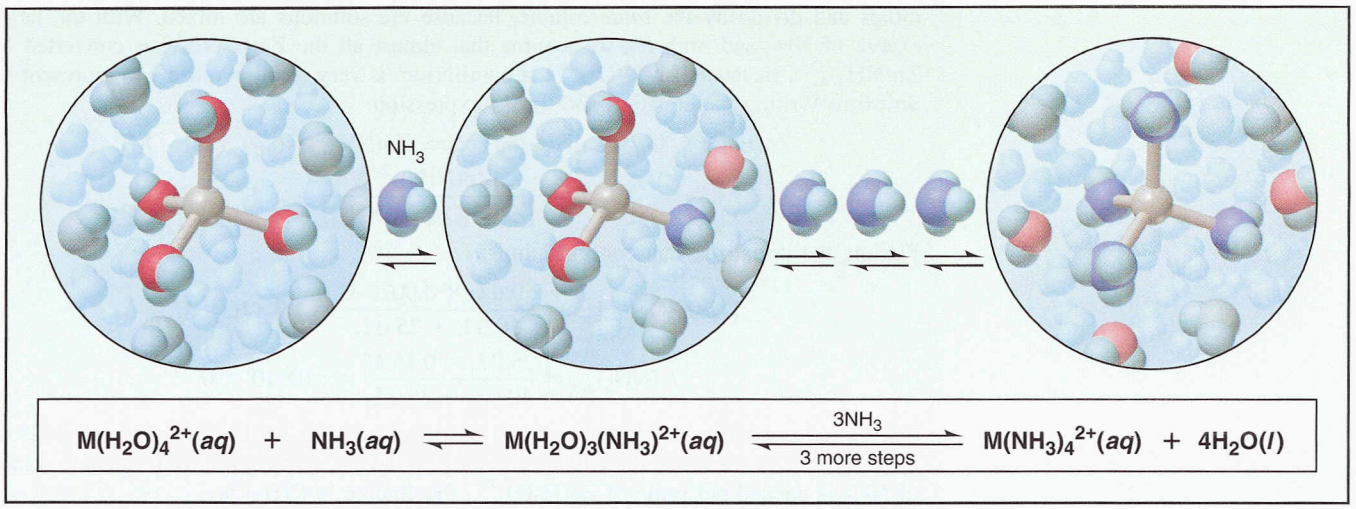

Figure 19.15 The stepwise exchange of NH_3 for H_2O in $M(H_2O)_4^{2+}$. The ligands of a complex ion can exchange for other ligands. When ammonia is added to a solution of the hydrated M^{2+} ion, $M(H_2O)_4^{2+}$, NH_3 molecules replace the bound H_2O molecules one at a time to form the $M(NH_3)_4^{2+}$ ion. The molecular-scale views show the first exchange and the fully ammoniated ion.

$$M(H_2O)_3(NH_3)^{2+}(aq) + NH_3(aq) \rightleftharpoons M(H_2O)_2(NH_3)_2{}^{2+}(aq) + H_2O(l)$$

$$K_{f2} = \frac{[M(H_2O)_2(NH_3)_2{}^{2+}]}{[M(H_2O)_3(NH_3)^{2+}][NH_3]}$$

$$M(H_2O)_2(NH_3)_2{}^{2+}(aq) + NH_3(aq) \rightleftharpoons M(H_2O)(NH_3)_3{}^{2+}(aq) + H_2O(l)$$

$$K_{f3} = \frac{[M(H_2O)(NH_3)_3{}^{2+}]}{[M(H_2O)_2(NH_3)_2{}^{2+}][NH_3]}$$

$$M(H_2O)(NH_3)_3{}^{2+}(aq) + NH_3(aq) \rightleftharpoons M(NH_3)_4{}^{2+}(aq) + H_2O(l)$$

$$K_{f4} = \frac{[M(NH_3)_4{}^{2+}]}{[M(H_2O)(NH_3)_3{}^{2+}][NH_3]}$$

The *sum* of the equations gives the overall equation, so the *product* of the individual formation constants gives the overall formation constant:

$$K_f = K_{f1} \times K_{f2} \times K_{f3} \times K_{f4}$$

Figure 19.15 summarizes the process on the molecular level. In this case, the K_f for each step is much larger than 1 because ammonia is a stronger Lewis base than water. Therefore, if we add excess ammonia to the $M(H_2O)_4^{2+}$ solution, the H_2O ligands are replaced and essentially all the M^{2+} ion exists as $M(NH_3)_4^{2+}$.

Table 19.4 (and Appendix C) shows the formation constants of some complex ions. Notice that the K_f values are all 10^6 or greater, which means that these ions form readily. Because of this behavior, complex-ion formation is used to retrieve a metal from its ore, eliminate a toxic or unwanted metal ion from a solution, or convert a metal ion to a different form, as Sample Problem 19.10 shows for the zinc ion.

Table 19.4 Formation Constants (K_f) of Some Complex Ions at 25°C

Complex Ion	K_f
$Ag(CN)_2^-$	3.0×10^{20}
$Ag(NH_3)_2^+$	1.7×10^{7}
$Ag(S_2O_3)_2^{3-}$	4.7×10^{13}
AlF_6^{3-}	4×10^{19}
$Al(OH)_4^-$	3×10^{33}
~~$Be(OH)_4^{2-}$~~	4×10^{18}
CdI_4^{2-}	1×10^{6}
$Co(OH)_4^{2-}$	5×10^{9}
$Cr(OH)_4^-$	8.0×10^{29}
$Cu(NH_3)_4^{2+}$	5.6×10^{11}
$Fe(CN)_6^{4-}$	3×10^{35}
$Fe(CN)_6^{3-}$	4.0×10^{43}
$Hg(CN)_4^{2-}$	9.3×10^{38}
$Ni(NH_3)_6^{2+}$	2.0×10^{8}
$Pb(OH)_3^-$	8×10^{13}
$Sn(OH)_3^-$	3×10^{25}
$Zn(CN)_4^{2-}$	4.2×10^{19}
$Zn(NH_3)_4^{2+}$	7.8×10^{8}
$Zn(OH)_4^{2-}$	3×10^{15}

SAMPLE PROBLEM 19.10 Calculating the Concentration of a Complex Ion

Problem An industrial chemist converts $Zn(H_2O)_4^{2+}$ to the more stable $Zn(NH_3)_4^{2+}$ by mixing 50.0 L of 0.0020 *M* $Zn(H_2O)_4^{2+}$ and 25.0 L of 0.15 *M* NH_3. What is the final $[Zn(H_2O)_4^{2+}]$? K_f of $Zn(NH_3)_4^{2+}$ is 7.8×10^8.

Plan We write the equation and the K_f expression and use a reaction table to calculate the equilibrium concentrations. To set up the table, we must first find $[Zn(H_2O)_4^{2+}]_{init}$ and $[NH_3]_{init}$. We are given the individual volumes and molar concentrations, so we find the

moles and divide by the *total* volume, because the solutions are mixed. With the large excess of NH_3 and high K_f, we assume that almost all the $Zn(H_2O)_4^{2+}$ is converted to $Zn(NH_3)_4^{2+}$. Because $[Zn(H_2O)_4^{2+}]$ at equilibrium is very small, we use x to represent it.

Solution Writing the equation and the K_f expression:

$$Zn(H_2O)_4^{2+}(aq) + 4NH_3(aq) \rightleftharpoons Zn(NH_3)_4^{2+}(aq) + 4H_2O(l)$$

$$K_f = \frac{[Zn(NH_3)_4^{2+}]}{[Zn(H_2O)_4^{2+}][NH_3]^4}$$

Finding the initial reactant concentrations:

$$[Zn(H_2O)_4^{2+}]_{init} = \frac{50.0\ L \times 0.0020\ M}{50.0\ L + 25.0\ L} = 1.3\times10^{-3}\ M$$

$$[NH_3]_{init} = \frac{25.0\ L \times 0.15\ M}{50.0\ L + 25.0\ L} = 5.0\times10^{-2}\ M$$

Setting up a reaction table: We assume that nearly all the $Zn(H_2O)_4^{2+}$ is converted to $Zn(NH_3)_4^{2+}$, so we set up the table with $x = [Zn(H_2O)_4^{2+}]$ at equilibrium. Because 4 mol of NH_3 is needed per mole of $Zn(H_2O)_4^{2+}$, the change in $[NH_3]$ is

$$[NH_3]_{reacted} \approx 4(1.3\times10^{-3}\ M) = 5.2\times10^{-3}\ M$$

and

$$[Zn(NH_3)_4^{2+}] \approx 1.3\times10^{-3}\ M$$

Concentration (*M*)	$Zn(H_2O)_4^{2+}(aq)$	+	$4NH_3(aq)$	$\rightleftharpoons$	$Zn(NH_3)_4^{2+}(aq)$	+	$4H_2O(l)$
Initial	1.3×10^{-3}		5.0×10^{-2}		0		—
Change	$\sim(-1.3\times10^{-3})$		$\sim(-5.2\times10^{-3})$		$\sim(+1.3\times10^{-3})$		—
Equilibrium	x		4.5×10^{-2}		1.3×10^{-3}		—

Solving for x, the $[Zn(H_2O)_4^{2+}]$ remaining at equilibrium:

$$K_f = \frac{[Zn(NH_3)_4^{2+}]}{[Zn(H_2O)_4^{2+}][NH_3]^4} = 7.8\times10^8 \approx \frac{1.3\times10^{-3}}{x(4.5\times10^{-2})^4}$$

$$x = [Zn(H_2O)_4^{2+}] \approx 4.1\times10^{-7}\ M$$

Check The K_f is large, so we expect the $[Zn(H_2O)_4^{2+}]$ remaining to be very low.

FOLLOW-UP PROBLEM 19.10 Cyanide ion is toxic because it forms stable complex ions with the Fe^{3+} ion in certain iron-containing proteins engaged in energy production. To study this effect, a biochemist mixes 25.5 mL of 3.1×10^{-2} *M* $Fe(H_2O)_6^{3+}$ with 35.0 mL of 1.5 *M* NaCN. What is the final $[Fe(H_2O)_6^{3+}]$? K_f of $Fe(CN)_6^{3-}$ is 4.0×10^{43}.

Complex Ions and the Solubility of Precipitates

In Section 19.3, you saw that H_3O^+ increases the solubility of a slightly soluble ionic compound if its anion is that of a weak acid. Similarly, *a ligand increases the solubility of a slightly soluble ionic compound if it forms a complex ion with the cation*. For example, zinc sulfide is very slightly soluble:

$$ZnS(s) + H_2O(l) \rightleftharpoons Zn^{2+}(aq) + HS^-(aq) + OH^-(aq) \qquad K_{sp} = 2.0\times10^{-22}$$

When we add some 1.0 *M* NaCN, the CN^- ions act as ligands and react with the small amount of $Zn^{2+}(aq)$ to form the complex ion $Zn(CN)_4^{2-}$:

$$Zn^{2+}(aq) + 4CN^-(aq) \rightleftharpoons Zn(CN)_4^{2-}(aq) \qquad K_f = 4.2\times10^{19}$$

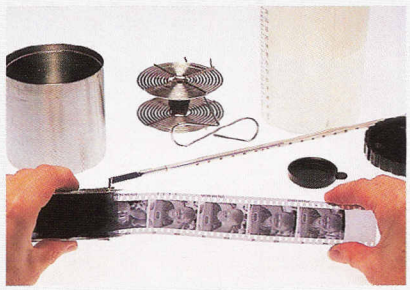
To see the effect of complex ion formation on the solubility of ZnS, we add the equations and, therefore, multiply their equilibrium constants:

$$ZnS(s) + 4CN^-(aq) + H_2O(l) \rightleftharpoons Zn(CN)_4^{2-}(aq) + HS^-(aq) + OH^-(aq)$$

$$K_{overall} = K_{sp} \times K_f = (2.0\times10^{-22})(4.2\times10^{19}) = 8.4\times10^{-3}$$

The overall equilibrium constant increased by more than a factor of 10^{19} in the presence of the ligand; this reflects the increased amount of ZnS in solution.

SAMPLE PROBLEM 19.11 Calculating the Effect of Complex-Ion Formation on Solubility



Developing the image in "hypo."

Problem In black-and-white film developing (see photo), excess AgBr is removed from the film negative by "hypo," an aqueous solution of sodium thiosulfate ($Na_2S_2O_3$), which forms the complex ion $Ag(S_2O_3)_2^{3-}$. Calculate the solubility of AgBr in **(a)** H_2O; **(b)** 1.0 *M* hypo. K_f of $Ag(S_2O_3)_2^{3-}$ is 4.7×10^{13} and K_{sp} of AgBr is 5.0×10^{-13}.

Plan **(a)** After writing the equation and the ion-product expression, we use the given K_{sp} to solve for *S*, the molar solubility of AgBr. **(b)** In hypo, Ag^+ forms a complex ion with $S_2O_3^{2-}$, which shifts the equilibrium and dissolves more AgBr. We write the complex-ion equation and add it to the equation for dissolving AgBr to obtain the overall equation for dissolving AgBr in hypo. We multiply K_{sp} by K_f to find $K_{overall}$. To find the solubility of AgBr in hypo, we set up a reaction table, with $S = [Ag(S_2O_3)_2^{3-}]$, substitute into the expression for $K_{overall}$, and solve for *S*.

Solution **(a)** Solubility in water. Writing the equation for the saturated solution and the ion-product expression:

$$AgBr(s) \rightleftharpoons Ag^+(aq) + Br^-(aq) \qquad K_{sp} = [Ag^+][Br^-]$$

Solving for solubility (*S*) directly from the equation: We know that

$$S = [AgBr]_{dissolved} = [Ag^+] = [Br^-]$$

Thus,
$$K_{sp} = [Ag^+][Br^-] = S^2 = 5.0\times10^{-13}$$

so
$$S = 7.1\times10^{-7}\ M$$

(b) Solubility in 1.0 *M* hypo. Writing the overall equation:

$$AgBr(s) \rightleftharpoons \cancel{Ag^+(aq)} + Br^-(aq)$$
$$\cancel{Ag^+(aq)} + 2S_2O_3^{2-}(aq) \rightleftharpoons Ag(S_2O_3)_2^{3-}(aq)$$
$$AgBr(s) + 2S_2O_3^{2-}(aq) \rightleftharpoons Ag(S_2O_3)_2^{3-}(aq) + Br^-(aq)$$

Calculating $K_{overall}$:

$$K_{overall} = \frac{[Ag(S_2O_3)_2^{3-}][Br^-]}{[S_2O_3^{2-}]^2} = K_{sp} \times K_f = (5.0\times10^{-13})(4.7\times10^{13}) = 24$$

Setting up a reaction table, with $S = [AgBr]_{dissolved} = [Ag(S_2O_3)_2^{3-}]$:

Concentration (*M*)	$AgBr(s)$	+	$2S_2O_3^{2-}(aq)$	$\rightleftharpoons$	$Ag(S_2O_3)_2^{3-}(aq)$	+	$Br^-(aq)$
Initial	—		1.0		0		0
Change	—		$-2S$		$+S$		$+S$
Equilibrium	—		$1.0 - 2S$		S		S

Substituting the values into the expression for $K_{overall}$ and solving for *S*:

$$K_{overall} = \frac{[Ag(S_2O_3)_2^{3-}][Br^-]}{[S_2O_3^{2-}]^2} = \frac{S^2}{(1.0\ M - 2S)^2} = 24$$

Taking the square root of both sides gives

$$\frac{S}{1.0\ M - 2S} = \sqrt{24} = 4.9 \qquad [Ag(S_2O_3)_2^{3-}] = S = 0.45\ M$$

Check **(a)** From the number of ions in the formula of AgBr, we know that $S = \sqrt{K_{sp}}$, so the order of magnitude seems right: $\sim\sqrt{10^{-14}} = 10^{-7}$. **(b)** The $K_{overall}$ seems correct: the exponents cancel, and $5 \times 5 = 25$. Most importantly, the answer makes sense because the photographic process requires the remaining AgBr to be washed off the film and the large $K_{overall}$ confirms that. We can check *S* by rounding and working backward to find $K_{overall}$: from the reaction table, we find that

$$[(S_2O_3)^{2-}] = 1.0\ M - 2S = 1.0\ M - 2(0.45\ M) = 1.0\ M - 0.90\ M = 0.1\ M$$

so $K_{overall} \approx (0.45)^2/(0.1)^2 = 20$, within rounding of the calculated value.

FOLLOW-UP PROBLEM 19.11 How does the solubility of AgBr in 1.0 *M* NH_3 compare with its solubility in hypo? K_f of $Ag(NH_3)_2^+$ is 1.7×10^7.

Complex Ions of Amphoteric Hydroxides

Many of the same metals that form amphoteric oxides (Chapter 8, p. 315, and Interchapter Topic 4, p. 547) also form slightly soluble *amphoteric hydroxides*. These compounds dissolve very little in water, but they dissolve to a much greater extent in both acidic and basic solutions. Aluminum hydroxide is one of several examples:

$$Al(OH)_3(s) \rightleftharpoons Al^{3+}(aq) + 3OH^-(aq)$$

It is insoluble in water ($K_{sp} = 3\times10^{-34}$), but

- It dissolves in acid because H_3O^+ reacts with the OH^- anion (Section 19.3),

$$3H_3O^+(aq) + 3OH^-(aq) \longrightarrow 6H_2O(l)$$

  giving the overall equation

$$Al(OH)_3(s) + 3H_3O^+(aq) \longrightarrow Al^{3+}(aq) + 6H_2O(l)$$

- It dissolves in base through the formation of a complex ion:

$$Al(OH)_3(s) + OH^-(aq) \longrightarrow Al(OH)_4^-(aq)$$

Figure 19.16 illustrates this amphoteric behavior but includes some unexpected formulas for the species. Let's see how these species arise. When we dissolve a soluble aluminum salt, such as $Al(NO_3)_3$, in water and then slowly add a strong base, a white precipitate first forms and then dissolves as more base is added.

What reactions are occurring? The formula for the hydrated Al^{3+} ion is $Al(H_2O)_6^{3+}(aq)$. It acts as a weak polyprotic acid and reacts with added OH^- ions in a stepwise manner. In each step, one of the bound H_2O molecules loses a proton and becomes a bound OH^- ion, so the number of bound H_2O molecules is reduced by 1:

$$Al(H_2O)_6^{3+}(aq) + OH^-(aq) \rightleftharpoons Al(H_2O)_5OH^{2+}(aq) + H_2O(l)$$

$$Al(H_2O)_5OH^{2+}(aq) + OH^-(aq) \rightleftharpoons Al(H_2O)_4(OH)_2^+(aq) + H_2O(l)$$

$$Al(H_2O)_4(OH)_2^+(aq) + OH^-(aq) \rightleftharpoons Al(H_2O)_3(OH)_3(s) + H_2O(l)$$

After three protons have been removed from each $Al(H_2O)_6^{3+}$, the white precipitate has formed, which is the insoluble hydroxide $Al(H_2O)_3(OH)_3(s)$, often written more simply as $Al(OH)_3(s)$. Now you can see that the precipitate actually consists of the hydrated Al^{3+} ion with an H^+ removed from each of three bound H_2O molecules. Addition of H_3O^+ protonates the OH^- ions and re-forms the hydrated Al^{3+} ion.

Further addition of OH^- removes a fourth H^+ and the precipitate dissolves as the soluble ion $Al(H_2O)_2(OH)_4^-(aq)$ forms, which we usually write with the formula $Al(OH)_4^-(aq)$:

$$Al(H_2O)_3(OH)_3(s) + OH^-(aq) \rightleftharpoons Al(H_2O)_2(OH)_4^-(aq) + H_2O(l)$$

In other words, this complex ion is not created by ligands substituting for bound water molecules but through an acid-base reaction in which added OH^- ions titrate bound water molecules.

Several other slightly soluble hydroxides, including those of cadmium, chromium(III), cobalt(III), lead(II), tin(II), and zinc, are amphoteric and exhibit similar reactions:

$$Zn(H_2O)_2(OH)_2(s) + OH^-(aq) \rightleftharpoons Zn(H_2O)(OH)_3^-(aq) + H_2O(l)$$

In contrast to the preceding hydroxides, the slightly soluble hydroxides of iron(II), iron(III), and calcium dissolve in acid, but do *not* dissolve in base, because the

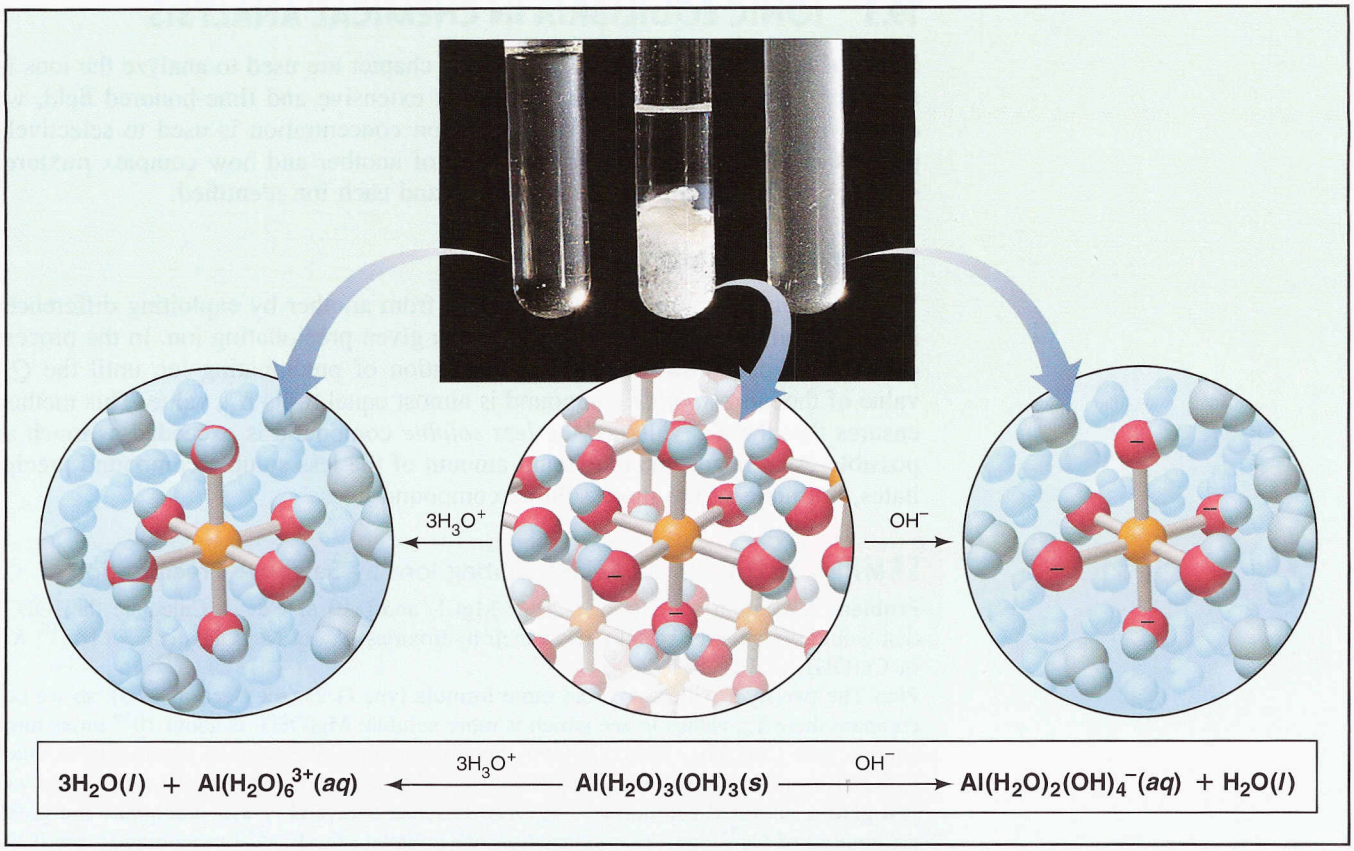


Figure 19.16 The amphoteric behavior of aluminum hydroxide. When solid $Al(OH)_3$ is treated with H_3O^+ (*left*) or with OH^- (*right*), it dissolves as a result of the formation of soluble complex ions. The molecular views show that $Al(OH)_3$ is actually the hydrated species $Al(H_2O)_3(OH)_3$. (The extensive OH bridging that occurs between Al^{3+} ions throughout the solid is not shown.) Addition of OH^- (*right*) forms the soluble $Al(H_2O)_2(OH)_4^-$ ion; addition of H_3O^+ (*left*) forms the soluble $Al(H_2O)_6^{3+}$ ion.

three remaining bound water molecules are not acidic enough to lose any of their protons:

$$Fe(H_2O)_3(OH)_3(s) + 3H_3O^+(aq) \longrightarrow Fe(H_2O)_6^{3+}(aq) + 3H_2O(l)$$
$$Fe(H_2O)_3(OH)_3(s) + OH^-(aq) \longrightarrow \text{no reaction}$$

This difference in solubility in base between $Al(OH)_3$ and $Fe(OH)_3$ is the key to an important separation step in the production of aluminum metal, so we'll consider it again in Section 22.4. It is also employed in analyzing a mixture of ions, a process introduced briefly in the next section.

SECTION SUMMARY

A complex ion consists of a central metal ion covalently bonded to two or more negatively charged or neutral ligands. Its formation is described by a formation constant, K_f. A hydrated metal ion is a complex ion with water molecules as ligands. Other ligands can displace the water in a stepwise process. In most cases, the K_f value of each step is large, so the fully substituted complex ion forms almost completely in the presence of excess ligand. Adding a solution containing a ligand increases the solubility of an ionic precipitate if the cation forms a complex ion with the ligand. Amphoteric metal hydroxides dissolve in acid and base due to acid-base reactions that form soluble complex ions.

19.5 IONIC EQUILIBRIA IN CHEMICAL ANALYSIS

Many of the ideas we've discussed in this chapter are used to analyze the ions in a mixture. In this brief introduction to an extensive and time-honored field, we discuss how control of the precipitating-ion concentration is used to selectively precipitate one metal ion in the presence of another and how complex mixtures of ions are separated into smaller groups and each ion identified.

Selective Precipitation

We can often select one ion in a solution from another by exploiting differences in the solubility of their compounds with a given precipitating ion. In the process of **selective precipitation,** we add a solution of precipitating ion until the Q_{sp} value of the *more soluble* compound is almost equal to its K_{sp} value. This method ensures that the K_{sp} value of the *less soluble* compound is exceeded as much as possible. As a result, the maximum amount of the less soluble compound precipitates, but none of the more soluble compound does.

SAMPLE PROBLEM 19.12 Separating Ions by Selective Precipitation

Problem A solution consists of 0.20 M $MgCl_2$ and 0.10 M $CuCl_2$. Calculate the $[OH^-]$ that would separate the metal ions as their hydroxides. K_{sp} of $Mg(OH)_2$ is 6.3×10^{-10}; K_{sp} of $Cu(OH)_2$ is 2.2×10^{-20}.

Plan The two hydroxides have the same formula type (1:2) (see Section 19.3), so we can compare their K_{sp} values to see which is more soluble: $Mg(OH)_2$ is about 10^{10} times more soluble than $Cu(OH)_2$. Thus, $Cu(OH)_2$ precipitates first. We want to precipitate as much $Cu(OH)_2$ as possible without precipitating any $Mg(OH)_2$. We solve for the $[OH^-]$ that will just give a saturated solution of $Mg(OH)_2$ because this $[OH^-]$ will precipitate the greatest amount of Cu^{2+} ion. As confirmation, we calculate the $[Cu^{2+}]$ remaining to see if the separation was accomplished.

Solution Writing the equations and ion-product expressions:

$$Mg(OH)_2(s) \rightleftharpoons Mg^{2+}(aq) + 2OH^-(aq) \qquad K_{sp} = [Mg^{2+}][OH^-]^2$$
$$Cu(OH)_2(s) \rightleftharpoons Cu^{2+}(aq) + 2OH^-(aq) \qquad K_{sp} = [Cu^{2+}][OH^-]^2$$

Calculating the $[OH^-]$ that gives a saturated $Mg(OH)_2$ solution:

$$[OH^-] = \sqrt{\frac{K_{sp}}{[Mg^{2+}]}} = \sqrt{\frac{6.3\times10^{-10}}{0.20}} = 5.6\times10^{-5}\ M$$

This is the maximum $[OH^-]$ that will *not* precipitate Mg^{2+} ion.

Calculating the $[Cu^{2+}]$ remaining in the solution with this $[OH^-]$:

$$[Cu^{2+}] = \frac{K_{sp}}{[OH^-]^2} = \frac{2.2\times10^{-20}}{(5.6\times10^{-5})^2} = 7.0\times10^{-12}\ M$$

Since the initial $[Cu^{2+}]$ was 0.10 M, virtually all the Cu^{2+} ion is precipitated.

Check Rounding, we find that the $[OH^-]$ seems right: $\sim\sqrt{(6\times10^{-10})/0.2} = 5\times10^{-5}$. The $[Cu^{2+}]$ remaining also seems correct: $(200\times10^{-22})/(5\times10^{-5})^2 = 8\times10^{-12}$.

Comment Often, more than one approach will accomplish the same analytical step. Another possibility in this case is to add excess ammonia to make the solution basic enough to precipitate both hydroxides:

$$Mg^{2+}(aq) + 2NH_3(aq) + 2H_2O(l) \rightleftharpoons Mg(OH)_2(s) + 2NH_4^+(aq)$$
$$Cu^{2+}(aq) + 2NH_3(aq) + 2H_2O(l) \rightleftharpoons Cu(OH)_2(s) + 2NH_4^+(aq)$$

Then, the $Cu(OH)_2$ dissolves in excess NH_3 by forming a soluble complex ion:

$$Cu(OH)_2(s) + 4NH_3(aq) \rightleftharpoons Cu(NH_3)_4^{2+}(aq) + 2OH^-(aq)$$

FOLLOW-UP PROBLEM 19.12 A solution containing two alkaline earth metal ions is made from 0.050 M $BaCl_2$ and 0.025 M $CaCl_2$. What concentration of SO_4^{2-} must be present to leave 99.99% of only one of the cations in solution? K_{sp} of $BaSO_4$ is 1.1×10^{-10}, and K_{sp} of $CaSO_4$ is 2.4×10^{-5}.

Sometimes two or more types of ionic equilibria are controlled simultaneously to precipitate ions selectively. This approach is used commonly to separate ions as their sulfides, so the HS^- ion is the precipitating ion. In the manner used in Sample Problem 19.12, we control the $[HS^-]$ to exceed the K_{sp} value of one metal sulfide but not another. We exert this control on the $[HS^-]$ by controlling H_2S dissociation because H_2S is the source of HS^-; we control H_2S dissociation by adjusting the $[H_3O^+]$:

$$H_2S(aq) + H_2O(l) \rightleftharpoons H_3O^+(aq) + HS^-(aq)$$

These interactions are controlled in the following way: If we add strong acid to the solution, $[H_3O^+]$ is high, so H_2S dissociation shifts to the left, which decreases $[HS^-]$. With a low $[HS^-]$, the *less* soluble sulfide precipitates. Conversely, if we add strong base, $[H_3O^+]$ is low, so H_2S dissociation shifts to the right, which increases $[HS^-]$, and then the *more* soluble sulfide precipitates. In essence, what we have done is shift one equilibrium system (H_2S dissociation) by adjusting a second (H_2O ionization) to control a third (metal sulfide solubility).

Qualitative Analysis: Identifying Ions in Complex Mixtures

The practice of inorganic **qualitative analysis,** the separation and identification of the ions in a mixture, was once an essential part of a chemist's skills. Today, many of these wet chemical techniques have been replaced by instrumental methods. Nevertheless, they provide an excellent means for studying ionic equilibria, including some of the very ones utilized by those modern instruments. In this brief discussion, we apply solubility and complex-ion equilibria to separate and characterize a mixture of cations; similar procedures exist for anions.

Separation into Ion Groups The general approach begins by separating the unknown solution into *ion groups* (Figure 19.17). (Ion groups have *nothing* to do with periodic table groups.) The mixture of metal ions is treated with a solution that precipitates a certain group of them and leaves the others in solution. Filtration or centrifugation (the rapid spinning of the tube to collect the solid in a compact pellet at the bottom) separates the compounds containing the precipitated metal ions. The solution containing the remaining ions is decanted (poured off) and treated with a solution that precipitates a different group of ions. These steps are repeated until the original mixture has been separated into specific ion groups. In an actual analysis, a *known solution* (one that contains all the ions under study) and a *blank* of distilled water are treated in exactly the same way as the unknown solution, making it much easier to judge a positive or negative result.

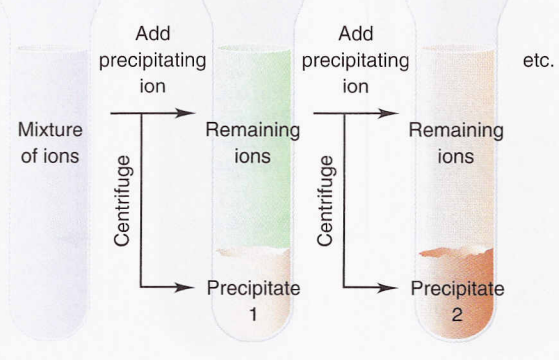

Figure 19.17 The general procedure for separating ions in qualitative analysis. A precipitating ion is added to a mixture of ions, the precipitate is separated by centrifugation, and the remaining dissolved ions are treated with another precipitating ion. The process is repeated until the ions are separated into ion groups.

Figure 19.18 shows a common scheme for separating cations into ion groups.

Ion group 1: Insoluble chlorides. The entire mixture of soluble ions is treated with 6 *M* HCl. Most metal chlorides are soluble, so only those few ions that form insoluble chlorides precipitate in this step. If a precipitate appears, it consists of chlorides of any of the following:

$$Ag^+,\ Hg_2^{2+},\ Pb^{2+}$$

If none appears, no ions from ion group 1 are present in the mixture. If a precipitate forms, the tube is centrifuged, and the solution is carefully decanted.

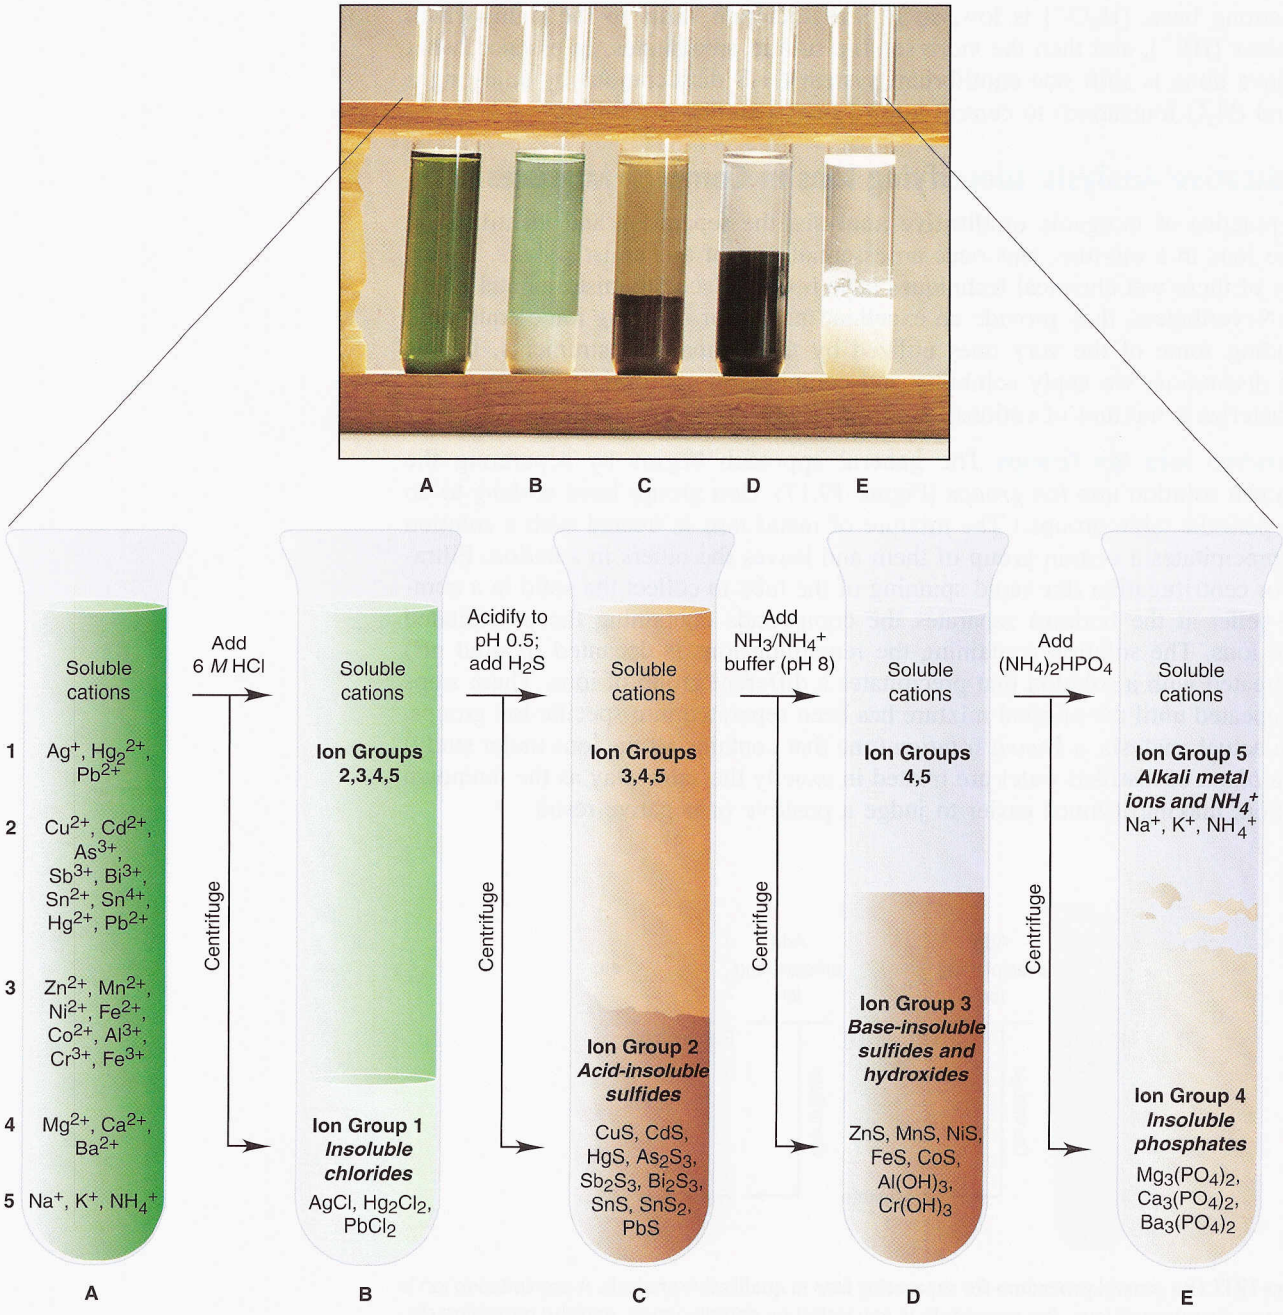

Figure 19.18 A qualitative analysis scheme for separating cations into five ion groups. The first tube contains a solution of ions (listed by ion group). It is treated with the first precipitating solution (6 *M* HCl), and the procedure continues, as shown in Figure 19.17.

Ion group 2: Acid-insoluble sulfides. The decanted solution is already acidic from the previous treatment with HCl. The pH is adjusted to 0.5 and the solution treated with aqueous H_2S. The H_3O^+ present keeps the $[HS^-]$ very low, so any precipitate contains one or more of the least soluble sulfides, which are those of

$$Cu^{2+},\ Cd^{2+},\ As^{3+},\ Sb^{3+},\ Bi^{3+},\ Sn^{2+},\ Sn^{4+},\ Hg^{2+},\ Pb^{2+}$$

($PbCl_2$ is slightly soluble in water, so a small amount of Pb^{2+} remains in solution after addition of HCl and appears in ion groups 1 *and* 2.) If no precipitate forms under these conditions, no members of ion group 2 are present. The tube is centrifuged and the solution decanted.

Ion group 3: Base-insoluble sulfides and hydroxides. The decanted solution is made slightly basic with an NH_4^+-NH_3 buffer. The OH^- present increases the $[HS^-]$, which causes precipitation of the more soluble sulfides and some hydroxides. The cations included are

$$Zn^{2+},\ Mn^{2+},\ Ni^{2+},\ Fe^{2+},\ Co^{2+} \text{ as sulfides, and } Al^{3+},\ Cr^{3+} \text{ as hydroxides}$$

(Fe^{3+} is reduced to Fe^{2+} in this step.) If no precipitate appears, none of these ions is present. Centrifuging and decanting gives the next solution.

Ion group 4: Insoluble phosphates. To the slightly basic solution, $(NH_4)_2HPO_4$ is added, which precipitates any alkaline earth ions as phosphates. Alternatively, Na_2CO_3 is added, and the precipitate contains alkaline earth carbonates. In either case, any of the following ions are precipitated:

$$Mg^{2+},\ Ca^{2+},\ Ba^{2+}$$

If no precipitate appears, none of these ions is present.

Ion group 5: Alkali metal and ammonium ions. After centrifuging and decanting, the final solution contains any of the following ions:

$$Na^+,\ K^+,\ NH_4^+$$

With the ions separated into ion groups, the analyst then devises schemes to identify various ions in the groups. For example, to separate a mixture of Ag^+ and Cu^{2+} ions, we note that Cl^- can act as both a ligand and a precipitating ion. We add dilute NaCl to the solution and centrifuge, and the Cl^- ion forms a white precipitate with $Ag^+(aq)$ and a green complex ion with $Cu^{2+}(aq)$:

$$Ag^+(aq) + Cl^-(aq;\ \text{added}) \longrightarrow AgCl(s)\ [\text{white}]$$
$$Cu^{2+}(aq) + 4Cl^-(aq;\ \text{added}) \longrightarrow CuCl_4^{2-}(aq)\ [\text{green}]$$

As another example, the ions in ion group 5 are identified through flame and color tests (Figure 19.19). (Because NH_4^+ ion is added during earlier steps and Na^+ is a common contaminant in ammonium salts, the analyst performs tests for these ions on the original ion mixture.) In flame tests, sodium has a characteristic yellow-orange color, and potassium has a violet color. Acid-base behavior is used to identify NH_4^+. The solution is made basic with NaOH and warmed gently; then moist red litmus paper is held over it. If the paper turns blue, NH_4^+ is present because the OH^- reacts to form NH_3, which reacts with the H_2O on the paper:

$$NH_4^+(aq) + OH^-(aq;\ \text{added}) \longrightarrow NH_3(g) + H_2O(l)$$
$$NH_3(g) + H_2O\ (\text{on paper}) \rightleftharpoons NH_4^+(aq) + OH^-\ (\text{turns red litmus blue})$$

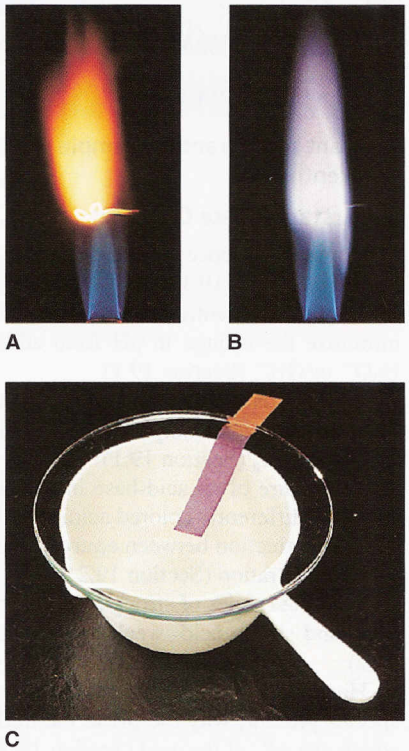

Figure 19.19 Tests to determine the presence of cations in ion group 5. Ion group 5 is soluble through all the steps in Figure 19.18. It consists of some alkali metal ions and NH_4^+ ion. Flame tests give characteristic colors for Na^+ ion **(A)** and K^+ ion **(B).** Adding OH^- to NH_4^+ and warming the solution forms gaseous NH_3, which turns moistened red litmus paper blue **(C).**

SECTION SUMMARY

Ions are precipitated selectively by adding a precipitating ion until the K_{sp} of one compound is exceeded as much as possible without exceeding the K_{sp} of the other. An extension of this approach is to control the equilibrium of the slightly soluble compound by simultaneously controlling an equilibrium system that contains the precipitating ion. Qualitative analysis of ion mixtures involves adding precipitating ions to separate the unknown ions into ion groups. The groups are then analyzed further through precipitation and complex-ion formation.

Chapter Perspective

This chapter is the last of three that explore the nature and variety of equilibrium systems. In Chapter 17, we discussed the central ideas of equilibrium in the context of gaseous systems. In Chapter 18, we extended our understanding to acid-base equilibria. In this chapter, we highlighted three types of aqueous ionic systems and examined their role in the laboratory and the environment. The equilibrium constant, in all its forms, is a number that provides a limit to changes in a system, whether a chemical reaction, a physical change, or the dissolution of a substance. You now have the skills to predict whether a change will take place and to calculate its result, but you still do not know why the change occurs in the first place, or why it stops when it does. In Chapter 20, you'll find out.

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. How the presence of a common ion suppresses a reaction that forms it (Section 19.1)
2. Why the concentrations of buffer components must be high to minimize the change in pH from addition of small amounts of H_3O^+ or OH^- (Section 19.1)
3. How buffer capacity depends on buffer concentration and on the pK_a of the acid component; why buffer range is within ± 1 pH unit of the pK_a (Section 19.1)
4. The nature of an acid-base indicator as a conjugate acid-base pair with differently colored acidic and basic forms (Section 19.2)
5. The distinction between equivalence point and end point in an acid-base titration (Section 19.2)
6. Why the shapes of strong acid–strong base, weak acid–strong base, and strong acid–weak base titration curves differ (Section 19.2)
7. How the pH at the equivalence point is determined by the species present; why the pH at the midpoint of the buffer region equals the pK_a of the acid (Section 19.2)
8. How the titration curve of a polyprotic acid has a buffer region and equivalence point for each ionizable proton (Section 19.2)
9. How a slightly soluble ionic compound reaches equilibrium in water, expressed by an equilibrium (solubility-product) constant, K_{sp} (Section 19.3)
10. Why incomplete dissociation of an ionic compound leads to approximate calculated values for K_{sp} and solubility (Section 19.3)
11. Why a common ion in a solution decreases the solubility of its compounds (Section 19.3)
12. How pH affects the solubility of a compound that contains a weak-acid anion (Section 19.3)
13. How precipitate formation depends on the relative values of Q_{sp} and K_{sp} (Section 19.3)
14. How complex-ion formation is stepwise and expressed by an overall equilibrium (formation) constant, K_f (Section 19.4)
15. Why addition of a ligand increases the solubility of a compound whose metal ion forms a complex ion (Section 19.4)
16. How the aqueous chemistry of amphoteric hydroxides involves precipitation, complex-ion formation, and acid-base equilibria (Section 19.4)
17. How selective precipitation and simultaneous equilibria are used to separate ions (Section 19.5)
18. How qualitative analysis is used to separate and identify the ions in a mixture (Section 19.5)

Master These Skills

1. Using stoichiometry and equilibrium problem-solving techniques to calculate the effect of added H_3O^+ or OH^- on buffer pH (SP 19.1)
2. Using the Henderson-Hasselbalch equation to calculate buffer pH (Section 19.1)
3. Choosing the components of a buffer with a given pH and calculating their quantities (SP 19.2)
4. Calculating the pH at any point in an acid-base titration (Section 19.2 and SP 19.3)
5. Choosing an appropriate indicator based on the pH at various points in a titration (Section 19.2)
6. Writing K_{sp} expressions for slightly soluble ionic compounds (SP 19.4)
7. Calculating a K_{sp} value from solubility data (SP 19.5)
8. Calculating solubility from a K_{sp} value (SP 19.6)
9. Using K_{sp} values to compare solubilities for compounds with the same total number of ions (Section 19.3)
10. Calculating the decrease in solubility caused by the presence of a common ion (SP 19.7)
11. Predicting the effect of added H_3O^+ on solubility (SP 19.8)
12. Using ion concentrations to calculate Q_{sp} and compare it with K_{sp} to predict whether a precipitate forms (SP 19.9)
13. Calculating the concentration of metal ion remaining after addition of excess ligand forms a complex ion (SP 19.10)
14. Using an overall equilibrium constant ($K_{sp} \times K_f$) to calculate the effect of complex-ion formation on solubility (SP 19.11)
15. Comparing K_{sp} values in order to separate ions by selective precipitation (SP 19.12)

Key Terms

Section 19.1
acid-base buffer (815)
common-ion effect (816)
Henderson-Hasselbalch equation (820)
buffer capacity (821)
buffer range (821)

Section 19.2
acid-base titration curve (824)
equivalence point (825)
end point (826)

Section 19.3
solubility-product constant (K_{sp}) (833)
molar solubility (834)

Section 19.4
complex ion (844)
ligand (844)
formation constant (K_f) (844)

Section 19.5
selective precipitation (850)
qualitative analysis (851)

Key Equations and Relationships

19.1 Finding the pH from known concentrations of a conjugate acid-base pair (Henderson-Hasselbalch equation) (820):

$$\text{pH} = \text{p}K_a + \log\left(\frac{[\text{base}]}{[\text{acid}]}\right)$$

19.2 Defining the equilibrium condition for a saturated solution of a slightly soluble compound, M_pX_q, composed of M^{n+} and X^{z-} ions (833):

$$Q_{sp} = [M^{n+}]^p[X^{z-}]^q = K_{sp}$$

Highlighted Figures and Tables

These figures (F) and tables (T) provide a review of key ideas.

F19.3 How a buffer works (817)
F19.4 Buffer capacity and pH change (821)
F19.5 Colors and pH ranges of acid-base indicators (824)
F19.7 A strong acid–strong base titration curve (825)
F19.8 A weak acid–strong base titration curve (827)
F19.9 A weak base–strong acid titration curve (830)

Brief Solutions to Follow-up Problems

19.1 (a) Before addition:
Assuming x is small enough to be neglected,
$[HF] = 0.50\ M$ and $[F^-] = 0.45\ M$

$$[H_3O^+] = K_a \times \frac{[HF]}{[F^-]} \approx (6.8\times10^{-4})\left(\frac{0.50}{0.45}\right) = 7.6\times10^{-4}\ M$$

$$\text{pH} = 3.12$$

(b) After addition of 0.40 g of NaOH (0.010 mol of NaOH) to 1.0 L of buffer,
$[HF] = 0.49\ M$ and $[F^-] = 0.46\ M$

$$[H_3O^+] \approx (6.8\times10^{-4})\left(\frac{0.49}{0.46}\right) = 7.2\times10^{-4}\ M;\ \text{pH} = 3.14$$

19.2 $[H_3O^+] = 10^{-\text{pH}} = 10^{-4.25} = 5.6\times10^{-5}$

$$[C_6H_5COOH] = \frac{[H_3O^+][C_6H_5COO^-]}{K_a} = \frac{(5.6\times10^{-5})(0.050)}{6.3\times10^{-5}} = 0.044\ M$$

Mass (g) of C_6H_5COOH

$$= 5.0\text{ L soln} \times \frac{0.044\text{ mol } C_6H_5COOH}{1\text{ L soln}} \times \frac{122.12\text{ g } C_6H_5COOH}{1\text{ mol } C_6H_5COOH} = 27\text{ g } C_6H_5COOH$$

Dissolve 27 g of C_6H_5COOH in 4.9 L of 0.050 M C_6H_5COONa and add solution to make 5.0 L. Adjust pH to 4.25 with strong acid or base.

19.3 (a) $[H_3O^+] \approx \sqrt{(2.3\times10^{-9})(0.2000)} = 2.1\times10^{-5}\ M$

$$\text{pH} = 4.68$$

(b) $[H_3O^+] = K_a \times \frac{[HBrO]}{[BrO^-]} = (2.3\times10^{-9})(1) = 2.3\times10^{-9}\ M$

$$\text{pH} = 8.64$$

(c) $[BrO^-] = \frac{\text{moles of } BrO^-}{\text{total volume}} = \frac{0.004000\text{ mol}}{0.06000\text{ L}} = 0.06667\ M$

$$K_b \text{ of } BrO^- = \frac{K_w}{K_a \text{ of HBrO}} = 4.3\times10^{-6}$$

$$[H_3O^+] = \frac{K_w}{\sqrt{K_b \times [BrO^-]}} \approx \frac{1.0\times10^{-14}}{\sqrt{(4.3\times10^{-6})(0.06667)}} = 1.9\times10^{-11}\ M$$

$$\text{pH} = 10.72$$

(d) Moles of OH^- added = 0.008000 mol
Volume (L) of OH^- soln = 0.08000 L

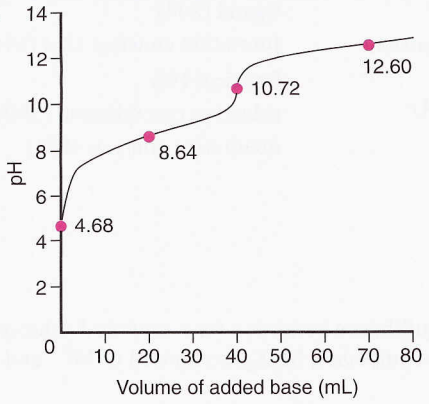
$$[OH^-] = \frac{\text{moles of } OH^- \text{ unreacted}}{\text{total volume}} = \frac{0.008000\text{ mol} - 0.004000\text{ mol}}{(0.02000 + 0.08000)\text{ L}} = 0.04000\ M$$

$$[H_3O^+] = \frac{K_w}{[OH^-]} = 2.5\times10^{-13}$$

$$\text{pH} = 12.60$$

Brief Solutions to Follow-up Problems *(continued)*

(e)



19.4 (a) $K_{sp} = [Ca^{2+}][SO_4^{2-}]$
(b) $K_{sp} = [Cr^{3+}]^2[CO_3^{2-}]^3$
(c) $K_{sp} = [Mg^{2+}][OH^-]^2$
(d) $K_{sp} = [As^{3+}]^2[HS^-]^3[OH^-]^3$

19.5 $[CaF_2] = \dfrac{1.5\times10^{-4}\text{ g CaF}_2}{10.0\text{ mL soln}} \times \dfrac{1000\text{ mL}}{1\text{ L}} \times \dfrac{1\text{ mol CaF}_2}{78.08\text{ g CaF}_2}$
$= 1.9\times10^{-4}\,M$

$CaF_2(s) \rightleftharpoons Ca^{2+}(aq) + 2F^-(aq)$

$[Ca^{2+}] = 1.9\times10^{-4}\,M$ and $[F^-] = 3.8\times10^{-4}\,M$
$K_{sp} = [Ca^{2+}][F^-]^2 = (1.9\times10^{-4})(3.8\times10^{-4})^2 = 2.7\times10^{-11}$

19.6 From the reaction table, $[Mg^{2+}] = S$ and $[OH^-] = 2S$
$K_{sp} = [Mg^{2+}][OH^-]^2 = 4S^3 = 6.3\times10^{-10}$; $S = 5.4\times10^{-4}\,M$

19.7 (a) In water: $K_{sp} = [Ba^{2+}][SO_4^{2-}] = S^2 = 1.1\times10^{-10}$;
$S = 1.0\times10^{-5}$
(b) In 0.10 M Na_2SO_4: $[SO_4^{2-}] = 0.10\,M$
$K_{sp} = 1.1\times10^{-10} \approx S \times 0.10$; $S = 1.1\times10^{-9}\,M$
S decreases in presence of the common ion SO_4^{2-}.

19.8 (a) Increases solubility.

$CaF_2(s) \rightleftharpoons Ca^{2+}(aq) + 2F^-(aq)$
$F^-(aq) + H_3O^+(aq) \longrightarrow HF(aq) + H_2O(l)$

(b) Increases solubility.

$ZnS(s) + H_2O(l) \rightleftharpoons Zn^{2+}(aq) + HS^-(aq) + OH^-(aq)$
$HS^-(aq) + H_3O^+(aq) \longrightarrow H_2S(aq) + H_2O(l)$
$OH^-(aq) + H_3O^+(aq) \longrightarrow 2H_2O(l)$

(c) No effect. $I^-(aq)$ is conjugate base of strong acid, HI.

19.9 $Ca_3(PO_4)_2(s) \rightleftharpoons 3Ca^{2+}(aq) + 2PO_4^{3-}(aq)$
$Q_{sp} = [Ca^{2+}]^3[PO_4^{3-}]^2 = (1.0\times10^{-9})^5 = 1.0\times10^{-45}$
$Q_{sp} < K_{sp}$, so $Ca_3(PO_4)_2$ will not precipitate.

19.10 $[Fe(H_2O)_6^{3+}]_{init} = \dfrac{(0.0255\text{ L})(3.1\times10^{-2}\,M)}{0.0255\text{ L} + 0.0350\text{ L}}$
$= 1.3\times10^{-2}\,M$

Similarly, $[CN^-]_{init} = 0.87\,M$. From the reaction table,

$K_f = \dfrac{[Fe(CN)_6^{3-}]}{[Fe(H_2O)_6^{3+}][CN^-]^6} = 4.0\times10^{43} \approx \dfrac{1.3\times10^{-2}}{x(0.79)^6}$

$x = [Fe(H_2O)_6^{3+}] \approx 1.3\times10^{-45}$

19.11 $AgBr(s) + 2NH_3(aq) \rightleftharpoons Ag(NH_3)_2^+(aq) + Br^-(aq)$
$K_{overall} = K_{sp}$ of AgBr $\times$ K_f of $Ag(NH_3)_2^+$
$= 8.5\times10^{-6}$

From the reaction table,

$\dfrac{S}{1.0 - 2S} = \sqrt{8.5\times10^{-6}} = 2.9\times10^{-3}$

$S = [Ag(NH_3)_2^+] = 2.9\times10^{-3}\,M$

Solubility is greater in 1 M hypo than in 1 M NH_3.

19.12 Both 1:1 salts, so K_{sp} values show that $CaSO_4$ is more soluble:

$[SO_4^{2-}] = \dfrac{K_{sp}}{[Ca^{2+}]} = \dfrac{2.4\times10^{-5}}{(0.025)(0.9999)} = 9.6\times10^{-4}\,M$

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

Note: Unless stated otherwise, all of the problems for this chapter refer to aqueous solutions at 298 K (25°C).

Equilibria of Acid-Base Buffer Systems

(Sample Problems 19.1 and 19.2)

Concept Review Questions

19.1 What is the purpose of an acid-base buffer?

19.2 How do the acid and base components of a buffer function? Why are they often a conjugate acid-base pair of a weak acid?

19.3 What is the common-ion effect? How is it related to Le Châtelier's principle? Explain with equations that include HF and NaF.

19.4 When a small amount of H_3O^+ is added to a buffer, does the pH remain constant? Explain.

19.5 What is the difference between buffers with high and low capacities? Will adding 0.01 mol of HCl produce a greater pH change in a buffer with a high or a low capacity? Explain.

19.6 Which of these factors influence buffer capacity? How?
(a) Conjugate acid-base pair
(b) pH of the buffer
(c) Concentration of buffer components
(d) Buffer range
(e) pK_a of the acid component

19.7 What is the relationship between the buffer range and the buffer-component concentration ratio?

19.8 A chemist needs a pH 3.5 buffer. Should she use NaOH with formic acid ($K_a = 1.8\times10^{-4}$) or with acetic acid ($K_a = 1.8\times10^{-5}$)? Why? What is the disadvantage of choosing the other acid? What is the role of the NaOH?

19.9 State and explain the relative change in pH and in buffer-component concentration ratio, [NaA]/[HA], for each addition:
(a) Add 0.1 M NaOH to the buffer
(b) Add 0.1 M HCl to the buffer

(c) Dissolve pure NaA in the buffer
(d) Dissolve pure HA in the buffer

19.10 Does the pH increase or decrease, and does it do so to a large or small extent, with each of the following additions?
(a) 5 drops of 0.1 *M* NaOH to 100 mL of 0.5 *M* acetate buffer
(b) 5 drops of 0.1 *M* HCl to 100 mL of 0.5 *M* acetate buffer
(c) 5 drops of 0.1 *M* NaOH to 100 mL of 0.5 *M* HCl
(d) 5 drops of 0.1 *M* NaOH to distilled water

Skill-Building Exercises *(grouped in similar pairs)*

19.11 What are the $[H_3O^+]$ and the pH of a propanoic acid–propanoate buffer that consists of 0.25 *M* CH_3CH_2COONa and 0.15 *M* CH_3CH_2COOH (K_a of propanoic acid = 1.3×10^{-5})?

19.12 What are the $[H_3O^+]$ and the pH of a benzoic acid–benzoate buffer that consists of 0.33 *M* C_6H_5COOH and 0.28 *M* C_6H_5COONa (K_a of benzoic acid = 6.3×10^{-5})?

19.13 What are the $[H_3O^+]$ and the pH of a buffer that consists of 0.50 *M* HNO_2 and 0.65 *M* KNO_2 (K_a of HNO_2 = 7.1×10^{-4})?

19.14 What are the $[H_3O^+]$ and the pH of a buffer that consists of 0.20 *M* HF and 0.25 *M* KF (K_a of HF = 6.8×10^{-4})?

19.15 Find the pH of a buffer that consists of 0.55 *M* HCOOH and 0.63 *M* HCOONa (pK_a of HCOOH = 3.74).

19.16 Find the pH of a buffer that consists of 0.95 *M* HBrO and 0.68 *M* KBrO (pK_a of HBrO = 8.64).

19.17 Find the pH of a buffer that consists of 1.0 *M* sodium phenolate (C_6H_5ONa) and 1.2 *M* phenol (C_6H_5OH) (pK_a of phenol = 10.00).

19.18 Find the pH of a buffer that consists of 0.12 *M* boric acid (H_3BO_3) and 0.82 *M* sodium borate (NaH_2BO_3) (pK_a of boric acid = 9.24).

19.19 Find the pH of a buffer that consists of 0.20 *M* NH_3 and 0.10 *M* NH_4Cl (pK_b of NH_3 = 4.75).

19.20 Find the pH of a buffer that consists of 0.50 *M* methylamine (CH_3NH_2) and 0.60 *M* CH_3NH_3Cl (pK_b of CH_3NH_2 = 3.35).

19.21 A buffer consists of 0.25 *M* $KHCO_3$ and 0.32 *M* K_2CO_3. Carbonic acid is a diprotic acid with $K_{a1} = 4.5\times10^{-7}$ and $K_{a2} = 4.7\times10^{-11}$. (a) Which K_a value is more important to this buffer? (b) What is the buffer pH?

19.22 A buffer consists of 0.50 *M* NaH_2PO_4 and 0.40 *M* Na_2HPO_4. Phosphoric acid is a triprotic acid ($K_{a1} = 7.2\times10^{-3}$, $K_{a2} = 6.3\times10^{-8}$, and $K_{a3} = 4.2\times10^{-13}$). (a) Which K_a value is most important to this buffer? (b) What is the buffer pH?

19.23 What is the buffer-component concentration ratio, $[Pr^-]/[HPr]$, of a buffer that has a pH of 5.11 (K_a of HPr = 1.3×10^{-5})?

19.24 What is the buffer-component concentration ratio, $[NO_2^-]/[HNO_2]$, of a buffer that has a pH of 2.95 (K_a of HNO_2 = 7.1×10^{-4})?

19.25 What is the buffer-component concentration ratio, $[BrO^-]/[HBrO]$, of a buffer that has a pH of 7.88 (K_a of HBrO = 2.3×10^{-9})?

19.26 What is the buffer-component concentration ratio, $[CH_3COO^-]/[CH_3COOH]$, of a buffer that has a pH of 4.39 (K_a of CH_3COOH = 1.8×10^{-5})?

19.27 A buffer containing 0.2000 *M* of acid, HA, and 0.1500 *M* of its conjugate base, A^-, has a pH of 3.35. What is the pH after 0.0015 mol of NaOH is added to 0.5000 L of this solution?

19.28 A buffer that contains 0.40 *M* base, B, and 0.25 *M* of its conjugate acid, BH^+, has a pH of 8.88. What is the pH after 0.0020 mol of HCl is added to 0.25 L of this solution?

19.29 A buffer that contains 0.110 *M* HY and 0.220 *M* Y^- has a pH of 8.77. What is the pH after 0.0010 mol of $Ba(OH)_2$ is added to 0.750 L of this solution?

19.30 A buffer that contains 1.05 *M* B and 0.750 *M* BH^+ has a pH of 9.50. What is the pH after 0.0050 mol of HCl is added to 0.500 L of this solution?

19.31 A buffer is prepared by mixing 184 mL of 0.442 *M* HCl and 0.500 L of 0.400 *M* sodium acetate. (See Appendix C.) (a) What is the pH? (b) How many grams of KOH must be added to 0.500 L of the buffer to change the pH by 0.15 units?

19.32 A buffer is prepared by mixing 50.0 mL of 0.050 *M* sodium bicarbonate and 10.7 mL of 0.10 *M* NaOH. (See Appendix C.) (a) What is the pH? (b) How many grams of HCl must be added to 25.0 mL of the buffer to change the pH by 0.07 units?

19.33 Choose specific acid-base conjugate pairs suitable for preparing the following buffers: (a) pH ≈ 4.0; (b) pH ≈ 7.0. (See Appendix C.)

19.34 Choose specific acid-base conjugate pairs suitable for preparing the following buffers: (a) $[H_3O^+] \approx 1\times10^{-9}$ *M*; (b) $[OH^-] \approx 3\times10^{-5}$ *M*. (See Appendix C.)

19.35 Choose specific acid-base conjugate pairs suitable for preparing the following buffers: (a) pH ≈ 2.5; (b) pH ≈ 5.5. (See Appendix C.)

19.36 Choose specific acid-base conjugate pairs suitable for preparing the following buffers: (a) $[OH^-] \approx 1\times10^{-6}$ *M*; (b) $[H_3O^+] \approx 4\times10^{-4}$ *M*. (See Appendix C.)

Problems in Context

19.37 An industrial chemist studying the effect of pH on bleaching and sterilizing processes prepares several hypochlorite buffers. Calculate the pH of the following buffers:
(a) 0.100 *M* HClO and 0.100 *M* NaClO
(b) 0.100 *M* HClO and 0.150 *M* NaClO
(c) 0.150 *M* HClO and 0.100 *M* NaClO
(d) One liter of the solution in part (a) after 0.0050 mol of NaOH has been added

19.38 Oxoanions of phosphorus are buffer components in blood. For a KH_2PO_4-Na_2HPO_4 solution with pH = 7.40 (pH of normal arterial blood), what is the buffer-component concentration ratio?

Acid-Base Titration Curves

(Sample Problem 19.3)

Concept Review Questions

19.39 How can you estimate the pH range of an indicator's color change? Why do some indicators have two separate pH ranges?

19.40 Why does the color change of an indicator take place over a range of about 2 pH units?

19.41 Why doesn't the addition of an acid-base indicator affect the pH of the test solution?

19.42 What is the difference between the end point of a titration and the equivalence point? Is the equivalence point always reached first? Explain.

19.43 Some automatic titrators measure the slope of a titration curve to determine the equivalence point. What happens to the slope that enables the instrument to recognize this point?

19.44 Explain how *strong acid*–strong base, *weak acid*–strong base, and *weak base*–strong acid titrations using the same concentrations differ in terms of (a) the initial pH and (b) the pH at the equivalence point. (The component in italics is in the flask.)

19.45 What species are in the buffer region of a weak acid–strong base titration? How are they different from the species at the equivalence point? How are they different from the species in the buffer region of a weak base–strong acid titration?

19.46 Why is the center of the buffer region of a weak acid–strong base titration significant?

19.47 How does the titration curve of a monoprotic acid differ from that of a diprotic acid?

Skill-Building Exercises *(grouped in similar pairs)*

19.48 The indicator cresol red has $K_a = 5.0\times10^{-9}$. Over what approximate pH range does it change color?

19.49 The indicator thymolphthalein has $K_a = 7.9\times10^{-11}$. Over what approximate pH range does it change color?

19.50 Use Figure 19.5 to find an indicator for these titrations:
(a) 0.10 *M* HCl with 0.10 *M* NaOH
(b) 0.10 *M* HCOOH (Appendix C) with 0.10 *M* NaOH

19.51 Use Figure 19.5 to find an indicator for these titrations:
(a) 0.10 *M* CH_3NH_2 (Appendix C) with 0.10 *M* HCl
(b) 0.50 *M* HI with 0.10 *M* KOH

19.52 Use Figure 19.5 to find an indicator for these titrations:
(a) 0.5 *M* $(CH_3)_2NH$ (Appendix C) with 0.5 *M* HBr
(b) 0.2 *M* KOH with 0.2 *M* HNO_3

19.53 Use Figure 19.5 to find an indicator for these titrations:
(a) 0.25 *M* C_6H_5COOH (Appendix C) with 0.25 *M* KOH
(b) 0.50 *M* NH_4Cl (Appendix C) with 0.50 *M* NaOH

19.54 Calculate the pH during the titration of 50.00 mL of 0.1000 *M* HCl with 0.1000 *M* NaOH solution after the following additions of base: (a) 0 mL; (b) 25.00 mL; (c) 49.00 mL; (d) 49.90 mL; (e) 50.00 mL; (f) 50.10 mL; (g) 60.00 mL.

19.55 Calculate the pH during the titration of 30.00 mL of 0.1000 *M* KOH with 0.1000 *M* HBr solution after the following additions of acid: (a) 0 mL; (b) 15.00 mL; (c) 29.00 mL; (d) 29.90 mL; (e) 30.00 mL; (f) 30.10 mL; (g) 40.00 mL.

19.56 Find the pH during the titration of 20.00 mL of 0.1000 *M* butanoic acid, $CH_3CH_2CH_2COOH$ ($K_a = 1.54\times10^{-5}$), with 0.1000 *M* NaOH solution after the following additions of titrant: (a) 0 mL; (b) 10.00 mL; (c) 15.00 mL; (d) 19.00 mL; (e) 19.95 mL; (f) 20.00 mL; (g) 20.05 mL; (h) 25.00 mL.

19.57 Find the pH during the titration of 20.00 mL of 0.1000 *M* triethylamine, $(CH_3CH_2)_3N$ ($K_b = 5.2\times10^{-4}$), with 0.1000 *M* HCl solution after the following additions of titrant: (a) 0 mL; (b) 10.00 mL; (c) 15.00 mL; (d) 19.00 mL; (e) 19.95 mL; (f) 20.00 mL; (g) 20.05 mL; (h) 25.00 mL.

19.58 Find the pH and volume (mL) of 0.0372 *M* NaOH needed to reach the equivalence point(s) in titrations of
(a) 42.2 mL of 0.0520 *M* CH_3COOH
(b) 18.9 mL of 0.0890 *M* H_2SO_3 (two equivalence points)

19.59 Find the pH and volume (mL) of 0.0588 *M* KOH needed to reach the equivalence point(s) in titrations of
(a) 23.4 mL of 0.0390 *M* HNO_2
(b) 17.3 mL of 0.130 *M* H_2CO_3 (two equivalence points)

19.60 Find the pH and the volume (mL) of 0.135 *M* HCl needed to reach the equivalence point(s) in titrations of the following:
(a) 55.5 mL of 0.234 *M* NH_3
(b) 17.8 mL of 1.11 *M* CH_3NH_2

19.61 Find the pH and volume (mL) of 0.447 *M* HNO_3 needed to reach the equivalence point(s) in titrations of
(a) 2.65 L of 0.0750 *M* pyridine (C_5H_5N)
(b) 0.188 L of 0.250 *M* ethylenediamine ($H_2NCH_2CH_2NH_2$)

Equilibria of Slightly Soluble Ionic Compounds

(Sample Problems 19.4 to 19.9)

Concept Review Questions

19.62 The molar solubility of M_2X is 5×10^{-5} *M*. What is the molarity of each ion? How do you set up the calculation to find K_{sp}? What assumption must you make about the dissociation of M_2X into ions? Why is the calculated K_{sp} higher than the actual value?

19.63 Why does pH affect the solubility of CaF_2 but not of $CaCl_2$?

19.64 A list of K_{sp} values like that in Appendix C can be used to compare the solubility of silver chloride directly with that of silver bromide but not with that of silver chromate. Explain.

19.65 In a gaseous equilibrium, the reverse reaction occurs when $Q_c > K_c$. What occurs in aqueous solution when $Q_{sp} > K_{sp}$?

Skill-Building Exercises *(grouped in similar pairs)*

19.66 Write the ion-product expressions for (a) silver carbonate; (b) barium fluoride; (c) copper(II) sulfide.

19.67 Write the ion-product expressions for (a) iron(III) hydroxide; (b) barium phosphate; (c) tin(II) sulfide.

19.68 Write the ion-product expressions for (a) calcium chromate; (b) silver cyanide; (c) nickel(II) sulfide.

19.69 Write the ion-product expressions for (a) lead(II) iodide; (b) strontium sulfate; (c) cadmium sulfide.

19.70 The solubility of silver carbonate is 0.032 *M* at 20°C. Calculate its K_{sp}.

19.71 The solubility of zinc oxalate is 7.9×10^{-3} *M* at 18°C. Calculate its K_{sp}.

19.72 The solubility of silver dichromate at 15°C is 8.3×10^{-3} g/100 mL solution. Calculate its K_{sp}.

19.73 The solubility of calcium sulfate at 30°C is 0.209 g/100 mL solution. Calculate its K_{sp}.

19.74 Find the molar solubility of $SrCO_3$ ($K_{sp} = 5.4\times10^{-10}$) in (a) pure water and (b) 0.13 *M* $Sr(NO_3)_2$.

19.75 Find the molar solubility of $BaCrO_4$ ($K_{sp} = 2.1\times10^{-10}$) in (a) pure water and (b) 1.5×10^{-3} *M* Na_2CrO_4.

19.76 Calculate the molar solubility of $Ca(IO_3)_2$ in (a) 0.060 *M* $Ca(NO_3)_2$ and (b) 0.060 *M* $NaIO_3$. (See Appendix C.)

19.77 Calculate the molar solubility of Ag_2SO_4 in (a) 0.22 *M* $AgNO_3$ and (b) 0.22 *M* Na_2SO_4. (See Appendix C.)

19.78 Which compound in each pair is more soluble in water?
(a) Magnesium hydroxide or nickel(II) hydroxide
(b) Lead(II) sulfide or copper(II) sulfide
(c) Silver sulfate or magnesium fluoride

19.79 Which compound in each pair is more soluble in water?
(a) Strontium sulfate or barium chromate
(b) Calcium carbonate or copper(II) carbonate
(c) Barium iodate or silver chromate

19.80 Which compound in each pair is more soluble in water?
(a) Barium sulfate or calcium sulfate
(b) Calcium phosphate or magnesium phosphate
(c) Silver chloride or lead(II) sulfate

19.81 Which compound in each pair is more soluble in water?
(a) Manganese(II) hydroxide or calcium iodate
(b) Strontium carbonate or cadmium sulfide
(c) Silver cyanide or copper(I) iodide

19.82 Write equations to show whether the solubility of either of the following is affected by pH: (a) AgCl; (b) $SrCO_3$.

19.83 Write equations to show whether the solubility of either of the following is affected by pH: (a) CuBr; (b) $Ca_3(PO_4)_2$.

19.84 Write equations to show whether the solubility of either of the following is affected by pH: (a) $Fe(OH)_2$; (b) CuS.

19.85 Write equations to show whether the solubility of either of the following is affected by pH: (a) PbI_2; (b) $Hg_2(CN)_2$.

19.86 Does any solid $Cu(OH)_2$ form when 0.075 g of KOH is dissolved in 1.0 L of 1.0×10^{-3} *M* $Cu(NO_3)_2$?

19.87 Does any solid $PbCl_2$ form when 3.5 mg of NaCl is dissolved in 0.250 L of 0.12 *M* $Pb(NO_3)_2$?

19.88 Does any solid $Ba(IO_3)_2$ form when 6.5 mg of $BaCl_2$ is dissolved in 500. mL of 0.033 *M* $NaIO_3$?

19.89 Does any solid Ag_2CrO_4 form when 2.7×10^{-5} g of $AgNO_3$ is dissolved in 15.0 mL of 4.0×10^{-4} *M* K_2CrO_4?

Problems in Context

19.90 When blood is donated, sodium oxalate solution is used to precipitate Ca^{2+}, which triggers clotting. A 104-mL sample of blood contains 9.7×10^{-5} g Ca^{2+}/mL. A technologist treats the sample with 100.0 mL of 0.1550 *M* $Na_2C_2O_4$. Calculate $[Ca^{2+}]$ after the treatment. (See Appendix C for K_{sp} of $CaC_2O_4\cdot H_2O$.)

Equilibria Involving Complex Ions

(Sample Problems 19.10 and 19.11)

Concept Review Questions

19.91 How can a positive metal ion be at the center of a negative complex ion?

19.92 Write equations to show the stepwise reaction of $Cd(H_2O)_4^{2+}$ in an aqueous solution of KI to form CdI_4^{2-}. Show that $K_{f(overall)} = K_{f1} \times K_{f2} \times K_{f3} \times K_{f4}$.

19.93 Consider the dissolution of PbS in water:

$$PbS(s) + H_2O(l) \rightleftharpoons Pb^{2+}(aq) + HS^-(aq) + OH^-(aq)$$

Adding aqueous NaOH causes more PbS to dissolve. Does this violate Le Châtelier's principle? Explain.

Skill-Building Exercises *(grouped in similar pairs)*

19.94 Write a balanced equation for the reaction of $Hg(H_2O)_4^{2+}$ in aqueous KCN.

19.95 Write a balanced equation for the reaction of $Zn(H_2O)_4^{2+}$ in aqueous NaCN.

19.96 Write a balanced equation for the reaction of $Ag(H_2O)_2^+$ in aqueous $Na_2S_2O_3$.

19.97 Write a balanced equation for the reaction of $Al(H_2O)_6^{3+}$ in aqueous KF.

19.98 Potassium thiocyanate, KSCN, is often used to detect the presence of Fe^{3+} ions in solution through the formation of the red $Fe(H_2O)_5SCN^{2+}$ (or, more simply, $FeSCN^{2+}$). What is $[Fe^{3+}]$ when 0.50 L each of 0.0015 *M* $Fe(NO_3)_3$ and 0.20 *M* KSCN are mixed? K_f of $FeSCN^{2+} = 8.9\times10^2$.

19.99 What is $[Ag^+]$ when 25.0 mL each of 0.044 *M* $AgNO_3$ and 0.57 *M* $Na_2S_2O_3$ are mixed [K_f of $Ag(S_2O_3)_2^{3+} = 4.7\times10^{13}$]?

19.100 When 0.82 g of $ZnCl_2$ is dissolved in 255 mL of 0.150 *M* NaCN, what are $[Zn^{2+}]$, $[Zn(CN)_4^{2-}]$, and $[CN^-]$ [K_f of $Zn(CN)_4^{2-} = 4.2\times10^{19}$]?

19.101 When 2.4 g of $Co(NO_3)_2$ is dissolved in 0.350 L of 0.22 *M* KOH, what are $[Co^{2+}]$, $[Co(OH)_4^{2-}]$, and $[OH^-]$ [K_f of $Co(OH)_4^{2-} = 5\times10^9$]?

19.102 Find the solubility of AgI in 2.5 *M* NH_3 [K_{sp} of AgI = 8.3×10^{-17}; K_f of $Ag(NH_3)_2^+ = 1.7\times10^7$].

19.103 Find the solubility of $Cr(OH)_3$ in a buffer of pH 13.0 [K_{sp} of $Cr(OH)_3 = 6.3\times10^{-31}$; K_f of $Cr(OH)_4^- = 8.0\times10^{29}$].

Ionic Equilibria in Chemical Analysis

(Sample Problem 19.12)

Problems in Context

19.104 A 50.0-mL volume of 0.50 *M* $Fe(NO_3)_3$ is mixed with 125 mL of 0.25 *M* $Cd(NO_3)_2$.
(a) If aqueous NaOH is added, which ion precipitates first? (See Appendix C.)
(b) Describe how the metal ions can be separated using NaOH.
(c) Calculate the $[OH^-]$ that will accomplish the separation.

19.105 In a qualitative analysis procedure, a chemist adds 0.3 *M* HCl to a group of ions and then saturates the solution with H_2S.
(a) What is the $[HS^-]$ of the solution?
(b) If 0.01 *M* of each of these ions is present, which will form a precipitate: Pb^{2+}, Mn^{2+}, Hg^{2+}, Cu^{2+}, Ni^{2+}, Fe^{2+}, Ag^+, K^+?

Comprehensive Problems

19.106 What volumes of 0.200 *M* HCOOH and 2.00 *M* NaOH would make 500. mL of a buffer with the same pH as one made from 475 mL of 0.200 *M* benzoic acid and 25 mL of 2.00 *M* NaOH?

19.107 A microbiologist is preparing a medium on which to culture *E. coli* bacteria. She buffers the medium at pH 7.00 to minimize the effect of acid-producing fermentation. What volumes of equimolar aqueous solutions of K_2HPO_4 and KH_2PO_4 must she combine to make 100. mL of the pH 7.00 buffer?

19.108 As an FDA physiologist, you need 0.600 L of formic acid–formate buffer with a pH of 3.74.
(a) What is the required buffer-component concentration ratio?
(b) How do you prepare this solution from stock solutions of 1.0 *M* HCOOH and 1.0 *M* NaOH?
(c) What is the final concentration of HCOOH in this solution?

19.109 Tris(hydroxymethyl)aminomethane $[(HOCH_2)_3CNH_2$, known as TRIS or THAM] is a weak base widely used in biochemical experiments to make buffer solutions in the pH range of 7 to 9. A certain TRIS buffer has a pH of 8.10 at 25°C and a pH of 7.80 at 37°C. Why does the pH change with temperature?

19.110 Gout is caused by an error in nucleic acid metabolism that leads to a buildup of uric acid in body fluids, which is deposited as slightly soluble sodium urate ($C_5H_3N_4O_3Na$) in the soft tissues of joints. If the extracellular $[Na^+]$ is 0.15 *M* and the solubility in water of sodium urate is 0.085 g/100. mL, what is the minimum urate ion concentration (abbreviated $[Ur^-]$) that will cause a deposit of sodium urate?

19.111 Cadmium ion in solution is analyzed by precipitation as the sulfide, a yellow compound used as a pigment in everything from artists' oil paints to glass and rubber. Calculate the molar solubility of cadmium sulfide at 25°C.

19.112 In the discussion of cave formation in the Chemical Connections essay (p. 840), the dissolution of CO_2 (equation 1) has a K_{eq} of 3.1×10^{-2}, and the formation of aqueous $Ca(HCO_3)_2$ (equation 2) has a K_{eq} of 1×10^{-12}. The fraction by volume of atmospheric CO_2 is 3×10^{-4}. (a) Find $[CO_2(aq)]$ in equilibrium with atmospheric CO_2. (b) Determine $[Ca^{2+}]$ arising from (equation 2) with atmospheric CO_2. (c) Calculate $[Ca^{2+}]$ if atmospheric CO_2 doubles.

19.113 Phosphate systems form essential buffers in organisms. Calculate the pH of a buffer made by dissolving 0.80 mol of NaOH in 0.50 L of 1.0 *M* H_3PO_4.

19.114 The solubility of KCl is 3.7 *M* at 20°C. Two beakers contain 100. mL of saturated KCl solution: 100. mL of 6.0 *M* HCl is added to the first beaker and 100. mL of 12 *M* HCl to the second. (a) Find the ion-product constant of KCl at 20°C. (b) What mass, if any, of KCl will precipitate from each beaker?

19.115 It is possible to detect NH_3 gas over 10^{-2} *M* NH_3. To what pH must 0.15 *M* NH_4Cl be raised to form detectable NH_3?

19.116 Manganese(II) sulfide is one of the compounds found in the nodules on the ocean floor that may eventually be a primary source of many transition metals. The solubility of MnS is 4.7×10^{-4} g/100 mL solution. Estimate the K_{sp} of MnS.

19.117 The normal pH of blood is 7.40 ± 0.05 and is controlled in part by the H_2CO_3-HCO_3^- buffer system.
(a) Assuming that the K_a value for carbonic acid at 25°C applies to blood, what is the $[H_2CO_3]/[HCO_3^-]$ ratio in normal blood?
(b) In a condition called *acidosis*, the blood is too acidic. What is the $[H_2CO_3]/[HCO_3^-]$ ratio in a patient whose blood pH is 7.20 (severe acidosis)?

19.118 Consider the following reaction:

$$Fe(OH)_3(s) + OH^-(aq) \rightleftharpoons Fe(OH)_4^-(aq) \qquad K_c = 4\times10^{-5}$$

(a) What is the solubility of $Fe(OH)_3$ in 0.010 *M* NaOH?
(b) How might this result be used in qualitative analysis?

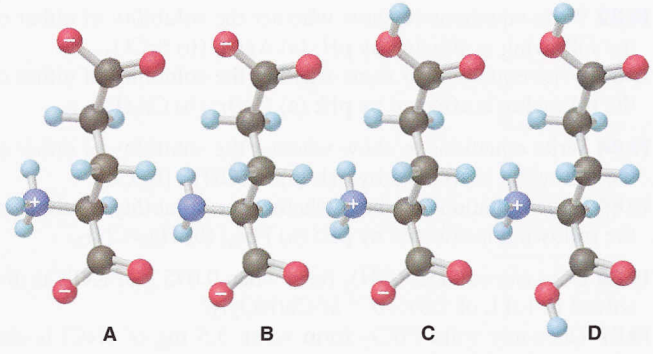
19.119 A bioengineer preparing cells for cloning bathes a small piece of rat epithelial tissue in a TRIS buffer (see Problem 19.109). The buffer is made by dissolving 43.0 g of TRIS ($pK_b = 5.91$) in enough 0.095 *M* HCl to make 1.00 L of solution. What is the molarity of TRIS and the pH of the buffer?

19.120 Sketch a qualitative curve for the titration of ethylenediamine, $H_2NCH_2CH_2NH_2$, with 0.1 *M* HCl.

19.121 A solution contains 0.10 *M* $ZnCl_2$ and 0.020 *M* $MnCl_2$. Given the following information, how would you adjust the pH to separate the ions as their sulfides ($[H_2S]$ of a saturated aqueous solution at 25°C = 0.10 *M*; $K_w = 1.0\times10^{-14}$ at 25°C)?

$$MnS + H_2O \rightleftharpoons Mn^{2+} + HS^- + OH^- \qquad K_{sp} = 3\times10^{-11}$$
$$ZnS + H_2O \rightleftharpoons Zn^{2+} + HS^- + OH^- \qquad K_{sp} = 2\times10^{-22}$$
$$H_2S + H_2O \rightleftharpoons H_3O^+ + HS^- \qquad K_{a1} = 9\times10^{-8}$$

19.122 Amino acids [general formula $NH_2CH(R)COOH$] can be considered polyprotic acids. In many cases, the R group contains additional amine and carboxyl groups.
(a) Can an amino acid dissolved in pure water have a protonated COOH group and an unprotonated NH_2 group (K_a of COOH group = 4.47×10^{-3}; K_b of NH_2 group = 6.03×10^{-5})? Use glycine, NH_2CH_2COOH, to explain why.
(b) Calculate $[^+NH_3CH_2COO^-]/[^+NH_3CH_2COOH]$ at pH 5.5.
(c) The R group of lysine is $—CH_2CH_2CH_2CH_2NH_2$ (pK_b = 3.47). Draw the structure of lysine at pH 1, physiological pH (~7), and pH 13.
(d) The R group of glutamic acid is $—CH_2CH_2COOH$ (pK_a = 4.07). Four ionic forms of glutamic acid (A to D) are shown below. Select the form that predominates at pH 1, at physiological pH (~7), and at pH 13.



19.123 Tooth enamel consists of hydroxyapatite, $Ca_5(PO_4)_3OH$ ($K_{sp} = 6.8\times10^{-37}$). Fluoride ion added to drinking water reacts with $Ca_5(PO_4)_3OH$ to form the more tooth decay–resistant fluorapatite, $Ca_5(PO_4)_3F$ ($K_{sp} = 1.0\times10^{-60}$). Fluoridated water has dramatically decreased cavities among children. Calculate the solubility of $Ca_5(PO_4)_3OH$ and of $Ca_5(PO_4)_3F$ in water.

19.124 The acid-base indicator ethyl orange turns from red to yellow over the pH range 3.4 to 4.8. Estimate K_a for ethyl orange.

19.125 The titration of a weak acid with a strong base has an end point at pH = 9.0. What indicator is suitable for the titration?

19.126 Use the values obtained in Problem 19.54 to sketch a curve of $[H_3O^+]$ vs. mL of added titrant. Are there advantages or disadvantages to viewing the results in this form? Explain.

19.127 Instrumental acid-base titrations use a pH meter to monitor the changes in pH and volume. The equivalence point is found from the volume at which the curve has the steepest slope.
(a) Use Figure 19.7 to calculate the slope $\Delta pH/\Delta V$ for all pairs of adjacent points and the average volume (V_{avg}) for each interval.
(b) Plot $\Delta pH/\Delta V$ vs. V_{avg} to find the steepest slope, and thus the volume at the equivalence point. (For example, the first pair of points gives $\Delta pH = 0.22$, $\Delta V = 10.00$ mL; hence, $\Delta pH/\Delta V = 0.022\ mL^{-1}$, and $V_{avg} = 5.00$ mL.)

19.128 What is the pH of a solution of 6.5×10^{-9} mol of $Ca(OH)_2$ in 10.0 L of water [K_{sp} of $Ca(OH)_2 = 6.5\times10^{-6}$]?

19.129 Muscle physiologists study the accumulation of lactic acid [$CH_3CH(OH)COOH$] during exercise. Food chemists study its occurrence in sour milk, beer, wine, and fruit. Industrial microbiologists study its formation by various bacterial species from carbohydrates. A biochemist prepares a lactic acid–lactate buffer by mixing 225 mL of 0.85 *M* lactic acid ($K_a = 1.38\times10^{-4}$) with 435 mL of 0.68 *M* sodium lactate. What is the buffer pH?

19.130 A student wants to dissolve the maximum amount of CaF_2 ($K_{sp} = 3.2\times10^{-11}$) to make 1 L of aqueous solution.
(a) Into which of the following should she dissolve the salt?
(I) Pure water (II) 0.01 *M* HF (III) 0.01 *M* NaOH
(IV) 0.01 *M* HCl (V) 0.01 *M* $Ca(OH)_2$
(b) Which would dissolve the least amount of salt?

19.131 A 500.-mL solution consists of 0.050 mol of solid NaOH and 0.13 mol of hypochlorous acid (HClO; $K_a = 3.0\times10^{-8}$) dissolved in water. (a) Aside from water, what is the concentration of each species present? (b) What is the pH of the solution? (c) What is the pH after adding 0.0050 mol of HCl to the flask?

19.132 The Henderson-Hasselbalch equation gives a relationship for obtaining the pH of a buffer solution consisting of HA and A^-. Derive an analogous relationship for obtaining the pOH of a buffer solution consisting of B and BH^+.

19.133 Calculate the molar solubility of $Hg_2C_2O_4$ ($K_{sp} = 1.75\times10^{-13}$) in 0.13 *M* $Hg_2(NO_3)_2$.

19.134 The well water in an area is "hard" because it is in equilibrium with $CaCO_3$ in the surrounding rocks. What is the concentration of Ca^{2+} in the well water (assuming the water's pH is such that the CO_3^{2-} ion is not hydrolyzed)? (See Appendix C for K_{sp} of $CaCO_3$.)

19.135 Four samples of an unknown solution are tested individually by adding HCl, H_2S in acidic solution, H_2S in basic solution, or Na_2CO_3, respectively. No precipitate forms in any of the tests. When NaOH is added to the original solution, moistened litmus paper held above the solution turns blue. A drop of the original solution turns the color of a flame violet. Which ions are present in the unknown solution?

19.136 Human blood contains one buffer system based on phosphate species and one on carbonate species. Assuming that blood has a normal pH of 7.4, what are the principal phosphate and carbonate species present? What is the ratio of the two phosphate species? (In the presence of the dissolved ions and other species in blood, K_{a1} of $H_3PO_4 = 1.3\times10^{-2}$, $K_{a2} = 2.3\times10^{-7}$, and $K_{a3} = 6\times10^{-12}$; K_{a1} of $H_2CO_3 = 8\times10^{-7}$ and $K_{a2} = 1.6\times10^{-10}$.)

19.137 Most qualitative analysis schemes start with the separation of ion group 1, Ag^+, Hg_2^{2+}, and Pb^{2+}, by precipitating AgCl, Hg_2Cl_2, and $PbCl_2$. Develop a procedure for confirming the presence or absence of these ions from the following:

- $PbCl_2$ is soluble in hot water, but AgCl and Hg_2Cl_2 are not.
- $PbCrO_4$ is a yellow solid that is insoluble in hot water.
- AgCl forms colorless $Ag(NH_3)_2^+(aq)$ in aqueous NH_3.
- When a solution containing $Ag(NH_3)_2^+$ is acidified with HCl, AgCl precipitates.
- Hg_2Cl_2 forms an insoluble mixture of Hg(*l*; black) and $HgNH_2Cl$(*s*; white) in aqueous NH_3.

19.138 An environmental technician collects a sample of rainwater. A light on her portable pH meter indicates low battery power, so she uses indicator solutions to estimate the pH. A piece of litmus paper turns red, indicating acidity, so she divides the sample into thirds and obtains the following results: thymol blue turns yellow; bromphenol blue turns green; and methyl red turns red. Estimate the pH of the rainwater.

19.139 A 0.050 *M* H_2S solution contains 0.15 *M* $NiCl_2$ and 0.35 *M* $Hg(NO_3)_2$. What pH is required to precipitate the maximum amount of HgS but none of the NiS? (See Appendix C.)

19.140 Quantitative analysis of Cl^- ion is often performed by a titration with silver nitrate, using sodium chromate as an indicator. As standardized $AgNO_3$ is added, both white AgCl and red Ag_2CrO_4 precipitate, but so long as some Cl^- remains, the Ag_2CrO_4 redissolves as the mixture is stirred. When the red color is permanent, the equivalence point has been reached.

(a) Calculate the equilibrium constant for the reaction

$$2AgCl(s) + CrO_4^{2-}(aq) \rightleftharpoons Ag_2CrO_4(s) + 2Cl^-(aq)$$

(b) Explain why the silver chromate redissolves.

(c) If 25.00 cm^3 of 0.1000 *M* NaCl is mixed with 25.00 cm^3 of 0.1000 *M* $AgNO_3$, what is the concentration of Ag^+ remaining in solution? Is this sufficient to precipitate any silver chromate?

19.141 An ecobotanist separates the components of a tropical bark extract by chromatography. She discovers a large proportion of quinidine, a dextrorotatory isomer of quinine used for control of arrhythmic heartbeat. Quinidine has two basic nitrogens ($K_{b1} = 4.0\times10^{-6}$ and $K_{b2} = 1.0\times10^{-10}$). To measure the concentration, she carries out a titration. Because of the low solubility of quinidine, she first protonates both nitrogens with excess HCl and titrates the acidified solution with standardized base. A 33.85-mg sample of quinidine ($\mathcal{M} = 324.41$ g/mol) is acidified with 6.55 mL of 0.150 *M* HCl. (a) How many milliliters of 0.0133 *M* NaOH are needed to titrate the excess HCl? (b) How many additional milliliters of titrant are needed to reach the first equivalence point of quinidine dihydrochloride? (c) What is the pH at the first equivalence point?

19.142 Some kidney stones form by the precipitation of calcium oxalate monohydrate ($CaC_2O_4\cdot H_2O$, $K_{sp} = 2.3\times10^{-9}$). The pH of urine varies from 5.5 to 7.0, and the average $[Ca^{2+}]$ in urine is 2.6×10^{-3} *M*.

(a) If the concentration of oxalic acid in urine is 3.0×10^{-13} *M*, will kidney stones form at pH = 5.5?

(b) At pH = 7.0?

(c) Vegetarians have a urine pH above 7. Are they more or less likely to form kidney stones?

19.143 A biochemist needs a medium for acid-producing bacteria. The pH of the medium must not change by more than 0.05 pH units for every 0.0010 mol of H_3O^+ generated by the organisms per liter of medium. A buffer consisting of 0.10 *M* HA and 0.10 *M* A^- is included in the medium to control its pH. What volume of this buffer must be included in 1.0 L of medium?

19.144 A 35.00-mL solution of 0.2500 *M* HF is titrated with a standardized 0.1532 *M* solution of NaOH at 25°C.

(a) What is the pH of the HF solution before titrant is added?

(b) How many milliliters of titrant are required to reach the equivalence point?

(c) What is the pH at 0.50 mL before the equivalence point?

(d) What is the pH at the equivalence point?

(e) What is the pH at 0.50 mL after the equivalence point?

19.145 Because of the toxicity of mercury compounds, mercury(I) chloride is used in antibacterial salves. The mercury(I) ion (Hg_2^{2+}) consists of two bound Hg^+ ions.

(a) What is the empirical formula of mercury(I) chloride?

(b) Calculate $[Hg_2^{2+}]$ in a saturated solution of mercury(I) chloride ($K_{sp} = 1.5\times10^{-18}$).

(c) A seawater sample contains 0.20 lb of NaCl per gallon. Find $[Hg_2^{2+}]$ if the seawater is saturated with mercury(I) chloride.

(d) How many grams of mercury(I) chloride are needed to saturate 4900 km^3 of water (the volume of Lake Michigan)?

(e) How many grams of mercury(I) chloride are needed to saturate 4900 km^3 of seawater?

19.146 A lake that has a surface area of 10.0 acres (1 acre = 4.840×10^3 yd^2) receives 1.00 in. of rain of pH 4.20. (Assume the acidity of the rain is due to a strong, monoprotic acid.)

(a) How many moles of H_3O^+ are in the rain falling on the lake?

(b) If the lake is unbuffered (pH = 7.00) and its average depth is 10.0 ft before the rain, find the pH after the rain has been mixed with lake water. (Ignore runoff from the surrounding land.)

(c) If the lake contains hydrogen carbonate ions (HCO_3^-), what mass of HCO_3^- would neutralize the acid in the rain?

19.147 A 35.0-mL solution of 0.075 *M* $CaCl_2$ is mixed with 25.0 mL of 0.090 *M* $BaCl_2$. (a) If aqueous KF is added, which fluoride precipitates first? (b) Describe how the metal ions can be separated using KF to form the fluorides. (c) Calculate the fluoride ion concentration that will accomplish the separation.

19.148 Even before the industrial age, rainwater was slightly acidic due to dissolved CO_2. Use the following data to calculate pH of unpolluted rainwater at 25°C: vol % in air of CO_2 = 0.033 vol %; solubility of CO_2 in pure water at 25°C and 1 atm = 88 mL CO_2/100 mL H_2O; K_{a1} of $H_2CO_3 = 4.5\times10^{-7}$.

19.149 Seawater at the surface has a pH of about 8.5.
(a) Which of the following species has the highest concentration at this pH: H_2CO_3; HCO_3^-; CO_3^{2-}? Explain.
(b) What are the concentration ratios $[CO_3^{2-}]/[HCO_3^-]$ and $[HCO_3^-]/[H_2CO_3]$ at this pH?
(c) In the deep sea, light levels are low, and the pH is around 7.5. Suggest a reason for the lower pH at the greater ocean depth. (*Hint:* Consider the presence or absence of plant and animal life, and the effects on carbon dioxide concentrations.)

19.150 Ethylenediaminetetraacetic acid (abbreviated H_4EDTA) is a tetraprotic acid. Its salts are used to treat toxic metal poisoning by forming soluble complex ions that are then excreted. Because $EDTA^{4-}$ also binds essential calcium ions, it is often administered as the calcium disodium salt. For example, when $Na_2Ca(EDTA)$ is given to a patient, the $[Ca(EDTA)]^{2-}$ ions react with circulating Pb^{2+} ions and the metal ions are exchanged:

$$[Ca(EDTA)]^{2-}(aq) + Pb^{2+}(aq) \rightleftharpoons [Pb(EDTA)]^{2-}(aq) + Ca^{2+}(aq) \qquad K_c = 2.5\times10^7$$

A child has a dangerous blood lead level of 120 μg/100 mL. If the child is administered 100. mL of 0.10 *M* $Na_2Ca(EDTA)$, assuming the exchange reaction and excretion process are 100% efficient, what is the final concentration of Pb^{2+} in μg/100 mL blood? (Total blood volume is 1.5 L.)

19.151 EDTA binds metal ions to form complex ions (see Problem 19.150), so it is used to determine the concentrations of metal ions in solution:

$$M^{n+}(aq) + EDTA^{4-}(aq) \longrightarrow MEDTA^{n-4}(aq)$$

A 50.0-mL sample of 0.048 *M* Co^{2+} is titrated with 0.050 *M* $EDTA^{4-}$. Find $[Co^{2+}]$ and $[EDTA^{4-}]$ after (a) 25.0 mL and (b) 75.0 mL of $EDTA^{4-}$ are added (log K_f of $CoEDTA^{2-} = 16.31$).

19.152 Sodium chloride is purified for use as table salt by adding HCl to a saturated solution of NaCl (317 g/L). When 25.5 mL of 7.85 *M* HCl is added to 0.100 L of saturated solution, how many grams of purified NaCl precipitate?

19.153 The solubility of Ag(I) in aqueous solutions containing different concentrations of Cl^- is based on the following equilibria:

$$Ag^+(aq) + Cl^-(aq) \rightleftharpoons AgCl(s) \qquad K_{sp} = 1.8\times10^{-10}$$
$$Ag^+(aq) + 2Cl^-(aq) \rightleftharpoons AgCl_2^-(aq) \qquad K_f = 1.8\times10^5$$

When solid AgCl is shaken with a solution containing Cl^-, Ag(I) is present as both Ag^+ and $AgCl_2^-$. The solubility of AgCl is the sum of the concentrations of Ag^+ and $AgCl_2^-$.
(a) Show that $[Ag^+]$ in solution is given by

$$[Ag^+] = 1.8\times10^{-10}/[Cl^-]$$

and that $[AgCl_2^-]$ in solution is given by

$$[AgCl_2^-] = (3.2\times10^{-5})([Cl^-])$$

(b) Find the $[Cl^-]$ at which $[Ag^+] = [AgCl_2^-]$.
(c) Explain the shape of a plot of AgCl solubility vs. $[Cl^-]$.
(d) Find the solubility of AgCl at the $[Cl^-]$ in part (b), which is the minimum solubility of AgCl in the presence of Cl^-.

19.154 Environmental engineers use *alkalinity* as a measure of the capacity of carbonate buffering systems in water samples:

$$\text{Alkalinity (mol/L)} = [HCO_3^-] + 2[CO_3^{2-}] + [OH^-] + [H^+]$$

Find the alkalinity of a water sample that has a pH of 9.5, 26.0 mg/L CO_3^{2-}, and 65.0 mg/L HCO_3^-.

19.155 Calcium ion present in water supplies is easily precipitated as calcite ($CaCO_3$):

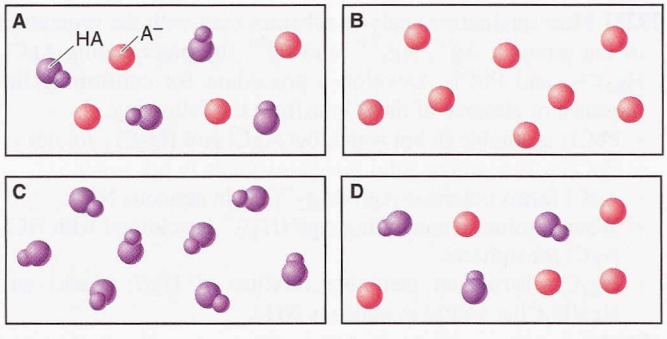
$$Ca^{2+}(aq) + CO_3^{2-}(aq) \rightleftharpoons CaCO_3(s)$$

Because the K_{sp} decreases with temperature, heating hard water forms a calcite "scale," which clogs pipes and water heaters. Find the solubility of calcite in water (a) at 10°C ($K_{sp} = 4.4\times10^{-9}$) and (b) at 30°C ($K_{sp} = 3.1\times10^{-9}$).

19.156 Litmus is an organic dye extracted from lichens. It is red below pH 4.5 and blue above pH 8.3. One drop of either 0.1 *M* HCl (pH 1) or a pH 3 buffer changes blue litmus paper to red, but a drop of 0.001 *M* HCl (also pH 3) does not. Explain.

19.157 Buffers that are based on 3-morpholinopropanesulfonic acid (MOPS) are often used in RNA analysis. The useful pH range of a MOPS buffer is 6.5 to 7.9. Estimate the K_a of MOPS.

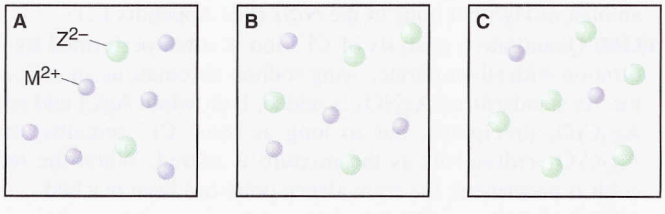
19.158 Scenes A to D represent tiny portions of 0.10 *M* aqueous solutions of a weak acid HA ($K_a = 4.5\times10^{-5}$), its conjugate base A^-, or a mixture of the two (only these species are shown):



(a) Which scene(s) show(s) a buffer?
(b) What is the pH of each solution?
(c) Arrange the scenes in sequence, assuming that they represent stages in a weak acid–strong base titration.
(d) Which scene represents the titration at its equivalence point?

19.159 Scenes A to C represent aqueous solutions of the slightly soluble salt MZ (only the ions of this salt are shown):

$$MZ(s) \rightleftharpoons M^{2+}(aq) + Z^{2-}(aq)$$



(a) Which scene represents the solution just after solid MZ is stirred thoroughly in distilled water?
(b) If each sphere represents 2.5×10^{-6} *M* of ions, what is the K_{sp} of MZ?
(c) Which scene represents the solution after $Na_2Z(aq)$ is added?
(d) If Z^{2-} is CO_3^{2-}, which scene represents the solution after the pH has been lowered?

Thermodynamics and the steam engine The relationship between heat and work was discovered in the search to understand and improve the newly invented steam engine. In this chapter we examine this relationship to learn the real-world limit of the energy that can be obtained from any chemical or physical change. In the process, we see *why* reactions occur.

Concepts & Skills to Review

before you study this chapter

- internal energy, heat, and work (Section 6.1)
- state functions (Section 6.1) and standard states (Section 6.6)
- enthalpy, ΔH, and Hess's law (Sections 6.2 and 6.5)
- entropy and solution formation (Section 13.3)
- comparing Q and K to find reaction direction (Section 17.4)

In the last few chapters, we've posed and answered some essential questions about chemical and physical change: How fast does the change occur, and how is this rate affected by concentration and temperature? How much product will be present when the net change ceases, and how is this yield affected by concentration and temperature? We've explored these questions for systems ranging from the stratosphere to a limestone cave and from the cells of your body to the lakes of Sweden.

Now it's time to stand back and ask the most profound question of all: why does a change occur in the first place? From everyday experience, it seems that some changes happen by themselves, almost as if a force were driving them in one direction and not the other. Turn on a gas stove, for example, and the methane mixes with oxygen and burns immediately with a vigorous burst of heat to yield carbon dioxide and water vapor. But those products will not remake methane and oxygen no matter how long they mix. A steel shovel left outside slowly rusts, but put a rusty one outside and it won't become shiny. A cube of sugar dissolves in a cup of coffee after a few seconds of stirring, but stir for another century and the dissolved sugar will never reappear as a cube.

Chemists speak of a process that occurs by itself as being *spontaneous*. Some absorb energy whereas others release it. The principles of thermodynamics, which were developed in the early 19th century to help utilize the newly invented steam engine, allow us to understand the nature of spontaneous change. Despite their narrow historical focus, these principles apply, as far as we know, to every system in the universe!

IN THIS CHAPTER . . . We begin by looking for a criterion to predict the direction of a spontaneous change. A review of the first law of thermodynamics shows that it accounts for the quantity of energy in a change but not the direction of the change. The sign of the enthalpy change is also *not* a criterion for predicting direction. Rather, we find this criterion in the second law of thermodynamics and its quantitative application of entropy (S), the state function that relates to the natural tendency of a system's energy to become more dispersed, and we examine these ideas for both exothermic and endothermic changes. The concept of free energy we develop gives a simplified criterion for spontaneous change, and we see how it relates to the work a system can do. Finally, we consider the key relationship between the free energy change and the equilibrium constant of a reaction.

20.1 THE SECOND LAW OF THERMODYNAMICS: PREDICTING SPONTANEOUS CHANGE

In a formal sense, a **spontaneous change** of a system, whether a chemical or physical change or just a change in location, is one that occurs by itself under specified conditions, without an ongoing input of energy from outside the system. The freezing of water, for example, is spontaneous at 1 atm and −5°C. A spontaneous process such as burning or falling may need a little "push" to get started—a spark to ignite gasoline, a shove to knock a book off your desk—but once the process begins, it continues without external aid because the system releases enough energy to keep the process going.

In contrast, for a nonspontaneous change to occur, the surroundings must supply the system with a *continuous* input of energy. A book falls spontaneously, but it rises only if something else, such as a human hand (or a hurricane-force wind), supplies energy in the form of work. Under a given set of conditions, *if a change is spontaneous in one direction, it is* ***not*** *spontaneous in the other.*

Note that the term *spontaneous* does not mean *instantaneous* and has nothing to do with how long a process takes to occur; it means that, given enough

time, the process will happen by itself. Many processes are spontaneous but slow—ripening, rusting, and (happily!) aging.

A chemical reaction proceeding toward equilibrium is an example of a spontaneous change. As you learned in Chapter 17, we can predict the net direction of the reaction—its spontaneous direction—by comparing the reaction quotient (Q) with the equilibrium constant (K). But *why* is there a drive to attain equilibrium? And what determines the value of the equilibrium constant? Can we tell the direction of a spontaneous change in cases that are not as obvious as burning gasoline or falling books? Because energy changes seem to be involved, let's begin by reviewing the idea of conservation of energy to see whether it can help uncover the criterion for spontaneity.

Limitations of the First Law of Thermodynamics

In Chapter 6, we discussed the first law of thermodynamics (the law of conservation of energy) and its application to chemical and physical systems. The first law states that the internal energy (E) of a system, the sum of the kinetic and potential energy of all its particles, changes when heat (q) and/or work (w) are added or removed:

$$\Delta E = q + w$$

Whatever is not part of the system (sys) is part of the surroundings (surr), so the system and surroundings together constitute the universe (univ):

$$E_{\text{univ}} = E_{\text{sys}} + E_{\text{surr}}$$

Heat and/or work gained by the system is lost by the surroundings, and vice versa:

$$(q + w)_{\text{sys}} = -(q + w)_{\text{surr}}$$

It follows from these ideas that *the total energy of the universe is constant:**

$$\Delta E_{\text{sys}} = -\Delta E_{\text{surr}} \qquad \text{therefore} \qquad \Delta E_{\text{sys}} + \Delta E_{\text{surr}} = 0 = \Delta E_{\text{univ}}$$

Is the first law sufficient to explain why a natural process takes place as it does? It certainly accounts for the energy involved. When a book that was resting on your desk falls to the floor, the first law guides us through the conversion from the potential energy of the resting book to the kinetic energy of the falling book to the heat dispersed in the floor near the point of contact. When gasoline burns in your car's engine, the first law explains that the potential energy difference between the chemical bonds in the fuel mixture and those in the exhaust gases is converted to the kinetic energy of the moving car and its parts plus the heat released to the environment. When an ice cube melts in your hand, the first law tells that energy from your hand was transferred to the ice to change it to a liquid. If you could measure the work and heat involved in each case, you would find that energy is conserved as it is converted from one form to another.

However, the first law does not help us make sense of the *direction* of the change. Why doesn't the heat in the floor near the fallen book change to kinetic energy in the book and move it back onto your desk? Why doesn't the heat released in the car engine convert exhaust fumes back into gasoline and oxygen? Why doesn't the pool of water in your cupped hand transfer the heat back to your hand and refreeze? None of these events would violate the first law—energy would still be conserved—but they never happen. The first law by itself tells nothing about the direction of a spontaneous change, so we must look elsewhere for a way to predict that direction.

*Any modern statement of conservation of energy must take into account mass-energy equivalence and the processes in stars, which convert enormous amounts of matter into energy. These can be included by stating that the total *mass-energy* of the universe is constant.

The Sign of ΔH Cannot Predict Spontaneous Change

In the mid-19th century, some thought that the sign of the enthalpy change (ΔH), the heat added or removed at constant pressure (q_P), was the criterion for spontaneity. They thought that exothermic processes ($\Delta H < 0$) were spontaneous and endothermic ones ($\Delta H > 0$) were nonspontaneous. This hypothesis had some experimental support; after all, many spontaneous processes *are* exothermic. All combustion reactions, such as methane burning, are spontaneous and exothermic:

$$CH_4(g) + 2O_2(g) \longrightarrow CO_2(g) + 2H_2O(g) \qquad \Delta H^0_{rxn} = -802 \text{ kJ}$$

Iron metal oxidizes spontaneously and exothermically:

$$2Fe(s) + \tfrac{3}{2}O_2(g) \longrightarrow Fe_2O_3(s) \qquad \Delta H^0_{rxn} = -826 \text{ kJ}$$

Ionic compounds, such as NaCl, form spontaneously and exothermically from their elements:

$$Na(s) + \tfrac{1}{2}Cl_2(g) \longrightarrow NaCl(s) \qquad \Delta H^0_{rxn} = -411 \text{ kJ}$$

However, in many other cases, the sign of ΔH is no help. An exothermic process occurs spontaneously under certain conditions, whereas the opposite, endothermic, process occurs spontaneously under other conditions. Consider the following examples of phase changes, dissolving salts, and chemical changes.

At ordinary pressure, water freezes below 0°C but melts above 0°C. Both changes are spontaneous, but the first is exothermic and the second endothermic:

$$H_2O(l) \longrightarrow H_2O(s) \qquad \Delta H^0_{rxn} = -6.02 \text{ kJ } (exothermic; \text{ spontaneous at } T < 0°C)$$
$$H_2O(s) \longrightarrow H_2O(l) \qquad \Delta H^0_{rxn} = +6.02 \text{ kJ } (endothermic; \text{ spontaneous at } T > 0°C)$$

At ordinary pressure and room temperature, liquid water vaporizes spontaneously in dry air, another endothermic change:

$$H_2O(l) \longrightarrow H_2O(g) \qquad \Delta H^0_{rxn} = +44.0 \text{ kJ}$$

In fact, all melting and vaporizing are endothermic changes that are spontaneous under proper conditions.

Recall from Chapter 13 that most water-soluble salts have a positive ΔH^0_{soln} but dissolve spontaneously:

$$NaCl(s) \xrightarrow{H_2O} Na^+(aq) + Cl^-(aq) \qquad \Delta H^0_{soln} = +3.9 \text{ kJ}$$
$$RbClO_3(s) \xrightarrow{H_2O} Rb^+(aq) + ClO_3^-(aq) \qquad \Delta H^0_{soln} = +47.7 \text{ kJ}$$
$$NH_4NO_3(s) \xrightarrow{H_2O} NH_4^+(aq) + NO_3^-(aq) \qquad \Delta H^0_{soln} = +25.7 \text{ kJ}$$

Some endothermic chemical changes are also spontaneous:

$$N_2O_5(s) \longrightarrow 2NO_2(g) + \tfrac{1}{2}O_2(g) \qquad \Delta H^0_{rxn} = +109.5 \text{ kJ}$$
$$Ba(OH)_2 \cdot 8H_2O(s) + 2NH_4NO_3(s) \longrightarrow$$
$$Ba^{2+}(aq) + 2NO_3^-(aq) + 2NH_3(aq) + 10H_2O(l) \qquad \Delta H^0_{rxn} = +62.3 \text{ kJ}$$

In the second reaction, the released waters of hydration solvate the ions, but the reaction mixture cannot absorb heat from the surroundings quickly enough, and the container becomes so cold that a wet block of wood freezes to it (Figure 20.1).

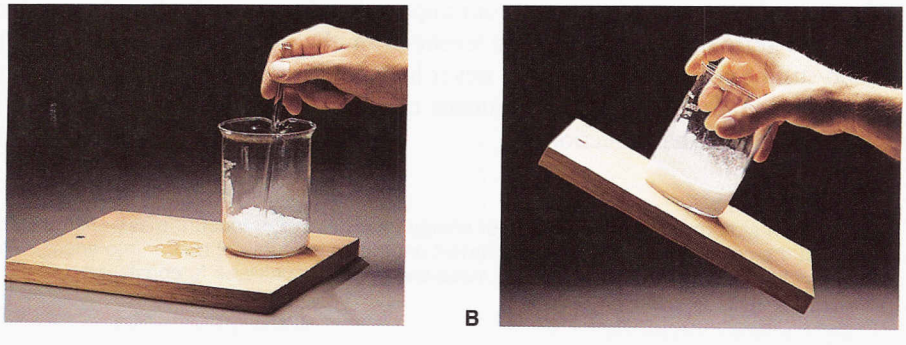

Figure 20.1 A spontaneous endothermic chemical reaction. A, When the crystalline solid reactants barium hydroxide octahydrate and ammonium nitrate are mixed, a slurry soon forms as waters of hydration are released. **B,** The reaction mixture absorbs heat so quickly from the surroundings that the beaker becomes covered with frost, and a moistened block of wood freezes to it.

Freedom of Particle Motion and Dispersal of Particle Energy

What features common to the previous endothermic processes can help us see why they occur spontaneously? In each case, the particles that make up the matter have more freedom of motion after the change occurs. And this means that their energy of motion becomes more dispersed. As we'll see below, "dispersed" means spread over more quantized energy levels.

Phase changes lead from a solid, in which particle motion is restricted, to a liquid, in which the particles have more freedom to move around each other, to a gas, with its much greater freedom of particle motion. Along with this greater freedom of motion, the energy of the particles becomes dispersed over more levels. Dissolving a salt leads from a crystalline solid and pure liquid to ions and solvent molecules moving and interacting throughout the solution; their energy of motion, therefore, is much more dispersed. In the chemical reactions shown, *fewer* moles of crystalline solids produce *more* moles of gases and/or solvated ions. In these cases, there is not only more freedom of motion, but more particles to disperse their energy over more levels.

Thus, in each process, the particles have more freedom of motion and, therefore, their energy of motion has more levels over which to be dispersed:

	less freedom of particle motion ⟶ more freedom of particle motion localized energy of motion ⟶ dispersed energy of motion
Phase change:	solid ⟶ liquid ⟶ gas
Dissolving of salt:	crystalline solid + liquid ⟶ ions in solution
Chemical change:	crystalline solids ⟶ gases + ions in solution

In thermodynamic terms, a change in the freedom of motion of particles in a system and in the dispersal of their energy of motion is a key factor determining the direction of a spontaneous process.

Entropy and the Number of Microstates

Let's see how freedom of motion and dispersal of energy relate to spontaneous change. In earlier chapters, we discussed the quantization of energy, not only quantized electronic energy levels of an atom or molecule, but also quantized kinetic energy levels—vibrational, rotational, and translational—of a molecule and its atoms (see Tools of the Laboratory, p. 345).

Picture a system of, say, 1 mol of N_2 gas and focus on one molecule. At any instant, it is moving through space (translating) at a certain speed and rotating at a certain speed, and its atoms are vibrating at a certain speed. In the next instant, the molecule collides with another, and these motional energy states change. The complete quantum state of the molecule at any instant is given by a combination of its particular electronic, translational, rotational, and vibrational states. Clearly, many such combinations are possible for this single molecule, and the number of quantized energy states possible for the system of a mole of molecules is staggering—on the order of $10^{10^{23}}$. Each quantized state of the system is called a *microstate*, and every microstate has the same total energy at a given set of conditions. With each microstate equally possible for the system, the laws of probability say that, over time, all microstates are equally occupied. If we focus only on microstates associated with thermal energy, we say that the number of microstates of a system is the number of ways it can disperse its thermal energy among the various modes of motion of all its molecules.

In 1877, the Austrian mathematician and physicist Ludwig Boltzmann related the number of microstates (W) to the **entropy** (S) of the system:

$$S = k \ln W \tag{20.1}$$

where k, the *Boltzmann constant,* is the universal gas constant divided by Avogadro's number, R/N_A, and equals 1.38×10^{-23} J/K. Because W is just a number

of microstates and has no units, S has units of joules/kelvin (J/K). From this relationship, we conclude that

- A system with fewer microstates (smaller W) among which to spread its energy has *lower entropy (lower S)*.
- A system with more microstates (larger W) among which to spread its energy has *higher entropy (higher S)*.

Thus, for our earlier examples,

lower entropy (fewer microstates) ⟶ higher entropy (more microstates)

Phase change: solid ⟶ liquid ⟶ gas

Dissolving of salt: crystalline solid + liquid ⟶ ions in solution

Chemical change: crystalline solids ⟶ gases + ions in solution

(In Chapter 13, we used some of these ideas to explain solution behavior.)

Changes in Entropy If the number of microstates increases during a physical or chemical change, there are more ways for the energy of the system to be dispersed among them. Thus, the entropy increases:

$$S_{\text{more microstates}} > S_{\text{fewer microstates}}$$

If the number of microstates decreases, the entropy decreases.

Like internal energy (E) and enthalpy (H), entropy is a state function, which means it depends only on the present state of the system, not on the path it took to arrive at that state (Chapter 6, p. 230). Therefore, the change in entropy of the system (ΔS_{sys}) depends only on the difference between its final and initial values:

$$\Delta S_{\text{sys}} = S_{\text{final}} - S_{\text{initial}}$$

Like any state function, $\Delta S_{\text{sys}} > 0$ when its value increases during a change. For example, when dry ice sublimes to gaseous carbon dioxide, we have

$$CO_2(s) \longrightarrow CO_2(g) \qquad \Delta S_{\text{sys}} = S_{\text{gaseous } CO_2} - S_{\text{solid } CO_2} > 0$$

Similarly, $\Delta S_{\text{sys}} < 0$ when the entropy decreases during a change, as when water vapor condenses:

$$H_2O(g) \longrightarrow H_2O(l) \qquad \Delta S_{\text{sys}} = S_{\text{liquid } H_2O} - S_{\text{gaseous } H_2O} < 0$$

Or consider the decomposition of dinitrogen tetraoxide (written as $O_2N{-}NO_2$):

$$O_2N{-}NO_2(g) \longrightarrow 2NO_2(g)$$

When the N—N bond in 1 mol of dinitrogen tetraoxide molecules breaks, the 2 mol of NO_2 molecules have much more freedom of motion; thus, their energy is spread over more microstates:

$$\Delta S_{\text{sys}} = \Delta S_{\text{rxn}} = S_{\text{final}} - S_{\text{initial}} = S_{\text{products}} - S_{\text{reactants}} = 2S_{NO_2} - S_{N_2O_4} > 0$$

Quantitative Meaning of the Entropy Change Two approaches for quantifying an entropy change look different but give the same result. The first is a statistical approach based on the number of microstates possible for the particles in a system. The second is based on the heat absorbed (or released) by a system. We'll explore both in a simple case of 1 mol of an ideal gas, say neon, expanding from 10 L to 20 L at 298 K:

1 mol neon (initial: 10 L and 298 K) ⟶ 1 mol neon (final: 20 L and 298 K)

We use a statistical approach to find ΔS_{sys} by applying the definition of entropy expressed by Equation 20.1. Figure 20.2 shows a container consisting of

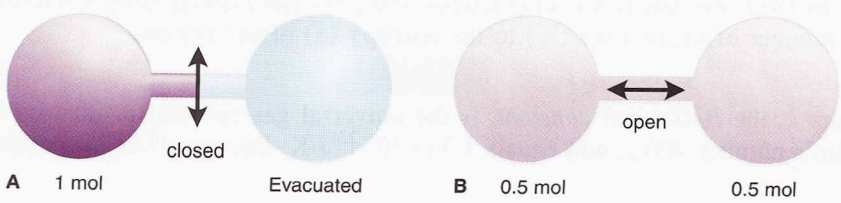

Figure 20.2 Spontaneous expansion of a gas. The container consists of two identical flasks connected by a stopcock. **A,** With the stopcock closed, 1 mol of neon gas occupies one flask, and the other is evacuated. **B,** Open the stopcock, and the gas expands spontaneously until each flask contains 0.5 mol.

two identical flasks connected by a stopcock, with 1 mol of neon in the left flask and an evacuated right flask. We know from experience that when we open the stopcock, the gas will expand to fill both flasks with 0.5 mol each—but *why*?

Let's start with one neon atom and think through what happens as we add more atoms and open the stopcock (Figure 20.3). One atom has some number of microstates (W) possible for it in the left flask and the same number possible in the right flask. Opening the stopcock increases the volume, which increases the number of possible translational energy levels. As a result, the system has 2^1, or 2 times as many microstates possible when the atom moves through both flasks (final state, W_{final}) as when it is confined to one flask (initial state, $W_{initial}$).

With more atoms, different combinations of atoms can occupy various energy levels, and each combination represents a microstate. With 2 atoms, A and B, moving through both flasks, there are 2^2, or 4 times as many microstates as when they are confined initially to one flask—some number of microstates with A and B in the left, the same number with A in the left and B in the right, that number with B in the left and A in the right, and that number with A and B in the right. Add another atom and there are 2^3 or 8 times as many microstates when the stopcock is open—some number with all three in the left, that number with A and B in the left and C in the right, that number with A and C in the left and B in the right, and so on. With 10 neon atoms, there are 2^{10} or 1024 times as many microstates for the gas in both flasks. Finally, with 1 mol (Avogadro's number, N_A) of neon atoms, there are 2^{N_A} times as many microstates possible for the atoms in both flasks (W_{final}) as in one flask ($W_{initial}$). In other words, for 1 mol, we have

$$W_{final}/W_{initial} = 2^{N_A}$$

Now let's find ΔS_{sys} through the Boltzmann equation. From Appendix A, we know that $\ln A - \ln B = \ln A/B$. Thus,

$$\Delta S_{sys} = S_{final} - S_{initial} = k \ln W_{final} - k \ln W_{initial} = k \ln (W_{final}/W_{initial})$$

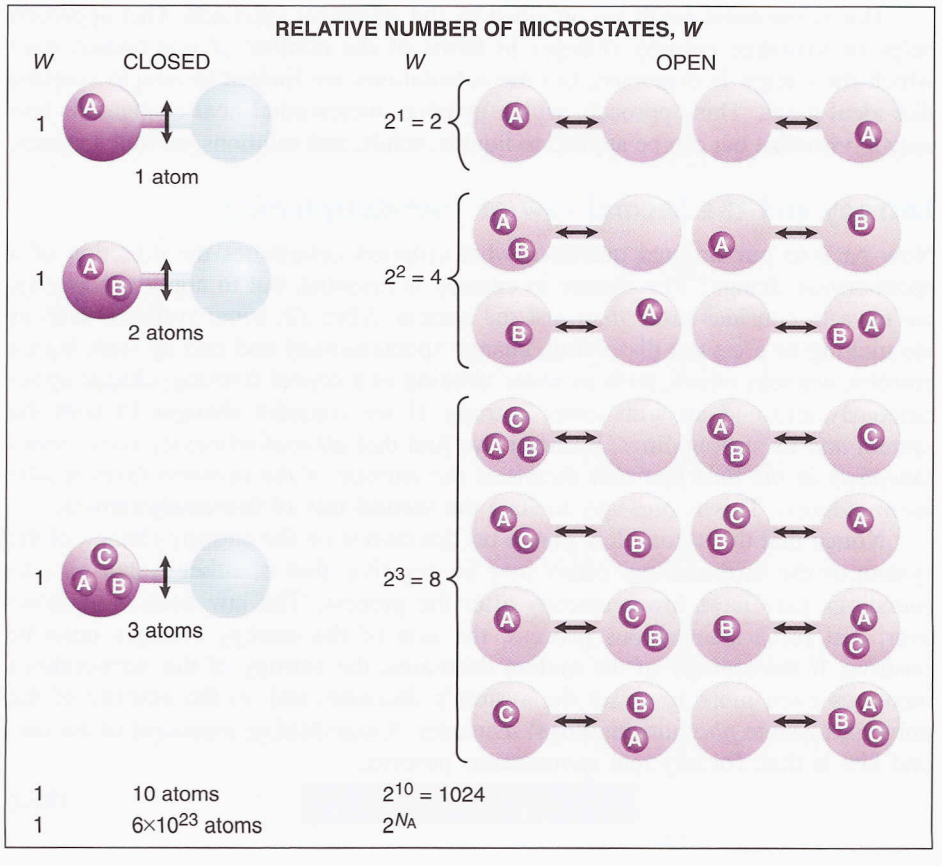

Figure 20.3 Expansion of a gas and the increase in number of microstates. When a gas confined to one flask is allowed to spread through two flasks, the energy of the particles is dispersed over more microstates, and so the entropy is higher. Each combination of particles in the available volume represents a different microstate. The increase in the number of possible microstates that occurs when the volume increases is given by 2^n, where n is the number of particles.

Also from Appendix A, $\ln A^y = y \ln A$; with $k = R/N_A$, we have

$$\Delta S_{sys} = R/N_A \ln 2^{N_A} = (R/N_A)N_A \ln 2 = R \ln 2 = (8.314 \text{ J/mol·K})(0.693)$$
$$= 5.76 \text{ J/mol·K}$$

or, for 1 mol, $\Delta S_{sys} = 5.76$ J/K

The second approach for finding ΔS_{sys} is based on heat changes and relates closely to 19th-century attempts to understand the work done by steam engines. In such a process, the entropy change is defined by

$$\Delta S_{sys} = \frac{q_{rev}}{T} \tag{20.2}$$

where T is the temperature at which the heat change occurs and q is the heat absorbed. The subscript "rev" refers to a *reversible process*, one that occurs slowly enough for equilibrium to be maintained continuously, so that the direction of the change can be reversed by an infinitesimal reversal of conditions.

A truly reversible expansion of an ideal gas can only be imagined, but we can approximate it by placing the 10-L neon sample in a piston-cylinder assembly surrounded by a heat reservoir maintained at 298 K, with a beaker of sand on the piston exerting the pressure. We remove one grain of sand (an "infinitesimal" change in pressure) with a pair of tweezers, and the gas expands a tiny amount, raising the piston and doing work on the surroundings, $-w$. If the neon behaves ideally, it absorbs from the reservoir a tiny increment of heat q, equivalent to $-w$. We remove another grain of sand, and the gas expands a tiny bit more and absorbs another tiny increment of heat. This expansion is very close to being reversible because we can reverse it at any point by putting a grain of sand back into the beaker, which causes a tiny compression of the gas. If we continue this expansion process to 20 L and apply calculus to add together all the tiny increments of heat, we find q_{rev} is 1718 J. Thus, applying Equation 20.2, the entropy change is

$$\Delta S_{sys} = q_{rev}/T = 1718 \text{ J}/298 \text{ K} = 5.76 \text{ J/K}$$

This is the same result we obtained by the statistical approach. That approach helps us visualize entropy changes in terms of the number of microstates over which the energy is dispersed, but the calculations are limited to simple systems like ideal gases. This approach, which involves incremental heat changes, is less easy to visualize but can be applied to liquids, solids, and solutions, as well as gases.

Entropy and the Second Law of Thermodynamics

Now back to our original question: what criterion determines the direction of a spontaneous change? The change in entropy is essential, but to apply it correctly, we have to consider more than just the system. After all, some systems, such as ice melting or a crystal dissolving, change spontaneously and end up with higher entropy, whereas others, such as water freezing or a crystal forming, change spontaneously and end up with lower entropy. If we consider changes in *both* the system *and* its surroundings, however, we find that *all real processes occur spontaneously in the direction that increases the entropy of the universe (system plus surroundings)*. This is one way to state the **second law of thermodynamics.**

Notice that the second law places no limitations on the entropy change of the system *or* the surroundings: either may be negative; that is, either system *or* surroundings may have lower entropy after the process. The law does state, however, that for a spontaneous process, the *sum* of the entropy changes must be positive. If the entropy of the system decreases, the entropy of the surroundings increases even more to offset the system's decrease, and so the entropy of the universe (system *plus* surroundings) increases. A quantitative statement of the second law is that, for any real spontaneous process,

$$\Delta S_{univ} = \Delta S_{sys} + \Delta S_{surr} > 0 \tag{20.3}$$

Standard Molar Entropies and the Third Law

Both entropy and enthalpy are state functions, but the nature of their values differs in a fundamental way. Recall that we cannot determine absolute enthalpies because we have no easily measurable starting point, no baseline value for the enthalpy of a substance. Therefore, we measure only enthalpy *changes*.

In contrast, we *can* determine the absolute entropy of a substance. To do so requires application of the **third law of thermodynamics,** which states that *a perfect crystal has zero entropy at a temperature of absolute zero:* $S_{sys} = 0$ at 0 K. "Perfect" means that all the particles are aligned flawlessly in the crystal structure, with no defects of any kind. At absolute zero, all particles in the crystal have the minimum energy, and there is only one way it can be dispersed: thus, in Equation 20.1, $W = 1$, so $S = k \ln 1 = 0$. When we warm the crystal, its total energy increases, so the particles' energy can be dispersed over more microstates (Figure 20.4). Thus, $W > 1$, $\ln W > 0$, and $S > 0$.

To obtain a value for S at a given temperature, we first cool a crystalline sample of the substance as close to 0 K as possible. Then we heat it in small increments, dividing q by T to get the increase in S for each increment, and add up all the entropy increases to the temperature of interest, usually 298 K. The entropy of a substance at a given temperature is therefore an *absolute* value that is equal to the entropy increase obtained when the substance is heated from 0 K to that temperature.

As with other thermodynamic variables, we usually compare entropy values for substances in their *standard states* at the temperature of interest: *1 atm for gases, 1 M for solutions, and the pure substance in its most stable form for solids or liquids.* Because entropy is an *extensive* property, that is, one that depends on the amount of substance, we are interested in the **standard molar entropy (S^0)** in units of J/mol·K (or $J \cdot mol^{-1} \cdot K^{-1}$). The S^0 values at 298 K for many elements, compounds, and ions appear, with other thermodynamic variables, in Appendix B.

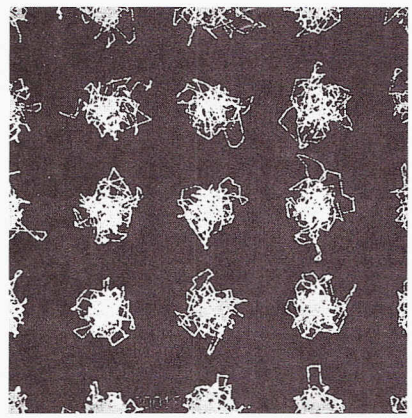

Figure 20.4 Random motion in a crystal. This computer simulation shows the paths of the particle centers in a crystalline solid. At any temperature greater than 0 K, each particle moves about its lattice position. The higher the temperature, the more vigorous the movement. Adding thermal energy increases the total energy, and the particle energies can be distributed over more microstates; thus, the entropy increases.

Predicting Relative S^0 Values of a System Based on an understanding of systems at the molecular level and the effects of heat absorbed, we can often predict how the entropy of a substance is affected by temperature, physical state, dissolution, and atomic or molecular complexity. (All S^0 values in the following discussion have units of J/mol·K and, unless stated otherwise, refer to the system at 298 K.)

1. *Temperature changes.* For a given substance, S^0 *increases as the temperature rises.* Consider these typical values for copper metal:

T (K):	273	295	298
S^0:	31.0	32.9	33.2

The temperature increases as heat is absorbed ($q > 0$), which represents an increase in the average kinetic energy of the particles. Recall from Figure 5.14 (p. 201) that the kinetic energies of gas particles in a sample are distributed over a range, which becomes wider as the temperature rises. The same general behavior occurs for liquids and solids. With more microstates in which the energy can be dispersed, the entropy of the substance goes up. In other words, raising the temperature populates more microstates. Thus, S^0 *increases for a substance as it is heated.*

2. *Physical states and phase changes.* For a phase change such as melting or vaporizing, heat is absorbed ($q > 0$). The particles have more freedom of motion and their energy is more dispersed, so the entropy change is positive. Thus, S^0 *increases for a substance as it changes from a solid to a liquid to a gas:*

	Na	H_2O	C(graphite)
$S^0(s \text{ or } l)$:	51.4(s)	69.9(l)	5.7(s)
$S^0(g)$:	153.6	188.7	158.0

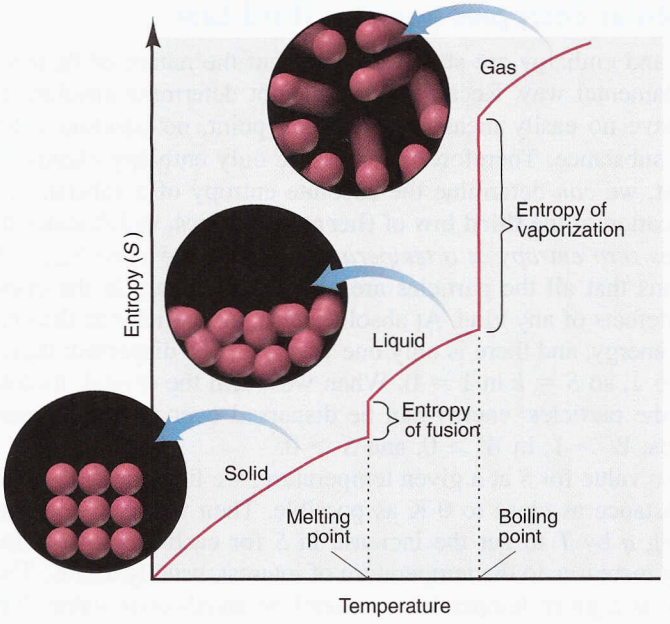

Figure 20.5 The increase in entropy from solid to liquid to gas. A plot of entropy vs. temperature shows the gradual increase in entropy within a phase and the abrupt increase with a phase change. The molecular-scale views depict the increase in freedom of motion of the particles as the solid melts and, even more so, as the liquid vaporizes.

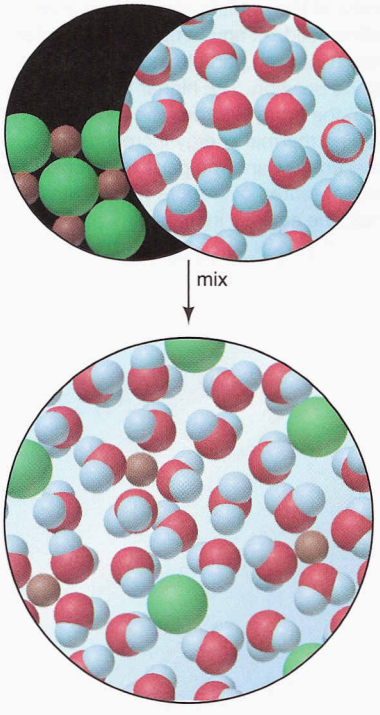

Figure 20.6 The entropy change accompanying the dissolution of a salt. When a crystalline salt and pure liquid water form a solution, the entropy change has two contributions: a positive contribution as the crystal separates into ions and the pure liquid disperses them, and a negative contribution as water molecules become organized around each ion. The relative magnitudes of these contributions determine the overall entropy change. The entropy of a solution is usually *greater* than that of the solid and water.

Figure 20.5 shows the entropy of a typical substance as it is heated and undergoes a phase change. Note the gradual increase within a phase as the temperature rises and the large, sudden increase at the phase change. The solid has the least energy dispersed within it and, thus, the lowest entropy. Its particles vibrate about their positions but, on average, remain fixed. As the temperature rises, the entropy gradually increases with the increase in the particles' kinetic energy. When the solid melts, the particles move much more freely between and around each other, so there is an abrupt increase in entropy. Further heating increases the speed of the particles in the liquid, and the entropy increases gradually. Finally, freed from intermolecular forces, the particles undergo another abrupt entropy increase and move chaotically as a gas. Note that *the increase in entropy from liquid to gas is much larger than that from solid to liquid:* $\Delta S^0_{vap} >> \Delta S^0_{fus}$.

3. *Dissolving a solid or liquid.* The entropy of a dissolved solid or liquid is usually *greater* than the entropy of the pure solute, but the nature of solute *and* solvent and the dissolving process affect the overall entropy change (Figure 20.6):

	NaCl	$AlCl_3$	CH_3OH
$S^0(s \text{ or } l)$:	72.1(s)	167(s)	127(l)
$S^0(aq)$:	115.1	−148	132

When an ionic solid dissolves in water, the crystal breaks down, and the ions experience a great increase in freedom of motion as they become hydrated and separate, with their energy dispersed over more microstates. We expect the entropy of the ions themselves to be greater in the solution than in the crystal. However, some of the water molecules become organized around the ions (see Figure 13.2, p. 491), which makes a negative contribution to the overall entropy change. In fact, for small, multiply charged ions, the solvent becomes so attracted to the ions, making its energy localized rather than dispersed, that this negative contribution can dominate and lead to negative S^0 values for the ions in solution.

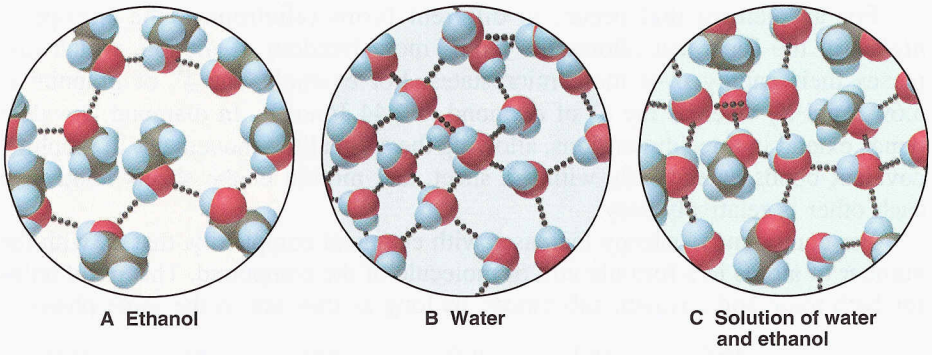

Figure 20.7 The small increase in entropy when ethanol dissolves in water. Pure ethanol **(A)** and pure water **(B)** have many intermolecular H bonds. **C,** In a solution of these two substances, the molecules form H bonds to one another, so their freedom of motion does not change significantly. Thus, the entropy increase is relatively small and is due solely to random mixing.

For example, the $Al^{3+}(aq)$ ion has such a negative S^0 value (−313 J/mol·K) that when $AlCl_3$ dissolves in water, even though S^0 of $Cl^-(aq)$ is positive, the overall entropy of aqueous $AlCl_3$ is lower than that of solid $AlCl_3$.*

For molecular solutes, the increase in entropy upon dissolving is typically much smaller than for ionic solutes. For a solid such as glucose, there is no separation into ions, and for a liquid such as ethanol, the breakdown of a crystal structure is absent as well. Furthermore, in pure ethanol and in pure water, the molecules form many H bonds, so there is relatively little change in their freedom of motion when they are mixed (Figure 20.7). The small increase in the entropy of dissolved ethanol arises from the random mixing of the molecules.

4. *Dissolving a gas.* The particles in a gas already have so much freedom of motion and such highly dispersed energy that they always lose freedom when they dissolve in a liquid or solid. Therefore, the entropy of a solution of a gas in a liquid or a solid is always *less* than the entropy of the gas. For instance, when gaseous O_2 [$S^0(g)$ = 205.0 J/mol·K] dissolves in water, its entropy decreases dramatically [$S^0(aq)$ = 110.9 J/mol·K] (Figure 20.8). When a gas dissolves in another gas, however, the entropy increases from the mixing of the molecules.

5. *Atomic size or molecular complexity.* In general, differences in entropy values for substances in the same phase are based on atomic size and molecular complexity. For elements within a periodic group, energy levels (microstates) become closer together for heavier atoms, so entropy increases down the group:

	Li	Na	K	Rb	Cs
Atomic radius (pm):	152	186	227	248	265
Molar mass (g/mol):	6.941	22.99	39.10	85.47	132.9
$S^0(s)$:	29.1	51.4	64.7	69.5	85.2

The same trend of increasing entropy down a group holds for similar compounds:

	HF	HCl	HBr	HI
Molar mass (g/mol):	20.01	36.46	80.91	127.9
$S^0(g)$:	173.7	186.8	198.6	206.3

*An S^0 value for a hydrated ion can be negative because it is relative to the S^0 value for the hydrated proton, $H^+(aq)$, which is assigned a value of 0. In other words, $Al^{3+}(aq)$ has a lower entropy than $H^+(aq)$.

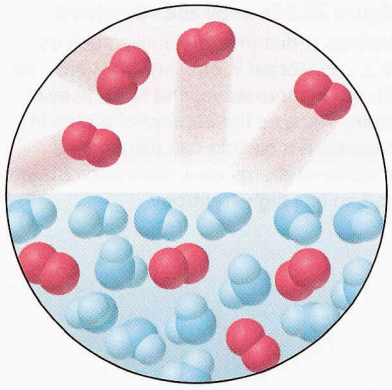

Figure 20.8 The large *decrease* in entropy of a gas when it dissolves in a liquid. The chaotic movement and high entropy of molecules of O_2 are reduced greatly when the gas dissolves in water.

For an element that occurs in different forms (allotropes), the entropy is *higher* in the form that allows the atoms more freedom of motion, which disperses their energy over more microstates. For example, the S^0 of graphite is 5.69 J/mol·K, whereas the S^0 of diamond is 2.44 J/mol·K. In diamond, covalent bonds extend in three dimensions, allowing the atoms little movement; in graphite, covalent bonds extend only within a sheet, and motion of the sheets relative to each other is relatively easy.

For compounds, entropy increases with chemical complexity, that is, with the number of atoms in a formula unit or molecule of the compound. This trend holds for both ionic and covalent substances, as long as they are in the same phase:

	NaCl	$AlCl_3$	P_4O_{10}	NO	NO_2	N_2O_4
$S^0(s)$:	72.1	167	229			
$S^0(g)$:				211	240	304

The trend is based on the types of movement, and thus number of microstates, possible for the atoms (or ions) in each compound. For example, as Figure 20.9 shows, among the nitrogen oxides listed above, the two atoms of NO can vibrate only toward and away from each other. The three atoms of NO_2 have more vibrational motions, and the six atoms of N_2O_4 have even more.

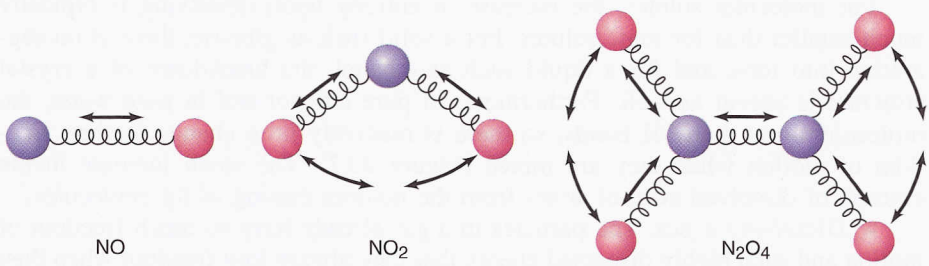

Figure 20.9 Entropy and vibrational motion. A diatomic molecule, such as NO, can vibrate in only one way. NO_2 can vibrate in more ways, and N_2O_4 in even more. Thus, as the number of atoms increases, a molecule can disperse its vibrational energy over more microstates, and so has higher entropy.

For larger molecules, we also consider how parts of the molecule move relative to other parts. A long hydrocarbon chain can rotate and vibrate in more ways than a short one, so entropy increases with chain length. A ring compound, such as cyclopentane (C_5H_{10}), has lower entropy than the corresponding chain compound, pentene (C_5H_{10}), because the ring structure restricts freedom of motion:

	$CH_4(g)$	$C_2H_6(g)$	$C_3H_8(g)$	$C_4H_{10}(g)$	$C_5H_{10}(g)$	C_5H_{10}(cyclo, g)	$C_2H_5OH(l)$
S^0:	186	230	270	310	348	293	161

Remember these trends hold only for *substances in the same physical state*. Gaseous methane (CH_4) has a greater entropy than liquid ethanol (C_2H_5OH), even though ethanol molecules are more complex. When gases are compared with liquids, *the effect of physical state usually dominates that of molecular complexity.*

SAMPLE PROBLEM 20.1 Predicting Relative Entropy Values

Problem Choose the member with the higher entropy in each of the following pairs, and justify your choice [assume constant temperature, except in part (e)]:

(a) 1 mol of $SO_2(g)$ or 1 mol of $SO_3(g)$
(b) 1 mol of $CO_2(s)$ or 1 mol of $CO_2(g)$
(c) 3 mol of $O_2(g)$ or 2 mol of $O_3(g)$
(d) 1 mol of KBr(s) or 1 mol of KBr(aq)
(e) Seawater in midwinter at 2°C or in midsummer at 23°C
(f) 1 mol of $CF_4(g)$ or 1 mol of $CCl_4(g)$

Plan In general, we know that particles with more freedom of motion or more dispersed energy have higher entropy and that raising the temperature increases entropy. We apply the general categories described in the text to choose the member with the higher entropy.

Solution **(a)** 1 mol of $SO_3(g)$. For equal numbers of moles of substances with the same types of atoms in the same physical state, the more atoms in the molecule, the more types of motion available, and thus the higher the entropy.

(b) 1 mol of $CO_2(g)$. For a given substance, entropy increases in the sequence $s < l < g$.

(c) 3 mol of $O_2(g)$. The two samples contain the same number of oxygen atoms but different numbers of molecules. Despite the greater complexity of O_3, the greater number of molecules dominates in this case because there are many more microstates possible for three moles of particles than for two moles.

(d) 1 mol of KBr(aq). The two samples have the same number of ions, but their motion is more limited and their energy less dispersed in the solid than in the solution.

(e) Seawater in summer. Entropy increases with rising temperature.

(f) 1 mol of $CCl_4(g)$. For similar compounds, entropy increases with molar mass.

FOLLOW-UP PROBLEM 20.1 For 1 mol of substance at a given temperature, select the member in each pair with the higher entropy, and give the reason for your choice:

(a) $PCl_3(g)$ or $PCl_5(g)$

(b) $CaF_2(s)$ or $BaCl_2(s)$

(c) $Br_2(g)$ or $Br_2(l)$

SECTION SUMMARY

A change is spontaneous if it occurs in a given direction under specified conditions without a continuous input of energy. Neither the first law of thermodynamics nor the sign of ΔH predicts the direction. All spontaneous processes involve an increase in the dispersion of energy. Entropy is a state function that measures the extent of energy dispersal through the number of microstates possible for a system, which is related to the freedom of motion of its particles. The second law of thermodynamics states that, in a spontaneous process, the entropy of the universe (system plus surroundings) increases. Absolute entropy values can be found because perfect crystals have zero entropy at 0 K (third law). Standard molar entropy S^0 (J/mol·K) is affected by temperature, phase changes, dissolution, and atomic size or molecular complexity.

20.2 CALCULATING THE CHANGE IN ENTROPY OF A REACTION

In addition to understanding trends in S^0 values for different substances or for the same substance in different phases, chemists are especially interested in learning how to predict the sign *and* calculate the value of the change in entropy as a reaction occurs.

Entropy Changes in the System: Standard Entropy of Reaction (ΔS^0_{rxn})

Based on the ideas we just discussed, we can often predict the sign of the **standard entropy of reaction, ΔS^0_{rxn},** the entropy change that occurs when all reactants and products are in their standard states. A deciding event is usually a change in the number of moles of gas. Because gases have such great freedom of motion and thus high molar entropies, *if the number of moles of gas increases, ΔS^0_{rxn} is usually positive; if the number decreases, ΔS^0_{rxn} is usually negative.*

For example, when $H_2(g)$ and $I_2(s)$ form $HI(g)$, the total number of moles stays the same, but we predict that the entropy increases because the number of moles of *gas* increases:

$$H_2(g) + I_2(s) \longrightarrow 2HI(g) \qquad \Delta S^0_{rxn} = S^0_{products} - S^0_{reactants} > 0$$

When ammonia forms from its elements, 4 mol of gas produces 2 mol of gas, so we predict that the entropy decreases during the reaction:

$$N_2(g) + 3H_2(g) \rightleftharpoons 2NH_3(g) \qquad \Delta S^0_{rxn} = S^0_{products} - S^0_{reactants} < 0$$

Sometimes, even when the amount (mol) of gases stays the same, another factor related to freedom of motion may help predict the sign of the entropy change. For example, when cyclopropane is heated to 500°C, the ring opens and propene forms. The chain has more freedom of motion than the ring, so the standard molar entropy of the product is greater than that of the reactant:

$$H_2C\text{—}CH_2(g) \longrightarrow CH_3\text{—}CH{=}CH_2(g) \qquad \Delta S^0 = S^0_{products} - S^0_{reactants} > 0$$

Keep in mind, however, that in general *we cannot predict the sign of the entropy change unless the reaction involves a change in number of moles of gas.*

Recall that by applying Hess's law (Chapter 6), we can combine ΔH^0_f values to find the standard heat of reaction, ΔH^0_{rxn}. Similarly, we combine S^0 values to find the standard entropy of reaction, ΔS^0_{rxn}:

$$\Delta S^0_{rxn} = \Sigma m S^0_{products} - \Sigma n S^0_{reactants} \qquad (20.4)$$

where m and n are the amounts of the individual species, represented by their coefficients in the balanced equation. For the formation of ammonia, we have

$$\Delta S^0_{rxn} = [(2 \text{ mol } NH_3)(S^0 \text{ of } NH_3)] - [(1 \text{ mol } N_2)(S^0 \text{ of } N_2) + (3 \text{ mol } H_2)(S^0 \text{ of } H_2)]$$

From Appendix B, we find the appropriate S^0 values:

$$\Delta S^0_{rxn} = [(2 \text{ mol})(193 \text{ J/mol·K})] - [(1 \text{ mol})(191.5 \text{ J/mol·K}) + (3 \text{ mol})(130.6 \text{ J/mol·K})]$$
$$= -197 \text{ J/K}$$

As we predicted, $\Delta S^0_{rxn} < 0$.

SAMPLE PROBLEM 20.2 Calculating the Standard Entropy of Reaction, ΔS^0_{rxn}

Problem Calculate ΔS^0_{rxn} for the combustion of 1 mol of propane at 25°C:

$$C_3H_8(g) + 5O_2(g) \longrightarrow 3CO_2(g) + 4H_2O(l)$$

Plan To determine ΔS^0_{rxn}, we apply Equation 20.4. We predict the sign of ΔS^0_{rxn} from the change in the number of moles of gas: 6 mol of gas yields 3 mol of gas, so the entropy will probably decrease ($\Delta S^0_{rxn} < 0$).

Solution Calculating ΔS^0_{rxn}. Using Appendix B values,

$$\Delta S^0_{rxn} = [(3 \text{ mol } CO_2)(S^0 \text{ of } CO_2) + (4 \text{ mol } H_2O)(S^0 \text{ of } H_2O)]$$
$$- [(1 \text{ mol } C_3H_8)(S^0 \text{ of } C_3H_8) + (5 \text{ mol } O_2)(S^0 \text{ of } O_2)]$$
$$= [(3 \text{ mol})(213.7 \text{ J/mol·K}) + (4 \text{ mol})(69.9 \text{ J/mol·K})]$$
$$- [(1 \text{ mol})(269.9 \text{ J/mol·K}) + (5 \text{ mol})(205.0 \text{ J/mol·K})]$$
$$= -374 \text{ J/K}$$

Check $\Delta S^0 < 0$, so our prediction is correct. Rounding gives $[3(200) + 4(70)] - [270 + 5(200)] = 880 - 1270 = -390$, close to the calculated value.

Comment We based our prediction on the fact that S^0 values of gases are much greater than those of solids or liquids. (This is usually true even when the condensed phases consist of more complex molecules.) Remember that when there is no change in the amount (mol) of gas, you *cannot* confidently predict the sign of ΔS^0_{rxn}.

FOLLOW-UP PROBLEM 20.2

Balance the following equations, predict the sign of ΔS^0_{rxn} if possible, and calculate its value at 25°C:

(a) $NaOH(s) + CO_2(g) \longrightarrow Na_2CO_3(s) + H_2O(l)$

(b) $Fe(s) + H_2O(g) \longrightarrow Fe_2O_3(s) + H_2(g)$

Entropy Changes in the Surroundings: The Other Part of the Total

In many spontaneous reactions, such as the synthesis of ammonia and the combustion of propane, we see that the entropy of the reacting system decreases ($\Delta S^0_{rxn} < 0$). The second law dictates that ***decreases*** *in the entropy of the system can occur only if* ***increases*** *in the entropy of the surroundings outweigh them.* Let's examine the influence of the surroundings—in particular, the addition (or removal) of heat and the temperature at which this heat change occurs—on the *total* entropy change.

The essential role of the surroundings is to *either add heat to the system or remove heat from it.* In essence, the surroundings function as an enormous heat source or heat sink, one so large that its temperature remains constant, even though its entropy changes through the loss or gain of heat. The surroundings participate in the two possible types of enthalpy changes as follows:

1. *Exothermic change.* Heat lost by the system is gained by the surroundings. This heat gain increases the freedom of motion of particles in the surroundings, which disperses their energy; so the entropy of the surroundings increases:

   For an exothermic change: $q_{sys} < 0$, $q_{surr} > 0$, and $\Delta S_{surr} > 0$

2. *Endothermic change.* Heat gained by the system is lost by the surroundings. This heat loss reduces the freedom of motion of particles in the surroundings, which localizes their energy; so the entropy of the surroundings decreases:

   For an endothermic change: $q_{sys} > 0$, $q_{surr} < 0$, and $\Delta S_{surr} < 0$

The *temperature* of the surroundings at which the heat is transferred also affects ΔS_{surr}. Consider the effect of an exothermic reaction at a low and at a high temperature. At a low temperature, such as 20 K, there is very little random motion in the surroundings, that is, relatively little energy is dispersed there. Therefore, transferring heat to the surroundings has a large effect on how much energy is dispersed. At a higher temperature, such as 298 K, the surroundings already have a relatively large quantity of energy dispersed, so transferring the same amount of heat has a smaller effect on the total energy dispersed. In other words, the change in entropy of the surroundings is greater when heat is added at a lower temperature. Putting these ideas together, *the change in entropy of the surroundings is directly related to an opposite change in the heat of the system and inversely related to the temperature at which the heat is transferred.* Combining these relationships gives an equation that is closely related to Equation 20.2:

$$\Delta S_{surr} = -\frac{q_{sys}}{T}$$

Recall that for a process at *constant pressure,* the heat (q_P) is ΔH, so

$$\Delta S_{surr} = -\frac{\Delta H_{sys}}{T} \qquad (20.5)$$

This means that we can calculate ΔS_{surr} by measuring ΔH_{sys} and the temperature T at which the change takes place.

To restate the central point, if a spontaneous reaction has a negative ΔS_{sys} (energy dispersed over fewer microstates), ΔS_{surr} must be positive enough (energy dispersed over many more microstates) that ΔS_{univ} is positive (energy dispersed over more microstates). Sample Problem 20.3 illustrates this situation for one of the reactions we considered earlier.

A Checkbook Analogy for Heating the Surroundings A monetary analogy may clarify the relative sizes of the changes that arise from heating the surroundings at different initial temperatures. If you have \$10 in your checking account, a \$10 deposit represents a 100% increase in your net worth; that is, a given change to a low initial state has a large impact. If, however, you have a \$1000 balance, a \$10 deposit represents only a 1% increase. That is, the same change to a high initial state has a smaller impact.

SAMPLE PROBLEM 20.3 Determining Reaction Spontaneity

Problem At 298 K, the formation of ammonia has a negative ΔS^0_{sys}:

$$N_2(g) + 3H_2(g) \longrightarrow 2NH_3(g) \qquad \Delta S^0_{sys} = -197 \text{ J/K}$$

Calculate ΔS_{univ}, and state whether the reaction occurs spontaneously at this temperature.

Plan For the reaction to occur spontaneously, $\Delta S_{univ} > 0$, and so ΔS_{surr} must be greater than +197 J/K. To find ΔS_{surr}, we need ΔH^0_{sys}, which is the same as ΔH^0_{rxn}. We use ΔH^0_f values from Appendix B to find ΔH^0_{rxn}. Then, we use ΔH^0_{rxn} and the given T (298 K) to find ΔS_{surr}. To find ΔS_{univ}, we add the calculated ΔS_{surr} to the given ΔS^0_{sys} (−197 J/K).

Solution Calculating ΔH^0_{sys}:

$$\begin{aligned}\Delta H^0_{sys} &= \Delta H^0_{rxn} \\ &= [(2 \text{ mol } NH_3)(-45.9 \text{ kJ/mol})] - [(3 \text{ mol } H_2)(0 \text{ kJ/mol}) + (1 \text{ mol } N_2)(0 \text{ kJ/mol})] \\ &= -91.8 \text{ kJ}\end{aligned}$$

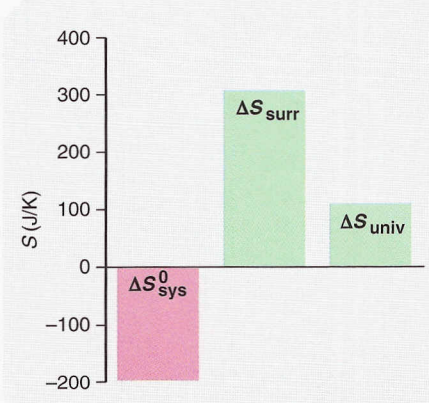
Calculating ΔS_{surr}:

$$\Delta S_{surr} = -\frac{\Delta H^0_{sys}}{T} = -\frac{-91.8 \text{ kJ} \times \dfrac{1000 \text{ J}}{1 \text{ kJ}}}{298 \text{ K}} = 308 \text{ J/K}$$

Determining ΔS_{univ}:

$$\Delta S_{univ} = \Delta S^0_{sys} + \Delta S_{surr} = -197 \text{ J/K} + 308 \text{ J/K} = 111 \text{ J/K}$$

$\Delta S_{univ} > 0$, so the reaction occurs spontaneously at 298 K (see figure in margin).



Check Rounding to check the math, we have

$$\Delta H^0_{rxn} \approx 2(-45 \text{ kJ}) = -90 \text{ kJ}$$
$$\Delta S_{surr} \approx -(-90{,}000 \text{ J})/300 \text{ K} = 300 \text{ J/K}$$
$$\Delta S_{univ} \approx -200 \text{ J/K} + 300 \text{ J/K} = 100 \text{ J/K}$$

Given the negative ΔH^0_{rxn}, Le Châtelier's principle predicts that low temperature should favor NH_3 formation, and so the answer is reasonable (see the Chemical Connections essay on the Haber process, pp. 755–756).

Comment **1.** Note that ΔH^0 has units of kJ, whereas ΔS has units of J/K. Don't forget to convert kJ to J, or you'll introduce a large error.

2. This example highlights the distinction between thermodynamic and kinetic considerations. Even though NH_3 forms spontaneously, it does so slowly; the chemical industry expends great effort to catalyze its formation at a practical rate.

FOLLOW-UP PROBLEM 20.3 Does the oxidation of FeO(*s*) to Fe_2O_3(*s*) occur spontaneously at 298 K?

As Sample Problem 20.3 shows, taking the surroundings into account is crucial to determining reaction spontaneity. Moreover, it clarifies the relevance of thermodynamics to biology, as the Chemical Connections essay shows.

The Entropy Change and the Equilibrium State

A process spontaneously approaches equilibrium, so $\Delta S_{univ} > 0$. When the process reaches equilibrium, there is no longer any force driving it to proceed further and, thus, no net change in either direction; that is, $\Delta S_{univ} = 0$. At that point, any entropy change in the system is exactly balanced by an opposite entropy change in the surroundings:

$$\text{At equilibrium:} \qquad \Delta S_{univ} = \Delta S_{sys} + \Delta S_{surr} = 0 \quad \text{or} \quad \Delta S_{sys} = -\Delta S_{surr}$$

For example, let's calculate ΔS_{univ} for a phase change. For the vaporization-condensation of 1 mol of water at 100°C (373 K),

$$H_2O(l;\ 373 \text{ K}) \rightleftharpoons H_2O(g;\ 373 \text{ K})$$

Do Living Things Obey the Laws of Thermodynamics?

Organisms can be thought of as chemical machines that evolved by extracting energy as efficiently as possible from the environment. Such a mechanical view holds that all processes, whether they involve living or nonliving systems, are consistent with thermodynamic principles. Let's examine the first and second laws of thermodynamics to see if they apply to living systems.

Organisms certainly comply with the first law. The chemical bond energy in food is converted into the mechanical energy of sprouting, crawling, swimming, and countless other movements; the electrical energy of nerve conduction; the thermal energy of warming the body; and so forth. Many experiments have demonstrated that in all these energy conversions, the total energy is conserved. Some of the earliest studies of this question were performed by Lavoisier, who included animal respiration in his new theory of combustion (Figure B20.1). He was the first to show that "animal heat" was produced by a slow combustion process occurring continually in the body. In experiments with guinea pigs, he measured the intake of food and O_2 and the output of CO_2 and heat, for which he invented a calorimeter based on the melting of ice, and he established the principles and methods for measuring the basal rate of metabolism. Modern experiments using a calorimeter large enough to contain an exercising human continue to confirm the conservation of energy (Figure B20.2).

It may not seem as clear, however, that an organism, and even the whole parade of life, complies with the second law. Mature humans are far more complex than the simple egg and sperm cells from which they develop, and modern organisms are far more complex than the one-celled ancestral specks from which they evolved. Energy must be highly localized and macromolecules constrained to carry out myriad reactions that synthesize biopolymers from their monomers. Are the growth of an organism and the evolution of life exceptions to the spontaneous tendency of natural processes to disperse their energy and increase molecular freedom? Does biology violate the second law? Not at all, if we examine the system *and* its surroundings. For an organism to grow or a species to evolve, countless moles of food molecules—carbohydrates, proteins, and fats—and oxygen molecules undergo exothermic combustion reactions to form many more moles of gaseous CO_2 and H_2O. The formation and discharge of these waste gases represent a tremendous net increase in the entropy of the surroundings, as does the heat released. Thus, the localization of energy and restrictions on molecular freedom apparent in the growth and evolution of organisms occur at the expense of a far greater dispersal of energy and freedom of motion in the Earth-Sun surroundings. When system and surroundings are considered together, the entropy of the universe, as always, increases.

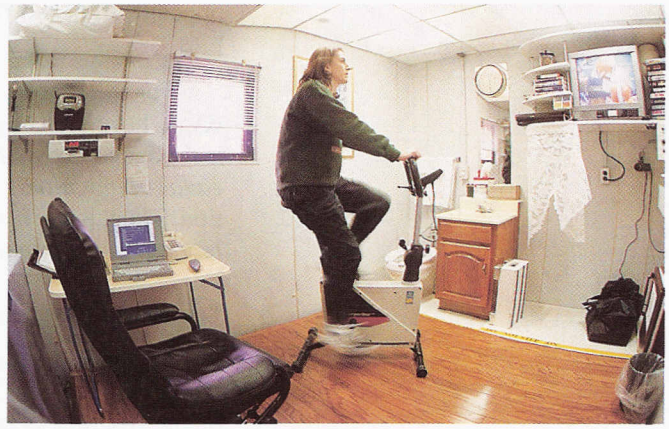


Figure B20.2 A whole-body calorimeter. In this room-sized apparatus, a subject exercises while respiratory gases, energy input and output, and other physiological variables are monitored.

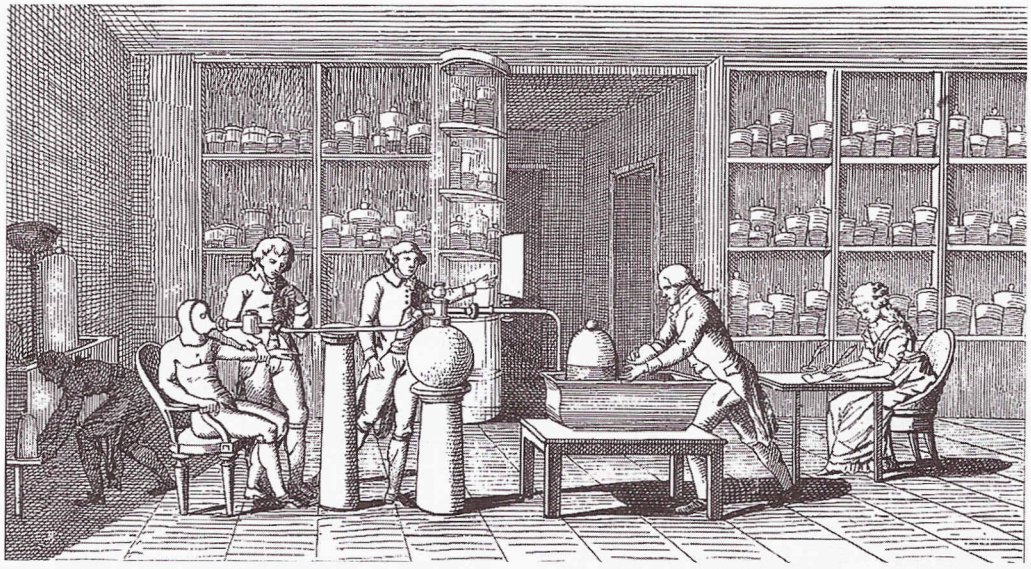

Figure B20.1 Lavoisier studying human respiration as a form of combustion. Lavoisier (standing at right) measured substances consumed and excreted in addition to changes in heat to understand the chemical nature of respiration. The artist (Mme. Lavoisier) shows herself taking notes (seated at right).

First, we find ΔS_{univ} for the forward change (vaporization) by calculating ΔS^0_{sys}:

$$\Delta S^0_{sys} = \Sigma m S^0_{products} - \Sigma n S^0_{reactants} = S^0 \text{ of } H_2O(g;\ 373\ K) - S^0 \text{ of } H_2O(l;\ 373\ K)$$
$$= 195.9\ J/K - 86.8\ J/K = 109.1\ J/K$$

As we expect, the entropy of the system increases ($\Delta S^0_{sys} > 0$) as the liquid absorbs heat and changes to a gas.

For ΔS_{surr}, we have

$$\Delta S_{surr} = -\frac{\Delta H^0_{sys}}{T}$$

where $\Delta H^0_{sys} = \Delta H^0_{vap}$ at 373 K = 40.7 kJ/mol = 40.7×10^3 J/mol. For 1 mol of water, we have

$$\Delta S_{surr} = -\frac{\Delta H^0_{vap}}{T} = -\frac{40.7\times10^3\ J}{373\ K} = -109\ J/K$$

The surroundings lose heat, and the negative sign means that the entropy of the surroundings decreases. The two entropy changes have the same magnitude but opposite signs, so they cancel:

$$\Delta S_{univ} = 109\ J/K + (-109\ J/K) = 0$$

For the reverse change (condensation), ΔS_{univ} also equals zero, but ΔS^0_{sys} and ΔS_{surr} have signs opposite those for vaporization. A similar treatment of a chemical change shows the same result: the entropy change of the forward reaction is *equal in magnitude but opposite in sign* to the entropy change of the reverse reaction. Thus, *when a system reaches equilibrium, neither the forward nor the reverse reaction is spontaneous,* and so there is no net reaction in either direction.

Spontaneous Exothermic and Endothermic Reactions: A Summary

We can now see why exothermic and endothermic spontaneous reactions occur. No matter what its *enthalpy* change, a reaction occurs because the total *entropy* of the reacting system *and* its surroundings increases. The two possibilities are

1. *For an exothermic reaction* ($\Delta H_{sys} < 0$), heat is released by the system, which increases the freedom of motion and energy dispersed and, thus, the entropy of the surroundings ($\Delta S_{surr} > 0$).

- If the reacting system yields products whose entropy is greater than that of the reactants ($\Delta S_{sys} > 0$), the total entropy change ($\Delta S_{sys} + \Delta S_{surr}$) will be positive (Figure 20.10A). For example, in the oxidation of glucose, an essential reaction for all higher organisms,

$$C_6H_{12}O_6(s) + 6O_2(g) \longrightarrow 6CO_2(g) + 6H_2O(g) + \textit{heat}$$

6 mol of gas yields 12 mol of gas and heat; thus, $\Delta S_{sys} > 0$, $\Delta S_{surr} > 0$, and $\Delta S_{univ} > 0$.

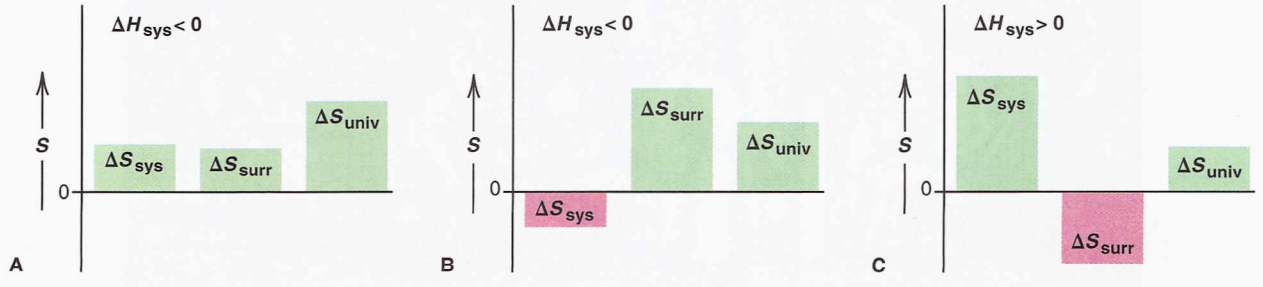

Figure 20.10 Components of ΔS_{univ} for spontaneous reactions. For a reaction to occur spontaneously, ΔS_{univ} must be positive. **A,** An exothermic reaction in which ΔS_{sys} increases; the size of ΔS_{surr} is not important. **B,** An exothermic reaction in which ΔS_{sys} decreases; ΔS_{surr} must be larger than ΔS_{sys}. **C,** An endothermic reaction in which ΔS_{sys} increases; ΔS_{surr} must be smaller than ΔS_{sys}.

- If, on the other hand, the entropy of the system decreases as the reaction occurs ($\Delta S_{sys} < 0$), the entropy of the surroundings must increase even more ($\Delta S_{surr} >> 0$) to make the total ΔS positive (Figure 20.10B). For example, when calcium oxide and carbon dioxide form calcium carbonate,

$$CaO(s) + CO_2(g) \longrightarrow CaCO_3(s) + \textit{heat}$$

the entropy of the system decreases because the amount (mol) of gas decreases. However, the heat released increases the entropy of the surroundings even more; thus, $\Delta S_{sys} < 0$, but $\Delta S_{surr} >> 0$, so $\Delta S_{univ} > 0$.

2. *For an endothermic reaction* ($\Delta H_{sys} > 0$), the heat lost by the surroundings decreases molecular freedom of motion and dispersal of energy and, thus, decreases the entropy of the surroundings ($\Delta S_{surr} < 0$). Therefore, the only way an endothermic reaction can occur spontaneously is if ΔS_{sys} is positive and large enough to outweigh the negative ΔS_{surr} (Figure 20.10C).

- In the solution process for many ionic compounds, heat is absorbed to form the solution, so the entropy of the surroundings decreases ($\Delta S_{surr} < 0$). However, when the crystalline solid becomes freely moving ions, the entropy increase is so large ($\Delta S_{sys} >> 0$) that it outweighs the negative ΔS_{surr}. Thus, ΔS_{univ} is positive.
- Spontaneous endothermic reactions have similar features. For example, in the reaction between barium hydroxide octahydrate and ammonium nitrate (see Figure 20.1, p. 866),

$$\textit{heat} + Ba(OH)_2{\cdot}8H_2O(s) + 2NH_4NO_3(s) \longrightarrow Ba^{2+}(aq) + 2NO_3^-(aq) + 2NH_3(aq) + 10H_2O(l)$$

3 mol of crystalline solids absorb heat from the surroundings ($\Delta S_{surr} < 0$) and yield 15 mol of dissolved ions and molecules, which have much more freedom of motion and so much greater entropy ($\Delta S_{sys} >> 0$).

SECTION SUMMARY

The standard entropy of reaction, ΔS^0_{rxn}, is calculated from S^0 values. When the amount (mol) of gas (Δn_{gas}) increases in a reaction, usually $\Delta S^0_{rxn} > 0$. The value of ΔS_{surr} is related directly to ΔH^0_{sys} and inversely to the T at which the change occurs. In a spontaneous change, the entropy of the system can decrease only if the entropy of the surroundings increases even more. For a system at equilibrium, $\Delta S_{univ} = 0$.

20.3 ENTROPY, FREE ENERGY, AND WORK

By making *two* separate measurements, ΔS_{sys} and ΔS_{surr}, we can predict whether a reaction will be spontaneous at a particular temperature. It would be useful, however, to have *one* criterion for spontaneity that applies only to the system. The Gibbs free energy, or simply **free energy (*G*),** is a function that combines the system's enthalpy and entropy:

$$G = H - TS$$

Named for Josiah Willard Gibbs, who proposed it and laid much of the foundation for chemical thermodynamics, this function provides the criterion for spontaneity we've been seeking.

Free Energy Change and Reaction Spontaneity

The free energy change (ΔG) is a measure of the spontaneity of a process and of the useful energy available from it. Let's see how the free energy change is derived from the second law of thermodynamics. Recall that by definition, the

The Greatness and Obscurity of J. Willard Gibbs Even today, one of the greatest minds in science is barely known outside chemistry and physics. In 1878, Josiah Willard Gibbs (1839–1903), a professor of mathematical physics at Yale, completed a 323-page paper that virtually established the science of chemical thermodynamics and included major principles governing chemical equilibria, phase-change equilibria, and the energy changes in electrochemical cells. The European scientists James Clerk Maxwell, Wilhelm Ostwald, and Henri Le Châtelier appreciated the significance of Gibbs's achievements long before most of his American colleagues did. In fact, he was elected to the Hall of Fame of Distinguished Americans only in 1950, because he had not received enough votes until then!

entropy change of the universe is the sum of the entropy changes of the system and the surroundings:

$$\Delta S_{univ} = \Delta S_{sys} + \Delta S_{surr}$$

At constant pressure,

$$\Delta S_{surr} = -\frac{\Delta H_{sys}}{T}$$

Substituting for ΔS_{surr} gives a relationship that lets us focus solely on the system:

$$\Delta S_{univ} = \Delta S_{sys} - \frac{\Delta H_{sys}}{T}$$

Multiplying both sides by $-T$ gives

$$-T\Delta S_{univ} = \Delta H_{sys} - T\Delta S_{sys}$$

Now we can introduce the new free energy quantity to replace the enthalpy and entropy terms. From $G = H - TS$, the *Gibbs equation* shows us the change in the free energy of the system (ΔG_{sys}) at constant temperature and pressure:

$$\Delta G_{sys} = \Delta H_{sys} - T\Delta S_{sys} \qquad (20.6)$$

Combining this equation with the previous one shows that

$$-T\Delta S_{univ} = \Delta H_{sys} - T\Delta S_{sys} = \Delta G_{sys}$$

*The **sign** of ΔG tells if a reaction is spontaneous.* The second law dictates

- $\Delta S_{univ} > 0$ for a spontaneous process
- $\Delta S_{univ} < 0$ for a nonspontaneous process
- $\Delta S_{univ} = 0$ for a process at equilibrium

Of course, absolute temperature is always positive, so

$$T\Delta S_{univ} > 0 \quad \text{or} \quad -T\Delta S_{univ} < 0 \text{ for a spontaneous process}$$

Because $\Delta G = -T\Delta S_{univ}$, we know that

- $\Delta G < 0$ for a spontaneous process
- $\Delta G > 0$ for a nonspontaneous process
- $\Delta G = 0$ for a process at equilibrium

An important point to keep in mind is that if a process is *nonspontaneous* in one direction ($\Delta G > 0$), it is *spontaneous* in the opposite direction ($\Delta G < 0$). By using ΔG, we have not incorporated any new ideas, but we can predict reaction spontaneity from one variable (ΔG_{sys}) rather than two (ΔS_{sys} and ΔS_{surr}).

As we noted at the beginning of the chapter, the degree of spontaneity of a reaction—that is, the sign *and* magnitude of ΔG—tells us nothing about its rate. Remember that some spontaneous reactions are extremely slow. For example, the reaction between $H_2(g)$ and $O_2(g)$ at room temperature is highly spontaneous—ΔG has a large negative value—but in the absence of a catalyst or a flame, the reaction doesn't occur to a measurable extent because its rate is so low.

Calculating Standard Free Energy Changes

Because free energy (G) combines three state functions, H, S, and T, it is also a state function. As with enthalpy, we focus on the free energy *change* (ΔG).

The Standard Free Energy Change As we did with the other thermodynamic variables, to compare the free energy changes of different reactions we calculate the ***standard* free energy change (ΔG^0),** which occurs when all components of the system are in their standard states. Adapting the Gibbs equation (20.6), we have

$$\Delta G^0_{sys} = \Delta H^0_{sys} - T\Delta S^0_{sys} \qquad (20.7)$$

This important relationship is used frequently to find any one of these three central thermodynamic variables, given the other two, as in this sample problem.

SAMPLE PROBLEM 20.4 Calculating ΔG^0_{rxn} from Enthalpy and Entropy Values

Problem Potassium chlorate, a common oxidizing agent in fireworks (see photo) and matchheads, undergoes a solid-state disproportionation reaction when heated:

$$4\overset{+5}{K}\overset{}{Cl}O_3(s) \xrightarrow{\Delta} 3\overset{+7}{K}\overset{}{Cl}O_4(s) + \overset{-1}{K}\overset{}{Cl}(s)$$

Use ΔH^0_f and S^0 values to calculate ΔG^0_{sys} (ΔG^0_{rxn}) at 25°C for this reaction.

Plan To solve for ΔG^0, we need values from Appendix B. We use ΔH^0_f values to calculate ΔH^0_{rxn} (ΔH^0_{sys}), use S^0 values to calculate ΔS^0_{rxn} (ΔS^0_{sys}), and then apply Equation 20.7.

Solution Calculating ΔH^0_{sys} from ΔH^0_f values (with Equation 6.8):

$$\begin{aligned}\Delta H^0_{sys} = \Delta H^0_{rxn} &= \Sigma m\Delta H^0_{f(products)} - \Sigma n\Delta H^0_{f(reactants)}\\ &= [(3\text{ mol } KClO_4)(\Delta H^0_f \text{ of } KClO_4) + (1\text{ mol KCl})(\Delta H^0_f \text{ of KCl})]\\ &\quad - [(4\text{ mol } KClO_3)(\Delta H^0_f \text{ of } KClO_3)]\\ &= [(3\text{ mol})(-432.8\text{ kJ/mol}) + (1\text{ mol})(-436.7\text{ kJ/mol})]\\ &\quad - [(4\text{ mol})(-397.7\text{ kJ/mol})]\\ &= -144\text{ kJ}\end{aligned}$$

Calculating ΔS^0_{sys} from S^0 values (with Equation 20.4):

$$\begin{aligned}\Delta S^0_{sys} = \Delta S^0_{rxn} &= [(3\text{ mol } KClO_4)(S^0 \text{ of } KClO_4) + (1\text{ mol KCl})(S^0 \text{ of KCl})]\\ &\quad - [(4\text{ mol } KClO_3)(S^0 \text{ of } KClO_3)]\\ &= [(3\text{ mol})(151.0\text{ J/mol·K}) + (1\text{ mol})(82.6\text{ J/mol·K})]\\ &\quad - [(4\text{ mol})(143.1\text{ J/mol·K})]\\ &= -36.8\text{ J/K}\end{aligned}$$

Calculating ΔG^0_{sys} at 298 K:

$$\Delta G^0_{sys} = \Delta H^0_{sys} - T\Delta S^0_{sys} = -144\text{ kJ} - \left[(298\text{ K})(-36.8\text{ J/K})\left(\frac{1\text{ kJ}}{1000\text{ J}}\right)\right] = -133\text{ kJ}$$

Check Rounding to check the math:

$$\Delta H^0 \approx [3(-433\text{ kJ}) + (-440\text{ kJ})] - [4(-400\text{ kJ})] = -1740\text{ kJ} + 1600\text{ kJ} = -140\text{ kJ}$$
$$\Delta S^0 \approx [3(150\text{ J/K}) + 85\text{ J/K}] - [4(145\text{ J/K})] = 535\text{ J/K} - 580\text{ J/K} = -45\text{ J/K}$$
$$\Delta G^0 \approx -140\text{ kJ} - 300\text{ K}(-0.04\text{ kJ/K}) = -140\text{ kJ} + 12\text{ kJ} = -128\text{ kJ}$$

All values are close to the calculated ones. Another way to calculate ΔG^0 for this reaction is presented in Sample Problem 20.5.

Comment **1.** For a spontaneous reaction under *any* conditions, the free energy change, ΔG, is negative. Under standard-state conditions, a spontaneous reaction has a negative *standard* free energy change; that is, $\Delta G^0 < 0$.

2. This reaction is spontaneous, but the rate is very low in the solid. When $KClO_3$ is heated slightly above its melting point, the ions are free to move and the reaction occurs readily.

FOLLOW-UP PROBLEM 20.4 Determine the standard free energy change at 298 K for the reaction $2NO(g) + O_2(g) \longrightarrow 2NO_2(g)$.

Potassium chlorate is the oxidizing agent in fireworks.

The Standard Free Energy of Formation Another way to calculate ΔG^0_{rxn} is with values for the **standard free energy of formation** (ΔG^0_f) of the components; ΔG^0_f is the free energy change that occurs when 1 mol of compound is made *from its elements*, with all components in their standard states. Because free energy is a state function, we can combine ΔG^0_f values of reactants and products to calculate ΔG^0_{rxn} no matter how the reaction takes place:

$$\Delta G^0_{rxn} = \Sigma m\Delta G^0_{f(products)} - \Sigma n\Delta G^0_{f(reactants)} \qquad (20.8)$$

ΔG^0_f values have properties similar to ΔH^0_f values:

- ΔG^0_f of an element in its standard state is zero.
- An equation coefficient (m or n above) multiplies ΔG^0_f by that number.
- Reversing a reaction changes the sign of ΔG^0_f.

Many ΔG^0_f values appear along with those for ΔH^0_f and S^0 in Appendix B.

SAMPLE PROBLEM 20.5 Calculating ΔG^0_{rxn} from ΔG^0_f Values

Problem Use ΔG^0_f values to calculate ΔG^0_{rxn} for the reaction in Sample Problem 20.4:

$$4KClO_3(s) \longrightarrow 3KClO_4(s) + KCl(s)$$

Plan We apply Equation 20.8 to calculate ΔG^0_{rxn}.

Solution

$$\begin{aligned}\Delta G^0_{rxn} &= \Sigma m\Delta G^0_{f(products)} - \Sigma n\Delta G^0_{f(reactants)}\\ &= [(3 \text{ mol } KClO_4)(\Delta G^0_f \text{ of } KClO_4) + (1 \text{ mol } KCl)(\Delta G^0_f \text{ of } KCl)]\\ &\quad - [(4 \text{ mol } KClO_3)(\Delta G^0_f \text{ of } KClO_3)]\\ &= [(3 \text{ mol})(-303.2 \text{ kJ/mol}) + (1 \text{ mol})(-409.2 \text{ kJ/mol})]\\ &\quad - [(4 \text{ mol})(-296.3 \text{ kJ/mol})]\\ &= -134 \text{ kJ}\end{aligned}$$

Check Rounding to check the math:

$$\Delta G^0_{rxn} \approx [3(-300 \text{ kJ}) + 1(-400 \text{ kJ})] - 4(-300 \text{ kJ})$$
$$= -1300 \text{ kJ} + 1200 \text{ kJ} = -100 \text{ kJ}$$

Comment The slight discrepancy between this answer and that obtained in Sample Problem 20.4 is within experimental error. As you can see, when ΔG^0_f values are available for a reaction taking place at 25°C, this method is simpler than that in Sample Problem 20.4.

FOLLOW-UP PROBLEM 20.5 Use ΔG^0_f values to calculate the free energy change at 25°C for each of the following reactions:

(a) $2NO(g) + O_2(g) \longrightarrow 2NO_2(g)$ (from Follow-up Problem 20.4)

(b) $2C(\text{graphite}) + O_2(g) \longrightarrow 2CO(g)$

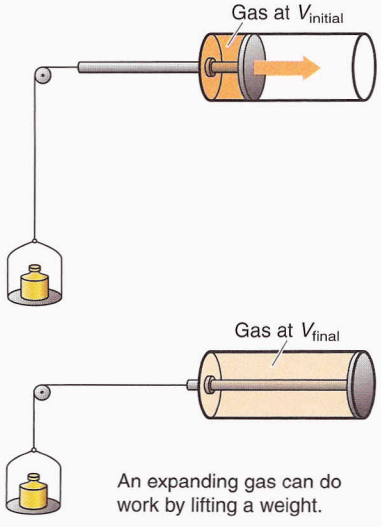
ΔG and the Work a System Can Do

Recall that the science of thermodynamics was born soon after the invention of the steam engine, and one of the most practical relationships in the field is that between the free energy change and the work a system can do:

- For a spontaneous process ($\Delta G < 0$) at constant T and P, ΔG is the *maximum useful work obtainable* ***from*** *the system ($-w$) as the process takes place:*

$$\Delta G = -w_{max} \qquad (20.9)$$

- For a nonspontaneous process ($\Delta G > 0$) at constant T and P, ΔG is the *minimum work that must be done* ***to*** *the system to make the process take place.*



An expanding gas can do work by lifting a weight.

The phrase "maximum useful work obtainable" requires some explanation. First, what do we mean by the "maximum work obtainable," and what determines this limit? The free energy change is the maximum work the system can *possibly* do. But the work the system *actually* does depends on how the free energy is released. To understand this, let's first consider a nonchemical process. Suppose a gas is confined within a cylinder, at $V_{initial}$, by a piston attached to a 1-kg weight (see margin). As the gas expands and lifts the weight, its pressure becomes just balanced by the weight at some final volume, V_{final}. The gas lifted the weight in one step, thus doing a certain quantity of work. The gas can do more work in two steps, by lifting a 2-kg weight to one-half V_{final} and then lifting a 1-kg weight the rest of the way to V_{final}. The gas can do even more work in three steps, by lifting a 3-kg weight to one-third V_{final}, the 2-kg weight to one-half V_{final}, and then the 1-kg weight the rest of the way to V_{final}. As the number of steps increases, the quantity of work done by the gas increases. The gas would do *much* more work, nearly the maximum, if the weights were replaced by a container of sand and the weight adjusted continually grain by grain, as described earlier. In this way, the gas would lift the container in a very high number of steps. Note that,

in a limiting hypothetical process, the work would be done in an infinite number of steps, and an infinitesimal increase in the weight would reverse the expansion. In general, *the maximum work is done by a spontaneous process only if the work is carried out reversibly.*

Of course, in any *real* process, work is performed *irreversibly*, that is, in a finite number of steps, so *we can never obtain the maximum work.* The free energy not used for work is lost to the surroundings as heat. This "unharnessed" energy is a consequence of any real process.

Next, what do we mean by "useful work"? As the gas expands and raises the weights, some of the work just pushes back the atmosphere. That work increases the atmosphere's energy, but it doesn't lift the weights, run a car, or do anything else useful. By the same token, if we wanted to compress the gas, the atmosphere would do part of the work by pushing on the piston, but that part of the work doesn't come from our muscles or from gasoline or from the power company. The ΔG function ignores the work done to or by the atmosphere and tells us about the work we can use or have to do ourselves.

Let's consider two examples of systems that use a chemical reaction to do work—a car engine and a battery. When gasoline (represented here by octane) is burned in a car engine,

$$C_8H_{18}(l) + \tfrac{25}{2}O_2(g) \longrightarrow 8CO_2(g) + 9H_2O(g),$$

a large amount of energy is given off as heat ($\Delta H_{sys} < 0$), and because the number of moles of gas increases, the entropy of the system increases ($\Delta S_{sys} > 0$). Therefore, the reaction is spontaneous ($\Delta G_{sys} < 0$). The free energy available does work turning wheels, moving belts, regenerating the battery, and so on. However, only if it is released reversibly, that is, in a series of infinitesimal steps, do we obtain the maximum work available from this reaction. In reality, the process is carried out irreversibly and much of the total free energy just warms the engine and the outside air, which increases the freedom of motion of the particles in the universe, in accord with the second law.

A battery is essentially a packaged spontaneous redox reaction that releases free energy to the surroundings (flashlight, radio, motor, etc.). If we connect the battery terminals to each other through a short piece of wire, the free energy change is released all at once but does no work—it just heats the wire and battery. If we connect the terminals to a motor, the free energy is released more slowly, and a sizeable portion of it runs the motor, but some is still converted to heat in the battery and the motor. If we discharge the battery still more slowly, more of the free energy change does work and less is converted to heat, but only when the battery discharges infinitely slowly can we obtain the maximum work.

This is the compromise that all engineers and machine designers must face—*in the real world, some free energy is always changed to heat and is, thereby, unharnessed: no real process uses all the available free energy to do work.*

Let's summarize the relationship between the free energy change of a reaction and the work it can actually do:

- A spontaneous reaction ($\Delta G_{sys} < 0$) will occur *and* can do work on the surroundings. In any real machine, however, the work actually obtained from the reaction is *always less than the maximum possible* because some of the ΔG released is lost as heat.
- A nonspontaneous reaction ($\Delta G_{sys} > 0$) will not occur unless the surroundings do work on it. In any real machine, however, the work needed to make the reaction occur is *always more than the minimum* because some of the ΔG added is lost as heat.
- A reaction at equilibrium ($\Delta G_{sys} = 0$) can no longer do any work.

The Wide Range of Energy Efficiency
One definition for the efficiency of a device is the percentage of the energy input that results in work output. The range of efficiencies is enormous for the common "energy-conversion systems" of society. For instance, a common incandescent lightbulb converts only 5% of incoming electrical energy to light, the rest is given off as heat. At the other extreme, a large electrical generator converts 99% of the incoming mechanical energy to electricity. Although improvements are continually being made, here are some efficiency values for other devices: home oil furnace, 65%; hand tool motor, 63%; liquid fuel rocket, 50%; car engine, <30%; fluorescent lamp, 20%; solar cell, ~15%.

The Effect of Temperature on Reaction Spontaneity

In most cases, the enthalpy contribution (ΔH) to the free energy change (ΔG) is much *larger* than the entropy contribution ($T\Delta S$). For this reason, most exothermic reactions are spontaneous: the negative ΔH helps make ΔG negative. However, the *temperature of a reaction influences the magnitude of the $T\Delta S$ term,* so the overall spontaneity of many reactions depends on the temperature.

By scrutinizing the signs of ΔH and ΔS, we can predict the effect of temperature on the sign of ΔG and thus on the spontaneity of a process at any temperature. The values for the thermodynamic variables in this discussion are based on standard state values from Appendix B, but we show them without the superscript zero to emphasize that the relationships among ΔG, ΔH, and ΔS are valid at any conditions. Also, we assume that ΔH and ΔS change little with temperature, which is true as long as no phase changes occur.

Let's examine the four combinations of positive and negative ΔH and ΔS; two combinations do not depend on temperature and two do:

- *Temperature-independent cases.* When ΔH and ΔS have *opposite* signs, the reaction occurs spontaneously either at all temperatures or at none.
  1. *Reaction is spontaneous at all temperatures:* $\Delta H < 0$, $\Delta S > 0$. Both contributions favor the spontaneity of the reaction. ΔH is negative and ΔS is positive, so $-T\Delta S$ is negative; thus, ΔG is always negative. Many combustion reactions are in this category, including those of glucose and octane that we considered earlier. The decomposition of hydrogen peroxide, a common disinfectant, is also spontaneous at all temperatures:

     $$2H_2O_2(l) \longrightarrow 2H_2O(l) + O_2(g) \qquad \Delta H = -196 \text{ kJ and } \Delta S = 125 \text{ J/K}$$

  2. *Reaction is nonspontaneous at all temperatures:* $\Delta H > 0$, $\Delta S < 0$. Both contributions oppose the spontaneity of the reaction. ΔH is positive and ΔS is negative, so $-T\Delta S$ is positive; thus, ΔG is always positive. The formation of ozone from oxygen is not spontaneous at any temperature:

     $$3O_2(g) \longrightarrow 2O_3(g) \qquad \Delta H = 286 \text{ kJ and } \Delta S = -137 \text{ J/K}$$

     This reaction occurs only if enough energy is supplied from the surroundings, as when ozone is synthesized by passing an electrical discharge through pure O_2.

- *Temperature-dependent cases.* When ΔH and ΔS have the *same* sign, the relative magnitudes of the $-T\Delta S$ and ΔH terms determine the sign of ΔG. In these cases, the magnitude of T is crucial to reaction spontaneity.
  3. *Reaction is spontaneous at higher temperatures:* $\Delta H > 0$ *and* $\Delta S > 0$. In these cases, ΔS favors spontaneity ($-T\Delta S < 0$), but ΔH does not. For example,

     $$2N_2O(g) + O_2(g) \longrightarrow 4NO(g) \qquad \Delta H = 197.1 \text{ kJ and } \Delta S = 198.2 \text{ J/K}$$

     With a positive ΔH, the reaction will occur spontaneously only when $-T\Delta S$ is large enough to make ΔG negative, which will happen at higher temperatures. The oxidation of N_2O occurs spontaneously at $T > 994$ K.
  4. *Reaction is spontaneous at lower temperatures:* $\Delta H < 0$ *and* $\Delta S < 0$. In these cases, ΔH favors spontaneity, but ΔS does not ($-T\Delta S > 0$). For example,

     $$4Fe(s) + 3O_2(g) \longrightarrow 2Fe_2O_3(s) \qquad \Delta H = -1651 \text{ kJ and } \Delta S = -549.4 \text{ J/K}$$

     With a negative ΔH, the reaction will occur spontaneously only if the $-T\Delta S$ term is smaller than the ΔH term, and this happens at lower temperatures. The production of iron(III) oxide occurs spontaneously at any $T < 3005$ K. Other examples are the formation of an ammonium halide from ammonia and a hydrogen halide, and the formation of metal oxides, fluorides, and chlorides from their elements.

Table 20.1 Reaction Spontaneity and the Signs of ΔH, ΔS, and ΔG

ΔH	ΔS	$-T\Delta S$	ΔG	Description
−	+	−	−	Spontaneous at all T
+	−	+	+	Nonspontaneous at all T
+	+	−	+ or −	Spontaneous at higher T; nonspontaneous at lower T
−	−	+	+ or −	Spontaneous at lower T; nonspontaneous at higher T

Table 20.1 summarizes these four possible combinations of ΔH and ΔS.

As you saw in Sample Problem 20.4, one way to calculate ΔG is from enthalpy and entropy changes. Because ΔH and ΔS usually change little with temperature, if no phase changes occur, we can use their values at 298 K to examine the effect of temperature on ΔG and, thus, on reaction spontaneity.

SAMPLE PROBLEM 20.6 Determining the Effect of Temperature on ΔG

Problem A key step in the production of sulfuric acid is the oxidation of $SO_2(g)$ to $SO_3(g)$:

$$2SO_2(g) + O_2(g) \longrightarrow 2SO_3(g)$$

At 298 K, $\Delta G = -141.6$ kJ; $\Delta H = -198.4$ kJ; and $\Delta S = -187.9$ J/K.

(a) Use the data to decide if this reaction is spontaneous at 25°C, and predict how ΔG will change with increasing T.

(b) Assuming that ΔH and ΔS are constant with T, is the reaction spontaneous at 900.°C?

Plan **(a)** We note the sign of ΔG to see if the reaction is spontaneous and the signs of ΔH and ΔS to see the effect of T. **(b)** We use Equation 20.7 to calculate ΔG from the given ΔH and ΔS at the higher T (in K).

Solution **(a)** $\Delta G < 0$, so the reaction is spontaneous at 298 K: SO_2 and O_2 will form SO_3 spontaneously. With $\Delta S < 0$, the term $-T\Delta S > 0$, and this term will become more positive at higher T. Therefore,

ΔG will become less negative, and the reaction less spontaneous, with increasing T.

(b) Calculating ΔG at 900.°C ($T = 273 + 900. = 1173$ K):

$$\Delta G = \Delta H - T\Delta S = -198.4 \text{ kJ} - [(1173 \text{ K})(-187.9 \text{ J/K})(1 \text{ kJ}/1000 \text{ J})] = 22.0 \text{ kJ}$$

$\Delta G > 0$, so the reaction is nonspontaneous at the higher T.

Check The answer in part (b) seems reasonable based on our prediction in part (a). The arithmetic seems correct, given considerable rounding:

$$\Delta G \approx -200 \text{ kJ} - [(1200 \text{ K})(-200 \text{ J/K})/1000] = +40 \text{ kJ}$$

FOLLOW-UP PROBLEM 20.6 A reaction is nonspontaneous at room temperature but *is* spontaneous at −40°C. What can you say about the signs and relative magnitudes of ΔH, ΔS, and $-T\Delta S$?

The Temperature at Which a Reaction Becomes Spontaneous As you have just seen, when the signs of ΔH and ΔS are the same, some reactions that are nonspontaneous at one temperature become spontaneous at another, and vice versa. It would certainly be useful to know the temperature at which a reaction becomes spontaneous. This is the temperature at which a positive ΔG switches to a negative ΔG because of the changing magnitude of the $-T\Delta S$ term. We find this crossover temperature by setting ΔG equal to zero and solving for T:

$$\Delta G = \Delta H - T\Delta S = 0$$

Therefore,

$$\Delta H = T\Delta S \quad \text{and} \quad T = \frac{\Delta H}{\Delta S} \tag{20.10}$$

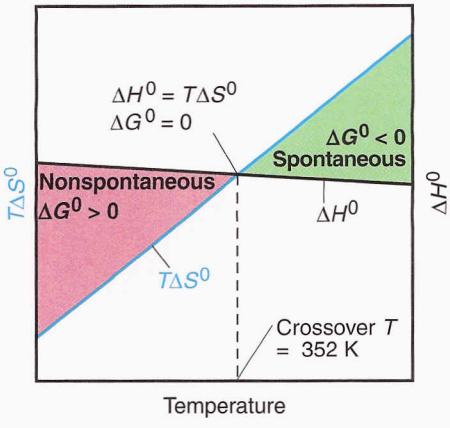


Figure 20.11 The effect of temperature on reaction spontaneity. The two terms that make up ΔG are plotted against T. The figure shows a relatively constant ΔH and a steadily increasing $T\Delta S$ (and thus more negative $-T\Delta S$) for the reaction between Cu_2O and C. At low T, the reaction is nonspontaneous ($\Delta G > 0$) because the positive ΔH term has a greater magnitude than the negative $T\Delta S$ term. At 352 K, $\Delta H = T\Delta S$, so $\Delta G = 0$. At any higher T, the reaction becomes spontaneous ($\Delta G < 0$) because the $-T\Delta S$ term dominates.

Consider the reaction of copper(I) oxide with carbon, which does *not* occur at lower temperatures but is used at higher temperatures in a step during the extraction of copper metal from chalcocite:

$$Cu_2O(s) + C(s) \longrightarrow 2Cu(s) + CO(g)$$

We predict this reaction has a positive entropy change because the number of moles of gas increases; in fact, $\Delta S = 165$ J/K. Furthermore, because the reaction is *non*spontaneous at lower temperatures, it must have a positive ΔH (58.1 kJ). As the $-T\Delta S$ term becomes more negative at higher temperatures, it will eventually outweigh the positive ΔH term, and the reaction will occur spontaneously.

We'll calculate ΔG for this reaction at 25°C and then find the temperature above which the reaction is spontaneous. At 25°C (298 K),

$$\Delta G = \Delta H - T\Delta S = 58.1 \text{ kJ} - \left(298 \text{ K} \times 165 \text{ J/K} \times \frac{1 \text{ kJ}}{1000 \text{ J}}\right) = 8.9 \text{ kJ}$$

Because ΔG is positive, the reaction will not proceed on its own at 25°C. At the crossover temperature, $\Delta G = 0$, so

$$T = \frac{\Delta H}{\Delta S} = \frac{58.1 \text{ kJ} \times \dfrac{1000 \text{ J}}{1 \text{ kJ}}}{165 \text{ J/K}} = 352 \text{ K}$$

At any temperature above 352 K (79°C), a moderate one for recovering a metal from its ore, the reaction occurs spontaneously. Figure 20.11 depicts this result. The line for $T\Delta S$ increases steadily (and thus the $-T\Delta S$ term becomes more negative) with rising temperature. This line crosses the relatively constant ΔH line at 352 K. At any higher temperature, the $-T\Delta S$ term is greater than the ΔH term, so ΔG is negative.

Coupling of Reactions to Drive a Nonspontaneous Change

When considering the spontaneity of a complex, multistep reaction, we often find that a nonspontaneous step is driven by a spontaneous step in a **coupling of reactions.** *One step supplies enough free energy for the other to occur*, just as the combustion of gasoline supplies enough free energy to move a car.

Look again at the reduction of copper(I) oxide by carbon. Previously, we found that the *overall* reaction becomes spontaneous at any temperature above 352 K. Dividing the reaction into two steps, however, we find that even at a higher temperature, such as 375 K, copper(I) oxide does not spontaneously decompose to its elements:

$$Cu_2O(s) \longrightarrow 2Cu(s) + \tfrac{1}{2}O_2(g) \qquad \Delta G_{375} = 140.0 \text{ kJ}$$

However, the oxidation of carbon to CO at 375 K is quite spontaneous:

$$C(s) + \tfrac{1}{2}O_2(g) \longrightarrow CO(g) \qquad \Delta G_{375} = -143.8 \text{ kJ}$$

Coupling these reactions means having the carbon in contact with the Cu_2O, which allows the reaction with the larger negative ΔG to "drive" the one with the smaller positive ΔG. Adding the reactions together and canceling the common substance ($\frac{1}{2}O_2$) gives an overall negative ΔG:

$$Cu_2O(s) + C(s) \longrightarrow 2Cu(s) + CO(g) \qquad \Delta G_{375} = -3.8 \text{ kJ}$$

Many biochemical reactions are also nonspontaneous. Key steps in the synthesis of proteins and nucleic acids, the formation of fatty acids, the maintenance of ion balance, and the breakdown of nutrients are among the many essential processes with positive ΔG values. Driving these energetically unfavorable steps by coupling them to a spontaneous one is a life-sustaining strategy common to all organisms—animals, plants, and microbes—as you'll see in the Chemical Connections essay.

The Universal Role of ATP

One of the most remarkable features of organisms, as well as a strong indication of a common ancestry, is the utilization of the same few biomolecules for all the reactions of life. Despite their incredible diversity of appearance and behavior, virtually all organisms use the same amino acids to make their proteins, the same nucleotides to make their nucleic acids, and the same carbohydrate (glucose) to provide energy.

In addition, *all organisms use the same spontaneous reaction to provide the free energy needed to drive a wide variety of nonspontaneous ones*. This reaction is the hydrolysis of a high-energy molecule called **adenosine triphosphate (ATP)** to adenosine diphosphate (ADP):

$$ATP^{4-} + H_2O \rightleftharpoons ADP^{3-} + HPO_4^{2-} + H^+ \qquad \Delta G^{0'} = -30.5 \text{ kJ}$$

(In biochemical systems, the standard-state concentration of H^+ is 10^{-7} M, not the usual 1 M, and the standard free energy change has the symbol $\Delta G^{0'}$.) In the metabolic breakdown of glucose, for example, the initial step is the addition of a phosphate group to a glucose molecule in a dehydration-condensation reaction:

$$\text{Glucose} + HPO_4^{2-} + H^+ \rightleftharpoons [\text{glucose phosphate}]^- + H_2O \qquad \Delta G^{0'} = 13.8 \text{ kJ}$$

Coupling this nonspontaneous reaction to ATP hydrolysis makes the overall process spontaneous. If we add the two reactions, HPO_4^{2-}, H^+, and H_2O cancel, and we obtain

$$\text{Glucose} + ATP^{4-} \rightleftharpoons [\text{glucose phosphate}]^- + ADP^{3-} \qquad \Delta G^{0'} = -16.7 \text{ kJ}$$

Like the reactions to extract copper that we just discussed, these two reactions cannot affect each other if they are physically separated. Coupling of the reactions is accomplished through an enzyme, a biological catalyst (Section 16.8) that simultaneously binds glucose and ATP such that the phosphate group of ATP to be transferred lies next to the particular —OH group of glucose that will accept it (Figure B20.3). Enzymes play similar catalytic roles in all the reactions driven by ATP hydrolysis.

The ADP formed in these energy-releasing reactions is combined with phosphate to regenerate ATP in energy-absorbing reactions catalyzed by other enzymes. In fact, one major biochemical reason an organism eats and breathes is to make ATP, so that it has the energy to move, grow, reproduce—and study chemistry, of course. Thus, there is a continuous cycling of ATP to ADP and back to ATP again to supply energy to the cells (Figure B20.4).

(continued)

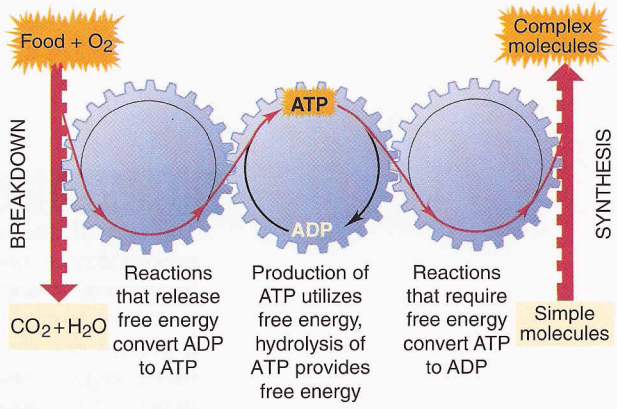

Figure B20.4 The cycling of metabolic free energy through ATP. Processes that release free energy are coupled to the formation of ATP from ADP, whereas those that require free energy are coupled to the hydrolysis of ATP to ADP.

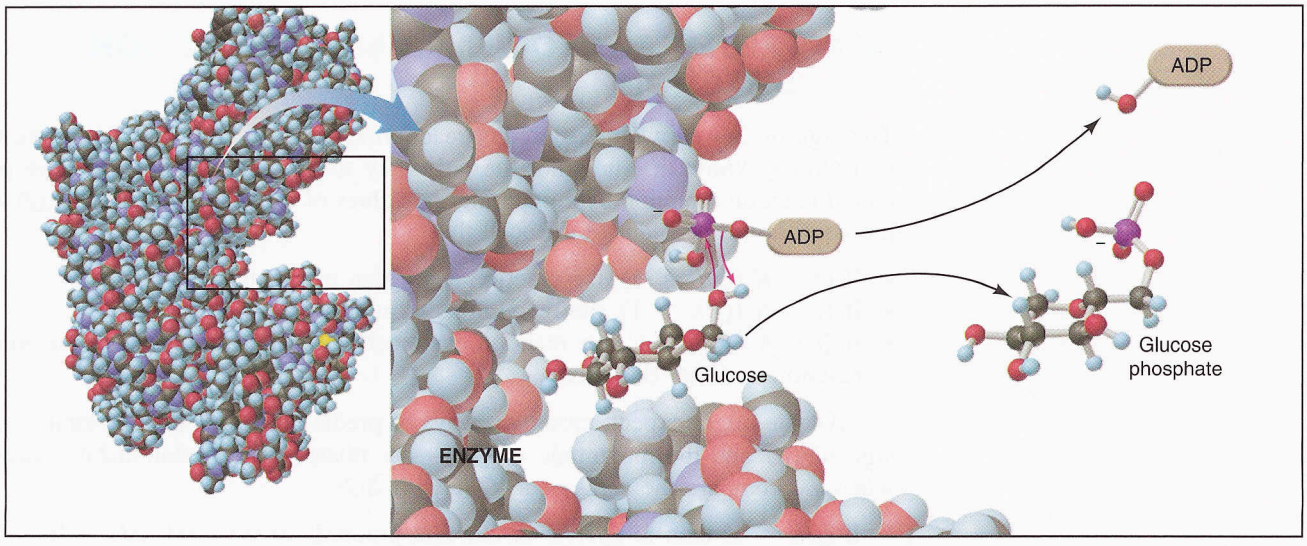

Figure B20.3 The coupling of a nonspontaneous reaction to the hydrolysis of ATP. The glucose molecule must lie next to the ATP molecule (shown as ADP—O—PO_3H) in the enzyme's active site for the correct atoms to form bonds. ADP (shown as ADP—OH) and glucose phosphate are released.

What makes ATP hydrolysis such a good supplier of free energy? By examining the phosphate portions of ATP, ADP, and HPO_4^{2-}, we can see two reasons (Figure B20.5). The first is that, at physiological pH (~7), the triphosphate portion of the ATP molecule has an average of four negative charges grouped closely together. As a result, the ATP molecule has a *high charge repulsion* built into its structure. In ADP, however, this charge repulsion is reduced.

The second reason relates to the greater delocalization of π electrons in the hydrolysis products, which we can see from resonance structures. For example, once ATP is hydrolyzed, the π electrons in HPO_4^{2-} can be more readily delocalized, which stabilizes the ion. Thus, greater charge repulsion and less electron delocalization make ATP higher in energy than the sum of ADP and HPO_4^{2-}. When ATP is hydrolyzed, some of this additional energy is released, to be harnessed by the organism to drive the metabolic reactions that could not otherwise take place.

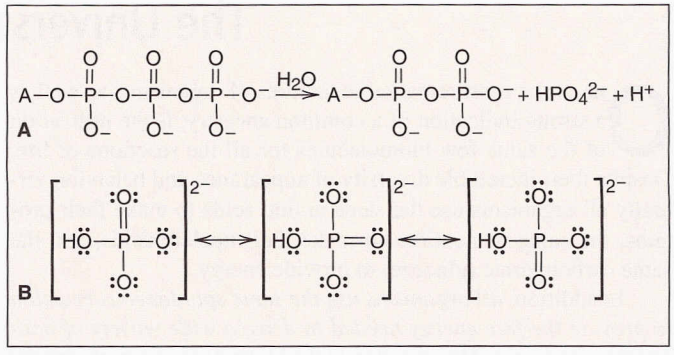

Figure B20.5 Why is ATP a high-energy molecule? The ATP molecule releases a large amount of free energy when it is hydrolyzed because **(A)** the high charge repulsion in the triphosphate portion of ATP is reduced, and **(B)** the free HPO_4^{2-} ion is stabilized by delocalization of its π electrons, as shown by these resonance forms.

SECTION SUMMARY

The sign of the free energy change, $\Delta G = \Delta H - T\Delta S$, is directly related to reaction spontaneity: a negative ΔG corresponds to a positive ΔS_{univ}. We use the standard free energy change (ΔG^0) to evaluate a reaction's spontaneity, and we use the standard free energy of formation (ΔG_f^0) to calculate ΔG_{rxn}^0 at 25°C. The maximum work a system can do is never obtained from a real (irreversible) process because some free energy is always converted to heat. The magnitude of T influences the spontaneity of temperature-dependent reactions (same signs of ΔH and ΔS) by affecting the size of $T\Delta S$. For such reactions, the T at which the reaction becomes spontaneous can be estimated by setting $\Delta G = 0$. A nonspontaneous reaction ($\Delta G > 0$) can be coupled to a more spontaneous one ($\Delta G << 0$) to make it occur. In organisms, the hydrolysis of ATP drives many reactions with a positive ΔG.

20.4 FREE ENERGY, EQUILIBRIUM, AND REACTION DIRECTION

The sign of ΔG allows us to predict reaction spontaneity and thus direction, but you already know that it is not the only way to do so. In Chapter 17, we predicted reaction direction by comparing the values of the reaction quotient (Q) and the equilibrium constant (K). Recall that

- If $Q < K$ ($Q/K < 1$), the reaction as written proceeds to the right.
- If $Q > K$ ($Q/K > 1$), the reaction as written proceeds to the left.
- If $Q = K$ ($Q/K = 1$), the reaction has reached equilibrium, and there is no net reaction in either direction.

As you might expect, these two ways of predicting reaction spontaneity—the sign of ΔG and the magnitude of Q/K—are related. Their relationship emerges when we compare the signs of $\ln Q/K$ with ΔG:

- If $Q/K < 1$, then $\ln Q/K < 0$: reaction proceeds to the right ($\Delta G < 0$).
- If $Q/K > 1$, then $\ln Q/K > 0$: reaction proceeds to the left ($\Delta G > 0$).
- If $Q/K = 1$, then $\ln Q/K = 0$: reaction is at equilibrium ($\Delta G = 0$).

Note that the signs of ΔG and ln Q/K are identical for a given reaction direction. In fact, ΔG and ln Q/K are proportional to each other and made equal through the constant RT:

$$\Delta G = RT \ln \frac{Q}{K} = RT \ln Q - RT \ln K \qquad (20.11)$$

What does this central relationship mean? As you know, Q represents the concentrations (or pressures) of a system's components at any time during the reaction, whereas K represents them when the reaction has reached equilibrium. Therefore, Equation 20.11 says the free energy change for a reaction, ΔG, depends on how different the ratio of concentrations, Q, is from the equilibrium ratio, K.

The last term in Equation 20.11 is very important. By choosing standard-state values for Q, we obtain the standard free energy change (ΔG^0). When all concentrations are 1 M (or all pressures 1 atm), ΔG equals ΔG^0 and Q equals 1:

$$\Delta G^0 = RT \ln 1 - RT \ln K$$

We know that ln 1 = 0, so the RT ln Q term drops out, and we have

$$\Delta G^0 = -RT \ln K \qquad (20.12)$$

This relationship allows us to calculate the standard free energy change of a reaction (ΔG^0) from its equilibrium constant, or vice versa. Because ΔG^0 is related logarithmically to K, even a small change in the value of ΔG^0 has a large effect on the value of K. Table 20.2 shows the K values that correspond to a range of ΔG^0 values. Note that as ΔG^0 becomes more positive, the equilibrium constant becomes smaller, which means the reaction reaches equilibrium with less product and more reactant. Similarly, as ΔG^0 becomes more negative, the reaction reaches equilibrium with more product and less reactant. For example, if $\Delta G^0 = +10$ kJ, $K \approx 0.02$, which means that the magnitudes of the product terms are about $\frac{1}{50}$ those of the reactant terms; whereas, if $\Delta G^0 = -10$ kJ, they are 50 times larger.

Of course, most reactions do not begin with all components in their standard states. By substituting the relationship between ΔG^0 and K (Equation 20.12) into the expression for ΔG (Equation 20.11), we obtain a relationship that applies to any starting concentrations:

$$\Delta G = \Delta G^0 + RT \ln Q \qquad (20.13)$$

Sample Problem 20.7 illustrates how Equations 20.12 and 20.13 are applied.

Table 20.2 The Relationship Between ΔG^0 and K at 298 K

ΔG^0 (kJ)	K	Significance
200	9×10^{-36}	Essentially no forward reaction; reverse reaction goes to completion
100	3×10^{-18}	
50	2×10^{-9}	
10	2×10^{-2}	
1	7×10^{-1}	
0	1	Forward and reverse reactions proceed to same extent
−1	1.5	
−10	5×10^{1}	
−50	6×10^{8}	
−100	3×10^{17}	
−200	1×10^{35}	Forward reaction goes to completion; essentially no reverse reaction

SAMPLE PROBLEM 20.7 Calculating ΔG at Nonstandard Conditions

Problem The oxidation of SO_2, which we considered in Sample Problem 20.6,

$$2SO_2(g) + O_2(g) \longrightarrow 2SO_3(g)$$

is too slow at 298 K to be useful in the manufacture of sulfuric acid. To overcome this low rate, the process is conducted at an elevated temperature.

(a) Calculate K at 298 K and at 973 K. ($\Delta G^0_{298} = -141.6$ kJ/mol for reaction as written; using ΔH^0 and ΔS^0 values at 973 K, $\Delta G^0_{973} = -12.12$ kJ/mol for reaction as written.)

(b) In experiments to determine the effect of temperature on reaction spontaneity, two sealed containers are filled with 0.500 atm of SO_2, 0.0100 atm of O_2, and 0.100 atm of SO_3 and kept at 25°C and at 700.°C. In which direction, if any, will the reaction proceed to reach equilibrium at each temperature?

(c) Calculate ΔG for the system in part (b) at each temperature.

Plan **(a)** We know ΔG^0, T, and R, so we can calculate the K's from Equation 20.12. **(b)** To determine if a net reaction will occur at the given pressures, we calculate Q with the given partial pressures and compare it with each K from part (a). **(c)** Because these are not standard-state pressures, we calculate ΔG at each T from Equation 20.13 with the values of ΔG^0 (given) and Q [found in part (b)].

Solution **(a)** Calculating K at the two temperatures:

$$\Delta G^0 = -RT \ln K \qquad \text{so} \qquad K = e^{-(\Delta G^0/RT)}$$

At 298 K, the exponent is

$$-(\Delta G^0/RT) = -\left(\frac{-141.6 \text{ kJ/mol} \times \dfrac{1000 \text{ J}}{1 \text{ kJ}}}{8.314 \text{ J/mol·K} \times 298 \text{ K}}\right) = 57.2$$

So $$K = e^{-(\Delta G^0/RT)} = e^{57.2} = 7\times10^{24}$$

At 973 K, the exponent is

$$-(\Delta G^0/RT) = -\left(\frac{-12.12 \text{ kJ/mol} \times \dfrac{1000 \text{ J}}{1 \text{ kJ}}}{8.314 \text{ J/mol·K} \times 973 \text{ K}}\right) = 1.50$$

So $$K = e^{-(\Delta G^0/RT)} = e^{1.50} = 4.5$$

(b) Calculating the value of Q:

$$Q = \frac{P^2_{SO_3}}{P^2_{SO_2} \times P_{O_2}} = \frac{0.100^2}{0.500^2 \times 0.0100} = 4.00$$

Because $Q < K$ at both temperatures, the denominator will decrease and the numerator increase—more SO_3 will form—until Q equals K. However, the reaction will go far to the right at 298 K before reaching equilibrium, whereas it will move only slightly to the right at 973 K.

(c) Calculating ΔG, the nonstandard free energy change, at 298 K:

$$\begin{aligned}\Delta G_{298} &= \Delta G^0 + RT \ln Q \\ &= -141.6 \text{ kJ/mol} + \left(8.314 \text{ J/mol·K} \times \frac{1 \text{ kJ}}{1000 \text{ J}} \times 298 \text{ K} \times \ln 4.00\right) \\ &= -138.2 \text{ kJ/mol}\end{aligned}$$

Calculating ΔG at 973 K:

$$\begin{aligned}\Delta G_{973} &= \Delta G^0 + RT \ln Q \\ &= -12.12 \text{ kJ/mol} + \left(8.314 \text{ J/mol·K} \times \frac{1 \text{ kJ}}{1000 \text{ J}} \times 973 \text{ K} \times \ln 4.00\right) \\ &= -0.9 \text{ kJ/mol}\end{aligned}$$

Check Note that in parts (a) and (c) we made the energy units in free energy changes (kJ) consistent with those in R (J). Based on the rules for significant figures in addition and subtraction, we retain one digit to the right of the decimal place in part (c).

Comment For these starting gas pressures at 973 K, the process is barely spontaneous ($\Delta G = -0.9$ kJ/mol), so why use a higher temperature? Like the synthesis of NH_3 (Chem-

ical Connections, p. 755), this process is carried out at a higher temperature *with a catalyst* to attain a higher *rate*, even though the *yield* is greater at a lower temperature. We discuss the details of the industrial production of sulfuric acid in Chapter 22.

FOLLOW-UP PROBLEM 20.7 At 298 K, hypobromous acid (HBrO) dissociates in water with a K_a of 2.3×10^{-9}.
(a) Calculate ΔG^0 for the dissociation of HBrO.
(b) Calculate ΔG if $[H_3O^+] = 6.0\times10^{-4}\ M$, $[BrO^-] = 0.10\ M$, and $[HBrO] = 0.20\ M$.

Another Look at the Meaning of Spontaneity At this point, let's consider some terminology related to, but distinct from, the terms *spontaneous* and *nonspontaneous*. Consider the general reaction A $\rightleftharpoons$ B, for which $K = [B]/[A] > 1$; therefore, the reaction proceeds largely from left to right (Figure 20.12A). From pure A to the equilibrium point, $Q < K$ and the curved *green* arrow indicates the reaction is spontaneous ($\Delta G < 0$). From there on, the curved *red* arrow shows the reaction is nonspontaneous ($\Delta G > 0$). From pure B to the equilibrium point, $Q > K$ and the reaction is also spontaneous ($\Delta G < 0$), but not thereafter. In either case, *the free energy decreases as the reaction proceeds, until it reaches a minimum at the equilibrium mixture:* $Q = K$ *and* $\Delta G = 0$. For the overall reaction A $\rightleftharpoons$ B (starting with all components in their standard states), G^0_B is smaller than G^0_A, so ΔG^0 is negative, which corresponds to $K > 1$. We call this a *product-favored* reaction because the final state of the system contains mostly product.

Now consider the opposite situation, a general reaction C $\rightleftharpoons$ D, for which $K = [D]/[C] < 1$: the reaction proceeds only slightly from left to right (Figure 20.12B). Here, too, whether we start with pure C or pure D, the reaction is spontaneous ($\Delta G < 0$) until the equilibrium point. But in this case, the equilibrium mixture contains mostly C (the reactant), so we say the reaction is *reactant favored*. In this case, G^0_D is *larger* than G^0_C, so ΔG^0 is *positive*, which corresponds to $K < 1$. The point is that *spontaneous* refers to that portion of a reaction in which the free energy is decreasing, that is, from some starting mixture to the equilibrium mixture, whereas *product-favored* refers to a reaction that goes predominantly, but not necessarily completely, to product (see Table 20.2).

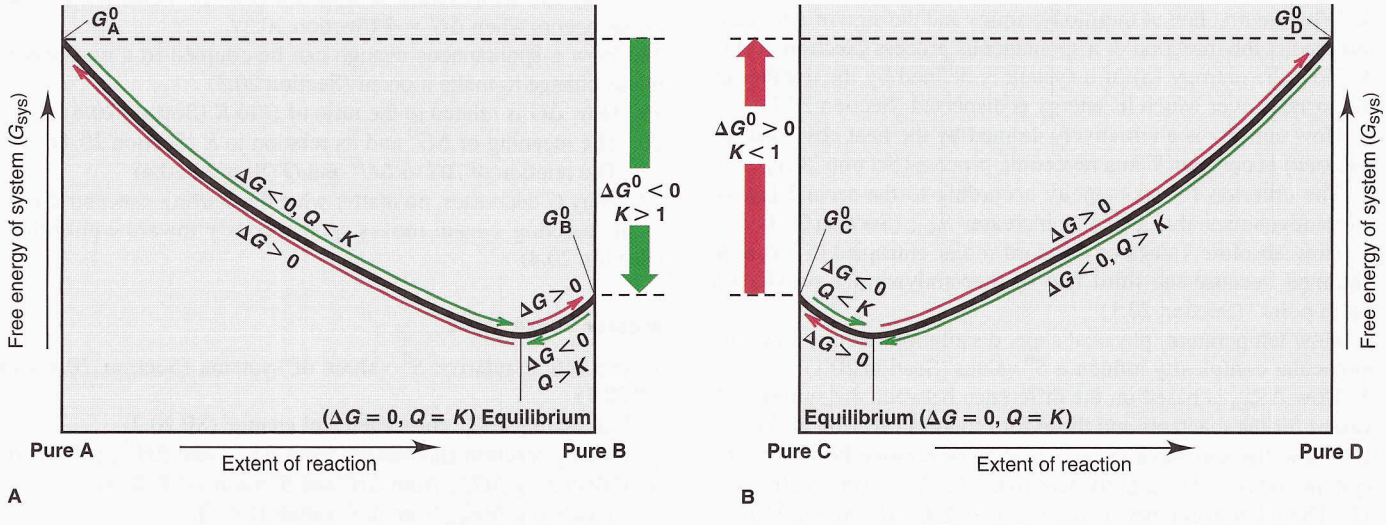

Figure 20.12 The relation between free energy and the extent of reaction. The free energy of the system is plotted against the extent of reaction. Each reaction proceeds spontaneously ($Q \neq K$ and $\Delta G < 0$; *curved green arrows*) from either pure reactants (A or C) or pure products (B or D) *to* the equilibrium mixture, at which point $\Delta G = 0$. The reaction *from* the equilibrium mixture to either pure reactants or products is nonspontaneous ($\Delta G > 0$; *curved red arrows*). **A,** For the product-favored reaction A $\rightleftharpoons$ B, $G^0_A > G^0_B$, so $\Delta G^0 < 0$ and $K > 1$. **B,** For the reactant-favored reaction C $\rightleftharpoons$ D, $G^0_D > G^0_C$, so $\Delta G^0 > 0$ and $K < 1$.

SECTION SUMMARY

Two ways of predicting reaction direction are from the value of ΔG and from the relation of Q to K. These variables represent different aspects of the same phenomenon and are related to each other by $\Delta G = RT \ln Q/K$. When $Q = K$, the system can release no more free energy. Beginning with Q at the standard state, the free energy change is ΔG^0, and it is related to the equilibrium constant by $\Delta G^0 = -RT \ln K$. For nonstandard conditions, ΔG has two components: ΔG^0 and $RT \ln Q$. Any nonequilibrium mixture of reactants and products moves spontaneously ($\Delta G < 0$) toward the equilibrium mixture. A product-favored reaction has $K > 1$ and, thus, $\Delta G^0 < 0$.

Chapter Perspective

As processes move toward equilibrium, some of the energy released becomes degraded to unusable heat, and the entropy of the universe increases. This unalterable necessity built into all natural processes has led to speculation about the "End of Everything," when all possible processes have stopped occurring, no free energy remains in any system, and nothing but waste heat is dispersed evenly throughout the universe—the final equilibrium! Even if this grim future is in store, however, it is many billions of years away, so you have plenty of time to appreciate more hopeful applications of thermodynamics. In Chapter 21, you'll see how spontaneous reactions can generate electricity and how electricity supplies free energy to drive nonspontaneous ones.

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. How the tendency of a process to occur by itself is distinct from how long it takes to occur (Introduction)
2. The distinction between a spontaneous and a nonspontaneous change (Section 20.1)
3. Why the first law of thermodynamics and the sign of ΔH^0 cannot predict the direction of a spontaneous process (Section 20.1)
4. How the entropy (S) of a system is defined by the number of microstates over which its energy is dispersed (Section 20.1)
5. How entropy is alternatively defined by the heat absorbed (or released) at constant T in a reversible process (Section 20.1)
6. The criterion for spontaneity according to the second law of thermodynamics: that a change increases S_{univ} (Section 20.1)
7. How absolute values of standard molar entropies (S^0) can be obtained because the third law of thermodynamics provides a "zero point" (Section 20.1)
8. How temperature, physical state, dissolution, atomic size, and molecular complexity influence S^0 values (Section 20.1)
9. How ΔS^0_{rxn} is based on the difference between the summed S^0 values for the reactants and those for products (Section 20.2)
10. How the surroundings add heat to or remove heat from the system and how ΔS_{surr} influences overall ΔS^0_{rxn} (Section 20.2)
11. The relationship between ΔS_{surr} and ΔH_{sys} (Section 20.2)
12. How reactions proceed spontaneously toward equilibrium ($\Delta S_{univ} > 0$) but proceed no further at equilibrium ($\Delta S_{univ} = 0$) (Section 20.2)
13. How the free energy change (ΔG) combines the system's entropy and enthalpy changes (Section 20.3)
14. How the expression for the free energy change is derived from the second law (Section 20.3)
15. The relationship between ΔG and the maximum work a system can perform and why this quantity of work is never performed in a real process (Section 20.3)
16. How temperature determines spontaneity for reactions in which ΔS and ΔH have the same sign (Section 20.3)
17. Why the temperature at which a reaction becomes spontaneous occurs when $\Delta G = 0$ (Section 20.3)
18. How a spontaneous change can be coupled to a nonspontaneous change to make it occur (Section 20.3)
19. How ΔG is related to the ratio of Q to K (Section 20.4)
20. The meaning of ΔG^0 and its relation to K (Section 20.4)
21. The relation of ΔG to ΔG^0 and Q (Section 20.4)
22. Why G decreases, no matter what the starting concentrations, as the reacting system moves spontaneously toward equilibrium (Section 20.4)

Master These Skills

1. Predicting relative S^0 values of systems (Section 20.1 and SP 20.1)
2. Calculating ΔS^0_{rxn} for a chemical change (SP 20.2)
3. Finding reaction spontaneity from ΔS_{surr} and ΔH^0_{sys} (SP 20.3)
4. Calculating ΔG^0_{rxn} from ΔH^0_f and S^0 values (SP 20.4)
5. Calculating ΔG^0_{rxn} from ΔG^0_f values (SP 20.5)
6. Calculating the effect of temperature on ΔG (SP 20.6)
7. Calculating the temperature at which a reaction becomes spontaneous (Section 20.3)
8. Calculating K from ΔG^0 (Section 20.4 and SP 20.7)
9. Using ΔG^0 and Q to calculate ΔG at any conditions (SP 20.7)

Key Terms

Section 20.1
spontaneous change (864)
entropy (S) (867)
second law of thermodynamics (870)
third law of thermodynamics (871)
standard molar entropy (S^0) (871)

Section 20.2
standard entropy of reaction (ΔS^0_{rxn}) (875)

Section 20.3
free energy (G) (881)
standard free energy change (ΔG^0) (882)
standard free energy of formation (ΔG^0_f) (883)
coupling of reactions (888)
adenosine triphosphate (ATP) (889)

Key Equations and Relationships

20.1 Quantifying entropy in terms of the number of microstates (W) over which the energy of a system can be distributed (867):

$$S = k \ln W$$

20.2 Quantifying the entropy change in terms of heat absorbed (or released) in a reversible process (870)

$$\Delta S_{sys} = \frac{q_{rev}}{T}$$

20.3 Stating the second law of thermodynamics, for a spontaneous process (870):

$$\Delta S_{univ} = \Delta S_{sys} + \Delta S_{surr} > 0$$

20.4 Calculating the standard entropy of reaction from the standard molar entropies of reactants and products (876):

$$\Delta S^0_{rxn} = \Sigma m S^0_{products} - \Sigma n S^0_{reactants}$$

20.5 Relating the entropy change in the surroundings to the enthalpy change of the system and the temperature (877):

$$\Delta S_{surr} = -\frac{\Delta H_{sys}}{T}$$

20.6 Expressing the free energy change of the system in terms of its component enthalpy and entropy changes (Gibbs equation) (882):

$$\Delta G_{sys} = \Delta H_{sys} - T\Delta S_{sys}$$

20.7 Calculating the standard free energy change from standard enthalpy and entropy changes (882):

$$\Delta G^0_{sys} = \Delta H^0_{sys} - T\Delta S^0_{sys}$$

20.8 Calculating the standard free energy change from the standard free energies of formation (883):

$$\Delta G^0_{rxn} = \Sigma m \Delta G^0_{f(products)} - \Sigma n \Delta G^0_{f(reactants)}$$

20.9 Relating the free energy change to the maximum work a process can perform (884):

$$\Delta G = -w_{max}$$

20.10 Finding the temperature at which a reaction becomes spontaneous (887):

$$T = \frac{\Delta H}{\Delta S}$$

20.11 Expressing the free energy change in terms of Q and K (891):

$$\Delta G = RT \ln \frac{Q}{K} = RT \ln Q - RT \ln K$$

20.12 Expressing the free energy change when Q is evaluated at the standard state (891):

$$\Delta G^0 = -RT \ln K$$

20.13 Expressing the free energy change for a nonstandard initial state (891):

$$\Delta G = \Delta G^0 + RT \ln Q$$

Highlighted Figures and Tables

These figures (F) and tables (T) provide a review of key ideas.

F20.5 Entropy and phase changes (872)
F20.10 Components of ΔS_{univ} for spontaneous reactions (880)
T20.1 Reaction spontaneity and the signs of ΔH, ΔS, and ΔG (887)
T20.2 The relationship of ΔG^0 and K (891)
F20.12 Free energy and extent of reaction (893)

Brief Solutions to Follow-up Problems

20.1 (a) $PCl_5(g)$: higher molar mass and more complex molecule; (b) $BaCl_2(s)$: higher molar mass; (c) $Br_2(g)$: gases have more freedom of motion and dispersal of energy than liquids.

20.2 (a) $2NaOH(s) + CO_2(g) \longrightarrow Na_2CO_3(s) + H_2O(l)$
$\Delta n_{gas} = -1$, so $\Delta S^0_{rxn} < 0$
$\Delta S^0_{rxn} = [(1 \text{ mol } H_2O)(69.9 \text{ J/mol·K}) + (1 \text{ mol } Na_2CO_3)(139 \text{ J/mol·K})] - [(1 \text{ mol } CO_2)(213.7 \text{ J/mol·K}) + (2 \text{ mol NaOH})(64.5 \text{ J/mol·K})]$
$= -134 \text{ J/K}$

(b) $2Fe(s) + 3H_2O(g) \longrightarrow Fe_2O_3(s) + 3H_2(g)$
$\Delta n_{gas} = 0$, so cannot predict sign of ΔS^0_{rxn}
$\Delta S^0_{rxn} = [(1 \text{ mol } Fe_2O_3)(87.4 \text{ J/mol·K}) + (3 \text{ mol } H_2)(130.6 \text{ J/mol·K})] - [(2 \text{ mol Fe})(27.3 \text{ J/mol·K}) + (3 \text{ mol } H_2O)(188.7 \text{ J/mol·K})]$
$= -141.5 \text{ J/K}$

Brief Solutions to Follow-up Problems *(continued)*

20.3 $2FeO(s) + \frac{1}{2}O_2(g) \longrightarrow Fe_2O_3(s)$

$\Delta S^0_{sys} = (1\text{ mol } Fe_2O_3)(87.4\text{ J/mol·K}) - [(2\text{ mol FeO})(60.75\text{ J/mol·K}) + (\frac{1}{2}\text{ mol } O_2)(205.0\text{ J/mol·K})]$
$= -136.6\text{ J/K}$

$\Delta H^0_{sys} = (1\text{ mol } Fe_2O_3)(-825.5\text{ kJ/mol}) - [(2\text{ mol FeO})(-272.0\text{ kJ/mol}) + (\frac{1}{2}\text{ mol } O_2)(0\text{ kJ/mol})]$
$= -281.5\text{ kJ}$

$\Delta S_{surr} = -\dfrac{\Delta H^0_{sys}}{T} = -\dfrac{(-281.5\text{ kJ} \times 1000\text{ J/kJ})}{298\text{ K}} = +945\text{ J/K}$

$\Delta S_{univ} = \Delta S^0_{sys} + \Delta S_{surr} = -136.6\text{ J/K} + 945\text{ J/K}$
$= 808\text{ J/K}$; reaction is spontaneous at 298 K.

20.4 Using ΔH^0_f and S^0 values from Appendix B,

$\Delta H^0_{rxn} = -114.2\text{ kJ}$ and $\Delta S^0_{rxn} = -146.5\text{ J/K}$

$\Delta G^0_{rxn} = \Delta H^0_{rxn} - T\Delta S^0_{rxn} = -114.2\text{ kJ} - [(298\text{ K})(-146.5\text{ J/K})(1\text{ kJ}/1000\text{ J})]$
$= -70.5\text{ kJ}$

20.5 (a) $\Delta G^0_{rxn} = (2\text{ mol } NO_2)(51\text{ kJ/mol}) - [(2\text{ mol NO})(86.60\text{ kJ/mol}) + (1\text{ mol } O_2)(0\text{ kJ/mol})]$
$= -71\text{ kJ}$

(b) $\Delta G^0_{rxn} = (2\text{ mol CO})(-137.2\text{ kJ/mol}) - [(2\text{ mol C})(0\text{ kJ/mol}) + (1\text{ mol } O_2)(0\text{ kJ/mol})]$
$= -274.4\text{ kJ}$

20.6 ΔG becomes negative at lower T, so $\Delta H < 0$, $\Delta S < 0$, and $-T\Delta S > 0$. At lower T, the negative ΔH value becomes larger than the positive $-T\Delta S$ value.

20.7 (a) $\Delta G^0 = -RT \ln K$

$= -8.314\text{ J/mol·K} \times \dfrac{1\text{ kJ}}{1000\text{ J}} \times 298\text{ K} \times \ln(2.3\times10^{-9})$
$= 49\text{ kJ/mol}$

(b) $Q = \dfrac{[H_3O^+][BrO^-]}{[HBrO]} = \dfrac{(6.0\times10^{-4})(0.10)}{0.20} = 3.0\times10^{-4}$

$\Delta G = \Delta G^0 + RT \ln Q$
$= 49\text{ kJ/mol} + \left[8.314\text{ J/mol·K} \times \dfrac{1\text{ kJ}}{1000\text{ J}} \times 298\text{ K} \times \ln(3.0\times10^{-4})\right]$
$= 29\text{ kJ/mol}$

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

Note: Unless stated otherwise, problems refer to systems at 298 K (25°C). Solving these problems may require values from Appendix B.

The Second Law of Thermodynamics: Predicting Spontaneous Change

(Sample Problem 20.1)

Concept Review Questions

20.1 Distinguish between the terms *spontaneous* and *instantaneous*. Give an example of a process that is spontaneous but very slow, and one that is very fast but not spontaneous.

20.2 Distinguish between the terms *spontaneous* and *nonspontaneous*. Can a nonspontaneous process occur? Explain.

20.3 State the first law of thermodynamics in terms of (a) the energy of the universe; (b) the creation or destruction of energy; (c) the energy change of system and surroundings. Does the first law reveal the direction of spontaneous change? Explain.

20.4 State qualitatively the relationship between entropy and freedom of particle motion. Use this idea to explain why you will probably never (a) be suffocated because all the air near you has moved to the other side of the room; (b) see half the water in your cup of tea freeze while the other half boils.

20.5 Why is ΔS_{vap} of a substance always larger than ΔS_{fus}?

20.6 How does the entropy of the surroundings change during an exothermic reaction? An endothermic reaction? Other than the examples cited in text, describe a spontaneous endothermic process.

20.7 (a) What is the entropy of a perfect crystal at 0 K?
(b) Does entropy increase or decrease as the temperature rises?
(c) Why is $\Delta H^0_f = 0$ but $S^0 > 0$ for an element?
(d) Why does Appendix B list ΔH^0_f values but not ΔS^0_f values?

Skill-Building Exercises *(grouped in similar pairs)*

20.8 Which of the following processes are spontaneous?
(a) Water evaporating from a puddle in summer
(b) A lion chasing an antelope
(c) An unstable isotope undergoing radioactive disintegration

20.9 Which of the following processes are spontaneous?
(a) Earth moving around the Sun
(b) A boulder rolling up a hill
(c) Sodium metal and chlorine gas reacting to form solid sodium chloride

20.10 Which of the following processes are spontaneous?
(a) Methane burning in air
(b) A teaspoonful of sugar dissolving in a cup of hot coffee
(c) A soft-boiled egg becoming raw

20.11 Which of the following processes are spontaneous?
(a) A satellite falling to Earth's surface
(b) Water decomposing to H_2 and O_2 at 298 K and 1 atm
(c) Average car prices increasing

20.12 Predict the sign of ΔS_{sys} for each process:
(a) A piece of wax melting
(b) Silver chloride precipitating from solution
(c) Dew forming

20.13 Predict the sign of ΔS_{sys} for each process:
(a) Gasoline vapors mixing with air in a car engine
(b) Hot air expanding
(c) Breath condensing in cold air

20.14 Predict the sign of ΔS_{sys} for each process:
(a) Alcohol evaporating
(b) A solid explosive converting to a gas
(c) Perfume vapors diffusing through a room

20.15 Predict the sign of ΔS_{sys} for each process:
(a) A pond freezing in winter
(b) Atmospheric CO_2 dissolving in the ocean
(c) An apple tree bearing fruit

20.16 Without using Appendix B, predict the sign of ΔS^0 for
(a) $2K(s) + F_2(g) \longrightarrow 2KF(s)$
(b) $NH_3(g) + HBr(g) \longrightarrow NH_4Br(s)$
(c) $NaClO_3(s) \longrightarrow Na^+(aq) + ClO_3^-(aq)$

20.17 Without using Appendix B, predict the sign of ΔS^0 for
(a) $H_2S(g) + \frac{1}{2}O_2(g) \longrightarrow \frac{1}{8}S_8(s) + H_2O(g)$
(b) $HCl(aq) + NaOH(aq) \longrightarrow NaCl(aq) + H_2O(l)$
(c) $2NO_2(g) \longrightarrow N_2O_4(g)$

20.18 Without using Appendix B, predict the sign of ΔS^0 for
(a) $CaCO_3(s) + 2HCl(aq) \longrightarrow CaCl_2(aq) + H_2O(l) + CO_2(g)$
(b) $2NO(g) + O_2(g) \longrightarrow 2NO_2(g)$
(c) $2KClO_3(s) \longrightarrow 2KCl(s) + 3O_2(g)$

20.19 Without using Appendix B, predict the sign of ΔS^0 for
(a) $Ag^+(aq) + Cl^-(aq) \longrightarrow AgCl(s)$
(b) $KBr(s) \longrightarrow KBr(aq)$
(c) $CH_3CH{=}CH_2(g) \longrightarrow$

20.20 Predict the sign of ΔS for each process:
(a) $C_2H_5OH(g)$ (350 K and 500 torr) $\longrightarrow$ $C_2H_5OH(g)$ (350 K and 250 torr)
(b) $N_2(g)$ (298 K and 1 atm) $\longrightarrow$ $N_2(aq)$ (298 K and 1 atm)
(c) $O_2(aq)$ (303 K and 1 atm) $\longrightarrow$ $O_2(g)$ (303 K and 1 atm)

20.21 Predict the sign of ΔS for each process:
(a) $O_2(g)$ (1.0 L at 1 atm) $\longrightarrow$ $O_2(g)$ (0.10 L at 10 atm)
(b) $Cu(s)$ (350°C and 2.5 atm) $\longrightarrow$ $Cu(s)$ (450°C and 2.5 atm)
(c) $Cl_2(g)$ (100°C and 1 atm) $\longrightarrow$ $Cl_2(g)$ (10°C and 1 atm)

20.22 Predict which substance has greater molar entropy. Explain.
(a) Butane $CH_3CH_2CH_2CH_3(g)$ or 2-butene $CH_3CH{=}CHCH_3(g)$
(b) $Ne(g)$ or $Xe(g)$ (c) $CH_4(g)$ or $CCl_4(l)$

20.23 Predict which substance has greater molar entropy. Explain.
(a) $NO_2(g)$ or $N_2O_4(g)$ (b) $CH_3OCH_3(l)$ or $CH_3CH_2OH(l)$
(c) $HCl(g)$ or $HBr(g)$

20.24 Predict which substance has greater molar entropy. Explain.
(a) $CH_3OH(l)$ or $C_2H_5OH(l)$ (b) $KClO_3(s)$ or $KClO_3(aq)$
(c) $Na(s)$ or $K(s)$

20.25 Predict which substance has greater molar entropy. Explain.
(a) $P_4(g)$ or $P_2(g)$ (b) $HNO_3(aq)$ or $HNO_3(l)$
(c) $CuSO_4(s)$ or $CuSO_4 \cdot 5H_2O(s)$

20.26 Without consulting Appendix B, arrange each group in order of *increasing* standard molar entropy (S^0). Explain.
(a) Graphite, diamond, charcoal
(b) Ice, water vapor, liquid water (c) O_2, O_3, O atoms

20.27 Without consulting Appendix B, arrange each group in order of *increasing* standard molar entropy (S^0). Explain.
(a) Glucose ($C_6H_{12}O_6$), sucrose ($C_{12}H_{22}O_{11}$), ribose ($C_5H_{10}O_5$)
(b) $CaCO_3$, $Ca + C + \frac{3}{2}O_2$, $CaO + CO_2$
(c) $SF_6(g)$, $SF_4(g)$, $S_2F_{10}(g)$

20.28 Without consulting Appendix B, arrange each group in order of *decreasing* standard molar entropy (S^0). Explain.
(a) $ClO_4^-(aq)$, $ClO_2^-(aq)$, $ClO_3^-(aq)$
(b) $NO_2(g)$, $NO(g)$, $N_2(g)$ (c) $Fe_2O_3(s)$, $Al_2O_3(s)$, $Fe_3O_4(s)$

20.29 Without consulting Appendix B, arrange each group in order of *decreasing* standard molar entropy (S^0). Explain.
(a) Mg metal, Ca metal, Ba metal
(b) Hexane (C_6H_{14}), benzene (C_6H_6), cyclohexane (C_6H_{12})
(c) $PF_2Cl_3(g)$, $PF_5(g)$, $PF_3(g)$

Calculating the Change in Entropy of a Reaction

(Sample Problems 20.2 and 20.3)

Concept Review Questions

20.30 What property of entropy allows Hess's law to be used in the calculation of entropy changes?

20.31 Describe the equilibrium condition in terms of the entropy changes of a system and its surroundings. What does this description mean about the entropy change of the universe?

20.32 For the reaction $H_2O(g) + Cl_2O(g) \longrightarrow 2HClO(g)$, you know ΔS^0_{rxn} and S^0 of $HClO(g)$ and of $H_2O(g)$. Write an expression to determine S^0 of $Cl_2O(g)$.

Skill-Building Exercises *(grouped in similar pairs)*

20.33 For each reaction, predict the sign and find the value of ΔS^0:
(a) $3NO(g) \longrightarrow N_2O(g) + NO_2(g)$
(b) $3H_2(g) + Fe_2O_3(s) \longrightarrow 2Fe(s) + 3H_2O(g)$
(c) $P_4(s) + 5O_2(g) \longrightarrow P_4O_{10}(s)$

20.34 For each reaction, predict the sign and find the value of ΔS^0:
(a) $3NO_2(g) + H_2O(l) \longrightarrow 2HNO_3(l) + NO(g)$
(b) $N_2(g) + 3F_2(g) \longrightarrow 2NF_3(g)$
(c) $C_6H_{12}O_6(s) + 6O_2(g) \longrightarrow 6CO_2(g) + 6H_2O(g)$

20.35 Find ΔS^0 for the combustion of ethane (C_2H_6) to carbon dioxide and gaseous water. Is the sign of ΔS^0 as expected?

20.36 Find ΔS^0 for the combustion of methane to carbon dioxide and liquid water. Is the sign of ΔS^0 as expected?

20.37 Find ΔS^0 for the reaction of nitric oxide with hydrogen to form ammonia and water vapor. Is the sign of ΔS^0 as expected?

20.38 Find ΔS^0 for the combustion of ammonia to nitrogen dioxide and water vapor. Is the sign of ΔS^0 as expected?

20.39 Find ΔS^0 for the formation of $Cu_2O(s)$ from its elements.

20.40 Find ΔS^0 for the formation of $HI(g)$ from its elements.

20.41 Find ΔS^0 for the formation of $CH_3OH(l)$ from its elements.

20.42 Find ΔS^0 for the formation of $PCl_5(g)$ from its elements.

Problems in Context

20.43 Sulfur dioxide is released in the combustion of coal. Scrubbers use lime slurries of calcium hydroxide to remove the SO_2 from flue gases. Write a balanced equation for this reaction and calculate ΔS^0 at 298 K [S^0 of $CaSO_3(s)$ = 101.4 J/mol·K].

20.44 Oxyacetylene welding is used to repair metal structures, including bridges, buildings, and even the Statue of Liberty. Calculate ΔS^0 for the combustion of 1 mol of acetylene (C_2H_2).

Entropy, Free Energy, and Work

(Sample Problems 20.4 to 20.6)

Concept Review Questions

20.45 What is the advantage of calculating free energy changes rather than entropy changes to determine reaction spontaneity?

20.46 Given that $\Delta G_{sys} = -T\Delta S_{univ}$, explain how the sign of ΔG_{sys} correlates with reaction spontaneity.

20.47 Is an endothermic reaction more likely to be spontaneous at higher temperatures or lower temperatures? Explain.

20.48 With its components in their standard states, a certain reaction is spontaneous only at high T. What do you know about the signs of ΔH^0 and ΔS^0? Describe a process for which this is true.

20.49 How can ΔS^0 be relatively independent of T if S^0 of each reactant and product increases with T?

Skill-Building Exercises *(grouped in similar pairs)*

20.50 Calculate ΔG^0 for each reaction using ΔG_f^0 values:

(a) $2Mg(s) + O_2(g) \longrightarrow 2MgO(s)$

(b) $2CH_3OH(g) + 3O_2(g) \longrightarrow 2CO_2(g) + 4H_2O(g)$

(c) $BaO(s) + CO_2(g) \longrightarrow BaCO_3(s)$

20.51 Calculate ΔG^0 for each reaction using ΔG_f^0 values:

(a) $H_2(g) + I_2(s) \longrightarrow 2HI(g)$

(b) $MnO_2(s) + 2CO(g) \longrightarrow Mn(s) + 2CO_2(g)$

(c) $NH_4Cl(s) \longrightarrow NH_3(g) + HCl(g)$

20.52 Find ΔG^0 for the reactions in Problem 20.50 using ΔH_f^0 and S^0 values.

20.53 Find ΔG^0 for the reactions in Problem 20.51 using ΔH_f^0 and S^0 values.

20.54 Consider the oxidation of carbon monoxide:

$$CO(g) + \tfrac{1}{2}O_2(g) \longrightarrow CO_2(g)$$

(a) Predict the signs of ΔS^0 and ΔH^0. Explain.

(b) Calculate ΔG^0 by two different methods.

20.55 Consider the combustion of butane gas:

$$C_4H_{10}(g) + \tfrac{13}{2}O_2(g) \longrightarrow 4CO_2(g) + 5H_2O(g)$$

(a) Predict the signs of ΔS^0 and ΔH^0. Explain.

(b) Calculate ΔG^0 by two different methods.

20.56 For the gaseous reaction of xenon and fluorine to form xenon hexafluoride:

(a) Calculate ΔS^0 at 298 K ($\Delta H^0 = -402$ kJ/mol and $\Delta G^0 = -280.$ kJ/mol).

(b) Assuming that ΔS^0 and ΔH^0 change little with temperature, calculate ΔG^0 at 500. K.

20.57 For the gaseous reaction of carbon monoxide and chlorine to form phosgene ($COCl_2$):

(a) Calculate ΔS^0 at 298 K ($\Delta H^0 = -220.$ kJ/mol and $\Delta G^0 = -206$ kJ/mol).

(b) Assuming that ΔS^0 and ΔH^0 change little with temperature, calculate ΔG^0 at 450. K.

20.58 One reaction used to produce small quantities of pure H_2 is

$$CH_3OH(g) \rightleftharpoons CO(g) + 2H_2(g)$$

(a) Determine ΔH^0 and ΔS^0 for the reaction at 298 K.

(b) Assuming that these values are relatively independent of temperature, calculate ΔG^0 at 38°C, 138°C, and 238°C.

(c) What is the significance of the different values of ΔG^0?

20.59 A reaction that occurs in the internal combustion engine is

$$N_2(g) + O_2(g) \rightleftharpoons 2NO(g)$$

(a) Determine ΔH^0 and ΔS^0 for the reaction at 298 K.

(b) Assuming that these values are relatively independent of temperature, calculate ΔG^0 at 100.°C, 2560.°C, and 3540.°C.

(c) What is the significance of the different values of ΔG^0?

20.60 Use ΔH^0 and ΔS^0 values for the following process at 1 atm to find the normal boiling point of Br_2:

$$Br_2(l) \rightleftharpoons Br_2(g)$$

20.61 Use ΔH^0 and ΔS^0 values to find the temperature at which these sulfur allotropes reach equilibrium at 1 atm:

$$S(\text{rhombic}) \rightleftharpoons S(\text{monoclinic})$$

Problems in Context

20.62 As a fuel, $H_2(g)$ produces only nonpolluting $H_2O(g)$ when it burns. Moreover, it combines with $O_2(g)$ in a fuel cell (Chapter 21) to provide electrical energy.

(a) Calculate ΔH^0, ΔS^0, and ΔG^0 per mol of H_2 at 298 K.

(b) Is the spontaneity of this reaction dependent on T? Explain.

(c) At what temperature does the reaction become spontaneous?

20.63 The U.S. requires automobile fuels to contain a renewable component. The fermentation of glucose from corn produces ethanol, which is added to gasoline to fulfill this requirement:

$$C_6H_{12}O_6(s) \longrightarrow 2C_2H_5OH(l) + 2CO_2(g)$$

Calculate ΔH^0, ΔS^0, and ΔG^0 for the reaction at 25°C. Is the spontaneity of this reaction dependent on T? Explain.

Free Energy, Equilibrium, and Reaction Direction

(Sample Problem 20.7)

Concept Review Questions

20.64 (a) If $K << 1$ for a reaction, what do you know about the sign and magnitude of ΔG^0?

(b) If $\Delta G^0 << 0$ for a reaction, what do you know about the magnitude of K? Of Q?

20.65 How is the free energy change of a process related to the work that can be obtained from the process? Is this quantity of work obtainable in practice? Explain.

20.66 What happens to a portion of the useful energy as it does work?

20.67 What is the difference between ΔG^0 and ΔG? Under what circumstances does $\Delta G = \Delta G^0$?

Skill-Building Exercises *(grouped in similar pairs)*

20.68 Calculate K at 298 K for each reaction:

(a) $NO(g) + \tfrac{1}{2}O_2(g) \rightleftharpoons NO_2(g)$

(b) $2HCl(g) \rightleftharpoons H_2(g) + Cl_2(g)$

(c) $2C(\text{graphite}) + O_2(g) \rightleftharpoons 2CO(g)$

20.69 Calculate K at 298 K for each reaction:

(a) $MgCO_3(s) \rightleftharpoons Mg^{2+}(aq) + CO_3^{2-}(aq)$

(b) $2HCl(g) + Br_2(l) \rightleftharpoons 2HBr(g) + Cl_2(g)$

(c) $H_2(g) + O_2(g) \rightleftharpoons H_2O_2(l)$

20.70 Calculate K at 298 K for each reaction:

(a) $2H_2S(g) + 3O_2(g) \rightleftharpoons 2H_2O(g) + 2SO_2(g)$

(b) $H_2SO_4(l) \rightleftharpoons H_2O(l) + SO_3(g)$

(c) $HCN(aq) + NaOH(aq) \rightleftharpoons NaCN(aq) + H_2O(l)$

20.71 Calculate K at 298 K for each reaction:

(a) $SrSO_4(s) \rightleftharpoons Sr^{2+}(aq) + SO_4^{2-}(aq)$

(b) $2NO(g) + Cl_2(g) \rightleftharpoons 2NOCl(g)$

(c) $Cu_2S(s) + O_2(g) \rightleftharpoons 2Cu(s) + SO_2(g)$

20.72 Use Appendix B to determine the K_{sp} of Ag_2S.

20.73 Use Appendix B to determine the K_{sp} of CaF_2.

20.74 For the reaction $I_2(g) + Cl_2(g) \rightleftharpoons 2ICl(g)$, calculate K_p at 25°C [ΔG_f^0 of $ICl(g) = -6.075$ kJ/mol].

20.75 For the reaction $CaCO_3(s) \rightleftharpoons CaO(s) + CO_2(g)$, calculate the equilibrium P_{CO_2} at 25°C.

20.76 The K_{sp} of $PbCl_2$ is 1.7×10^{-5} at 25°C. What is ΔG^0? Is it possible to prepare a solution that contains $Pb^{2+}(aq)$ and $Cl^-(aq)$, at their standard-state concentrations?

20.77 The K_{sp} of ZnF_2 is 3.0×10^{-2} at 25°C. What is ΔG^0? Is it possible to prepare a solution that contains $Zn^{2+}(aq)$ and $F^-(aq)$ at their standard-state concentrations?

20.78 The equilibrium constant for the reaction

$$2Fe^{3+}(aq) + Hg_2^{2+}(aq) \rightleftharpoons 2Fe^{2+}(aq) + 2Hg^{2+}(aq)$$

is $K_c = 9.1\times10^{-6}$ at 298 K.

(a) What is ΔG^0 at this temperature?

(b) If standard-state concentrations of the reactants and products are mixed, in which direction does the reaction proceed?

(c) Calculate ΔG when $[Fe^{3+}] = 0.20\ M$, $[Hg_2^{2+}] = 0.010\ M$, $[Fe^{2+}] = 0.010\ M$, and $[Hg^{2+}] = 0.025\ M$. In which direction will the reaction proceed to achieve equilibrium?

20.79 The formation constant for the reaction

$$Ni^{2+}(aq) + 6NH_3(aq) \rightleftharpoons Ni(NH_3)_6^{2+}(aq)$$

is $K_f = 5.6\times10^8$ at 25°C.

(a) What is ΔG^0 at this temperature?

(b) If standard-state concentrations of the reactants and products are mixed, in which direction does the reaction proceed?

(c) Determine ΔG when $[Ni(NH_3)_6^{2+}] = 0.010\ M$, $[Ni^{2+}] = 0.0010\ M$, and $[NH_3] = 0.0050\ M$. In which direction will the reaction proceed to achieve equilibrium?

Problems in Context

20.80 High levels of ozone (O_3) make rubber deteriorate, green plants turn brown, and many people have difficulty breathing.

(a) Is the formation of O_3 from O_2 favored at all T, no T, high T, or low T?

(b) Calculate ΔG^0 for this reaction at 298 K.

(c) Calculate ΔG at 298 K for this reaction in urban smog where $[O_2] = 0.21$ atm and $[O_3] = 5\times10^{-7}$ atm.

20.81 A $BaSO_4$ slurry is ingested before the gastrointestinal tract is x-rayed because it is opaque to x-rays and defines the contours of the tract. Ba^{2+} ion is toxic, but the compound is nearly insoluble. If ΔG^0 at 37°C (body temperature) is 59.1 kJ/mol for the process

$$BaSO_4(s) \rightleftharpoons Ba^{2+}(aq) + SO_4^{2-}(aq)$$

what is $[Ba^{2+}]$ in the intestinal tract? (Assume that the only source of SO_4^{2-} is the ingested slurry.)

Comprehensive Problems

20.82 According to the advertisement, "a diamond is forever."

(a) Calculate ΔH^0, ΔS^0, and ΔG^0 at 298 K for the phase change

$$\text{Diamond} \longrightarrow \text{graphite}$$

(b) Given the conditions under which diamond jewelry is normally kept, argue for and against the statement in the ad.

(c) Given the answers in part (a), what would need to be done to make synthetic diamonds from graphite?

(d) Assuming ΔH^0 and ΔS^0 do not change with temperature, can graphite be converted to diamond spontaneously at 1 atm?

20.83 Replace each question mark with the correct information:

	ΔS_{rxn}	ΔH_{rxn}	ΔG_{rxn}	Comment
(a)	+	−	−	?
(b)	?	0	−	Spontaneous
(c)	−	+	?	Not spontaneous
(d)	0	?	−	Spontaneous
(e)	?	0	+	?
(f)	+	+	?	$T\Delta S > \Delta H$

20.84 Among the many complex ions of cobalt are the following:

$$Co(NH_3)_6^{3+}(aq) + 3en(aq) \rightleftharpoons Co(en)_3^{3+}(aq) + 6NH_3(aq)$$

where "en" stands for ethylenediamine, $H_2NCH_2CH_2NH_2$. Six Co—N bonds are broken and six Co—N bonds are formed in this reaction, so $\Delta H^0_{rxn} \approx 0$; yet $K > 1$. What are the signs of ΔS^0 and ΔG^0? What drives the reaction?

20.85 What is the change in entropy when 0.200 mol of potassium freezes at 63.7°C ($\Delta H_{fus} = 2.39$ kJ/mol)?

20.86 Is each statement true or false? If false, correct it.

(a) All spontaneous reactions occur quickly.

(b) The reverse of a spontaneous reaction is nonspontaneous.

(c) All spontaneous processes release heat.

(d) The boiling of water at 100°C and 1 atm is spontaneous.

(e) If a process increases the freedom of motion of the particles of a system, the entropy of the system decreases.

(f) The energy of the universe is constant; the entropy of the universe decreases toward a minimum.

(g) All systems disperse their energy spontaneously.

(h) Both ΔS_{sys} and ΔS_{surr} equal zero at equilibrium.

20.87 Hemoglobin carries O_2 from the lungs to tissue cells, where the O_2 is released. The protein is represented as Hb in its unoxygenated form and as $Hb{\cdot}O_2$ in its oxygenated form. One reason CO is toxic is that it competes with O_2 in binding to Hb:

$$Hb{\cdot}O_2(aq) + CO(g) \rightleftharpoons Hb{\cdot}CO(aq) + O_2(g)$$

(a) If $\Delta G^0 \approx -14$ kJ at 37°C (body temperature), what is the ratio of $[Hb{\cdot}CO]$ to $[Hb{\cdot}O_2]$ at 37°C with $[O_2] = [CO]$?

(b) How is Le Châtelier's principle used to treat CO poisoning?

20.88 An important ore of lithium is spodumene, $LiAlSi_2O_6$. To extract the metal, the α form of spodumene is first converted into the less dense β form in preparation for subsequent leaching and washing steps. Use the following data to calculate the lowest temperature at which the α ⟶ β conversion is feasible:

	ΔH_f^0 (kJ/mol)	S^0 (J/mol·K)
α-spodumene	−3055	129.3
β-spodumene	−3027	154.4

20.89 Magnesia (MgO) is used for fire brick, crucibles, and furnace linings because of its high melting point. It is produced by decomposing magnesite ($MgCO_3$) at around 1200°C.

(a) Write a balanced equation for magnesite decomposition.

(b) Use ΔH^0 and S^0 values to find ΔG^0 at 298 K.

(c) Assuming ΔH^0 and S^0 do not change with temperature, find the minimum temperature at which the reaction is spontaneous.

(d) Calculate the equilibrium P_{CO_2} above $MgCO_3$ at 298 K.

(e) Calculate the equilibrium P_{CO_2} above $MgCO_3$ at 1200 K.

20.90 To prepare nuclear fuel, U_3O_8 is converted to $UO_2(NO_3)_2$, which is then converted to UO_3 and finally UO_2 ("yellow cake"). The fuel is enriched (the proportion of the ^{235}U is increased) by a two-step conversion of UO_2 into UF_6, a volatile solid, followed

by a gaseous-diffusion separation of the ^{235}U and ^{238}U isotopes:

$$UO_2(s) + 4HF(g) \longrightarrow UF_4(s) + 2H_2O(g)$$
$$UF_4(s) + F_2(g) \longrightarrow UF_6(s)$$

Calculate ΔG^0 for the overall process at 85°C:

	ΔH_f^0 (kJ/mol)	S^0 (J/mol·K)	ΔG_f^0 (kJ/mol)
$UO_2(s)$	−1085	77.0	−1032
$UF_4(s)$	−1921	152	−1830.
$UF_6(s)$	−2197	225	−2068

20.91 Methanol, a major industrial feedstock, is made by several catalyzed reactions, such as $CO(g) + 2H_2(g) \longrightarrow CH_3OH(l)$.
(a) Show that this reaction is thermodynamically feasible.
(b) Is it favored at low or at high temperatures?
(c) One concern about using CH_3OH as an auto fuel is its oxidation in air to yield formaldehyde, $CH_2O(g)$, which poses a health hazard. Calculate ΔG^0 at 100.°C for this oxidation.

20.92 (a) Write a balanced equation for the gaseous reaction between N_2O_5 and F_2 to form NF_3 and O_2.
(b) Determine ΔG^0_{rxn}.
(c) Find ΔG_{rxn} at 298 K if $P_{N_2O_5} = P_{F_2} = 0.20$ atm, $P_{NF_3} = 0.25$ atm, and $P_{O_2} = 0.50$ atm.

20.93 Consider the following reaction:

$$2NOBr(g) \rightleftharpoons 2NO(g) + Br_2(g) \qquad K = 0.42 \text{ at } 373 \text{ K}$$

Given that S^0 of $NOBr(g) = 272.6$ J/mol·K and that ΔS^0_{rxn} and ΔH^0_{rxn} are constant with temperature, find
(a) ΔS^0_{rxn} at 298 K
(b) ΔG^0_{rxn} at 373 K
(c) ΔH^0_{rxn} at 373 K
(d) ΔH^0_f of NOBr at 298 K
(e) ΔG^0_{rxn} at 298 K
(f) ΔG^0_f of NOBr at 298 K

20.94 Calculate the equilibrium constants for decomposition of the hydrogen halides at 298 K:

$$2HX(g) \rightleftharpoons H_2(g) + X_2(g)$$

What do these values indicate about the extent of decomposition of HX at 298 K? Suggest a reason for this trend.

20.95 Hydrogenation is the addition of H_2 to double (or triple) carbon-carbon bonds. Peanut butter and most commercial baked goods include hydrogenated oils. Find ΔH^0, ΔS^0, and ΔG^0 for the hydrogenation of ethene (C_2H_4) to ethane (C_2H_6) at 25°C.

20.96 The key process in a blast furnace during the production of iron is the reaction of Fe_2O_3 and carbon to yield Fe and CO_2.
(a) Calculate ΔH^0 and ΔS^0. [Assume C(graphite).]
(b) Is the reaction spontaneous at low or at high T? Explain.
(c) Is the reaction spontaneous at 298 K?
(d) At what temperature does the reaction become spontaneous?

20.97 Bromine monochloride is formed from the elements:

$$Cl_2(g) + Br_2(g) \longrightarrow 2BrCl(g)$$
$$\Delta H^0_{rxn} = -1.35 \text{ kJ/mol} \qquad \Delta G^0_f = -0.88 \text{ kJ/mol}$$

Calculate (a) ΔH^0_f and (b) S^0 of $BrCl(g)$.

20.98 Solid N_2O_5 reacts with water to form liquid HNO_3. Consider the reaction with all substances in their standard states.
(a) Is the reaction spontaneous at 25°C?
(b) The solid decomposes to NO_2 and O_2 at 25°C. Is the decomposition spontaneous at 25°C? At what T is it spontaneous?
(c) At what T does *gaseous* N_2O_5 decompose spontaneously? Explain the difference between this T and that in part (b).

Note: Problems 20.99 to 20.102 relate to the thermodynamics of adenosine triphosphate (ATP). Refer to the Chemical Connections essay on pp. 889–890.

20.99 Find K for (a) the hydrolysis of ATP, (b) the dehydration-condensation to form glucose phosphate, and (c) the coupled reaction between ATP and glucose. (d) How does each K change when T changes from 25°C to 37°C?

20.100 The complete oxidation of 1 mol of glucose supplies enough metabolic energy to form 36 mol of ATP. But oxidation of a fat yields much more. For example, oxidation of 1 mol of tristearin ($C_{57}H_{116}O_6$), a typical dietary fat, yields enough energy to form 458 mol of ATP. (a) How many molecules of ATP can form per gram of glucose? (b) Per gram of tristearin?

20.101 Nonspontaneous processes like muscle contraction, protein building, and nerve conduction are "coupled" to the spontaneous hydrolysis of ATP to ADP. ATP is then regenerated by coupling its synthesis to other energy-yielding reactions such as

Creatine phosphate $\longrightarrow$ creatine + phosphate $\qquad \Delta G^{0'} = -43.1$ kJ/mol

ADP + phosphate $\longrightarrow$ ATP $\qquad \Delta G^{0'} = +30.5$ kJ/mol

Calculate $\Delta G^{0'}$ for the overall reaction that regenerates ATP.

20.102 Energy from ATP hydrolysis drives many nonspontaneous cell reactions:

$$ATP^{4-}(aq) + H_2O(l) \rightleftharpoons ADP^{3-}(aq) + HPO_4^{2-}(aq) + H^+(aq) \qquad \Delta G^{0'} = -30.5 \text{ kJ}$$

Energy for the reverse process comes ultimately from glucose metabolism:

$$C_6H_{12}O_6(s) + 6O_2(g) \longrightarrow 6CO_2(g) + 6H_2O(l)$$

(a) Find K for the hydrolysis of ATP at 37°C.
(b) Find $\Delta G^{0'}_{rxn}$ for metabolism of 1 mol of glucose.
(c) How many moles of ATP can be produced by metabolism of 1 mol of glucose?
(d) If 36 mol of ATP is formed, what is the actual yield?

20.103 From the following reaction and data, find (a) S^0 of $SOCl_2$ and (b) T at which the reaction becomes nonspontaneous:

$$SO_3(g) + SCl_2(l) \longrightarrow SOCl_2(l) + SO_2(g) \qquad \Delta G^0_{rxn} = -75.2 \text{ kJ}$$

	$SO_3(g)$	$SCl_2(l)$	$SOCl_2(l)$	$SO_2(g)$
ΔH^0_f (kJ/mol)	−396	−50.0	−245.6	−296.8
S^0 (J/mol·K)	256.7	184	—	248.1

20.104 Oxidation of a metal in air is called *corrosion*. Write equations for the corrosion of iron and aluminum. Use ΔG^0_f to determine whether either process is spontaneous at 25°C.

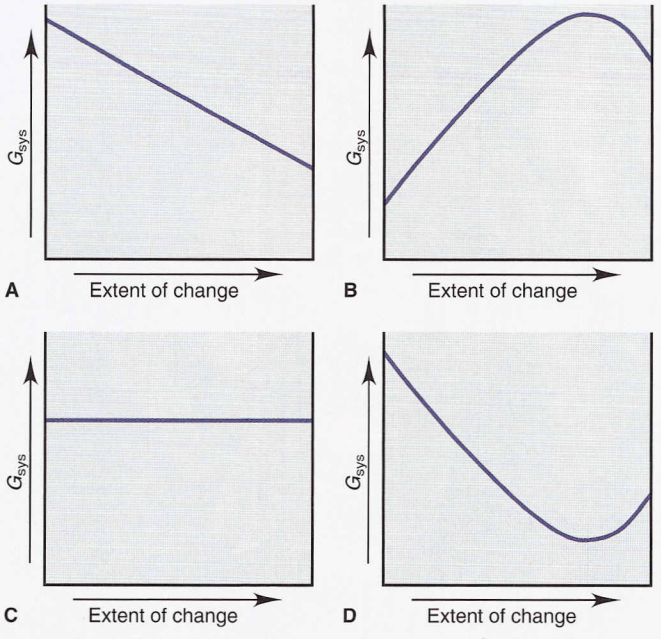
20.105 Antimony forms strong alloys with lead that are used in car batteries. Its main ore is stibnite (Sb_2S_3), which can be reduced to Sb with Fe:

$$Sb_2S_3(s) + 3Fe(s) \longrightarrow 2Sb(s) + 3FeS(s) \qquad \Delta H^0_{rxn} = -125 \text{ kJ}$$

Calculate (a) ΔH^0_f for Sb_2S_3, (b) ΔG^0_{rxn}, and (c) S^0 for Sb(s). [For FeS(s), $\Delta G^0_f = -100.$ kJ/mol, $\Delta H^0_f = -100.$ kJ/mol, and $S^0 = 60.3$ J/mol·K. For $Sb_2S_3(s)$, $\Delta G^0_f = -174$ kJ/mol and $S^0 = 182$ J/mol·K.]

20.106 A key step in the metabolism of glucose for energy is the isomerization of glucose-6-phosphate (G6P) to fructose-6-phosphate (F6P): G6P $\rightleftharpoons$ F6P; $K = 0.510$ at 298 K.
(a) Calculate ΔG^0 at 298 K.
(b) Calculate ΔG when Q, the [F6P]/[G6P] ratio, equals 10.0.
(c) Calculate ΔG when $Q = 0.100$.
(d) Calculate Q if $\Delta G = -2.50$ kJ/mol.

20.107 A chemical reaction, such as HI forming from its elements, can reach equilibrium at many temperatures. In contrast, a phase change, such as ice melting, is in equilibrium at a given pressure only at the melting point. (a) Which graph depicts how G_{sys} changes for the formation of HI? Explain. (b) Which graph depicts how G_{sys} changes as ice melts at 1°C and 1 atm? Explain.



20.108 When heated, the DNA double helix separates into two random-coil single strands. When cooled, the random coils reform the double helix: double helix $\rightleftharpoons$ 2 random coils.
(a) What is the sign of ΔS for the forward process? Why?
(b) Energy must be added to overcome H bonds and dispersion forces between the strands. What is the sign of ΔG for the forward process when $T\Delta S$ is smaller than ΔH?
(c) Write an expression that shows T in terms of ΔH and ΔS when the reaction is at equilibrium. (This temperature is called the *melting temperature* of the nucleic acid.)

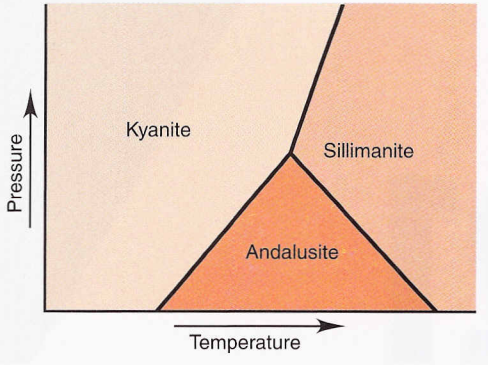
20.109 In the process of respiration, glucose is oxidized completely. In fermentation, O_2 is absent and glucose is broken down to ethanol and CO_2. Ethanol is oxidized to CO_2 and H_2O.
(a) Balance the following equations for these processes:
Respiration: $C_6H_{12}O_6(s) + O_2(g) \longrightarrow CO_2(g) + H_2O(l)$
Fermentation: $C_6H_{12}O_6(s) \longrightarrow C_2H_5OH(l) + CO_2(g)$
Ethanol oxidation: $C_2H_5OH(l) + O_2(g) \longrightarrow CO_2(g) + H_2O(l)$
(b) Calculate ΔG^0_{rxn} for respiration of 1.00 g of glucose.
(c) Calculate ΔG^0_{rxn} for fermentation of 1.00 g of glucose.
(d) Calculate ΔG^0_{rxn} for oxidation of the ethanol in part (c).

20.110 Consider the formation of ammonia:

$$N_2(g) + 3H_2(g) \rightleftharpoons 2NH_3(g)$$

(a) Assuming that ΔH^0 and ΔS^0 are constant with temperature, find the temperature at which $K_p = 1.00$.
(b) Find K_p at 400.°C, a typical temperature for NH_3 production.
(c) Given the lower K_p at the higher temperature, why are these conditions used industrially?

20.111 Kyanite, sillimanite, and andalusite all have the formula Al_2SiO_5. Each is stable under different conditions:



At the point where the three phases intersect:
(a) Which mineral, if any, has the lowest free energy?
(b) Which mineral, if any, has the lowest enthalpy?
(c) Which mineral, if any, has the highest entropy?
(d) Which mineral, if any, has the lowest density?

The bad side of a good thing The process in batteries that supplies electrical energy is, in principle, the same as the one that corrodes iron. In this chapter, we explore the two faces of electrochemistry—processes that create electricity as they occur and those that require electricity in order to occur. Both are indispensable to our way of life.

If you think thermodynamics relates mostly to expanding gases inside steam engines and has few practical, everyday applications, just look around. Some applications are probably within your reach right now, in the form of battery-operated devices—laptop computer, palm organizer, DVD remote, and, of course, wristwatch and calculator—or in the form of metal-plated jewelry or silverware. The operation and creation of these objects, and the many similar ones you use daily, involve the principles of electrochemistry, certainly one of the most important areas of applied thermodynamics.

Electrochemistry is the study of the relationship between chemical change and electrical work. It is typically investigated through the use of **electrochemical cells,** systems that incorporate a redox reaction to produce or utilize electrical energy. The common objects just mentioned highlight the essential difference between the two types of electrochemical cells:

- One type of cell *does work by releasing free energy from a spontaneous reaction to produce electricity*. A battery houses this type of cell.
- The other type of cell *does work by absorbing free energy from a source of electricity to drive a nonspontaneous reaction*. Such cells are used to plate a thin layer of metal on objects and, in major industrial processes, produce some compounds and nonmetals and recover many metals from their ores.

IN THIS CHAPTER . . . We review redox concepts and highlight a method for balancing redox equations (mentioned briefly in Chapter 4) that is particularly useful for electrochemical cells. An overview of the two cell types follows. The first type releases free energy to do electrical work, and we see how and why it operates. The cell's electrical output and its relation to the relative strengths of the redox species concern us next. We then examine the free energy change and equilibrium nature of the cell reaction and how they relate to the cell output. The concentration cells and batteries we consider are useful examples of this type of cell, and corrosion is a destructive electrochemical process that operates by the same principle. Next, we focus on cells that absorb free energy to do electrical work and see how they are used to isolate elements from their compounds and how to determine the identity and amount of product formed. Finally, we examine the redox system that generates energy in living cells.

Concepts & Skills to Review

before you study this chapter

- redox terminology (Section 4.5 and Interchapter Topic 5)
- balancing redox reactions (Section 4.5)
- activity series of the metals (Section 4.6)
- free energy, work, and equilibrium (Sections 20.3 and 20.4)
- Q vs. K (Section 17.4) and ΔG vs. ΔG^0 (Section 20.4)

The Electrochemical Future Is Here
As the combustion products of coal and gasoline continue to threaten our atmosphere, a new generation of electrochemical devices is being developed. Battery-gasoline hybrid cars are already common, achieving double or even triple the gas mileage of traditional gasoline-powered cars. Soon, electric cars, powered by banks of advanced fuel cells, may reduce the need for gasoline to a minimum. Virtually every car company has a fuel-cell prototype in operation. And these devices, once used principally on space missions, are now being produced for everyday residential and industrial applications as well.

21.1 REDOX REACTIONS AND ELECTROCHEMICAL CELLS

Whether an electrochemical process releases or absorbs free energy, it always involves the *movement of electrons from one chemical species to another* in an oxidation-reduction (redox) reaction. In this section, we review the redox process and describe the half-reaction method of balancing redox reactions that was mentioned in Section 4.5. Then we see how such reactions are used in the two types of electrochemical cells.

A Quick Review of Oxidation-Reduction Concepts

In electrochemical reactions, as in any redox process, *oxidation* is the loss of electrons, and *reduction* is the gain of electrons. An *oxidizing agent* is the species that does the oxidizing, taking electrons from the substance being oxidized. A *reducing agent* is the species that does the reducing, giving electrons to the substance being reduced. After the reaction, the oxidized substance has a higher (more positive or less negative) oxidation number, and the reduced substance has a lower (less positive or more negative) one. Keep in mind three key points:

- Oxidation (electron loss) always accompanies reduction (electron gain).
- The oxidizing agent is reduced, and the reducing agent is oxidized.
- The total number of electrons gained by the atoms/ions of the oxidizing agent always equals the total number lost by the atoms/ions of the reducing agent.

PROCESS	$Zn(s) + 2H^+(aq) \longrightarrow Zn^{2+}(aq) + H_2(g)$	
OXIDATION • One reactant loses electrons. • Reducing agent is oxidized. • Oxidation number increases.	Zinc **loses** electrons. Zinc is the reducing agent and becomes **oxidized**. The oxidation number of Zn **increases** from 0 to +2.	REDUCTION • Other reactant gains electrons. • Oxidizing agent is reduced. • Oxidation number decreases.	Hydrogen ion **gains** electrons. Hydrogen ion is the oxidizing agent and becomes **reduced**. The oxidation number of H **decreases** from +1 to 0.	

Figure 21.1 A summary of redox terminology. In the reaction between zinc and hydrogen ion, Zn is oxidized and H^+ is reduced.

Figure 21.1 presents these ideas for the aqueous reaction between zinc metal and a strong acid. Be sure you can identify the oxidation and reduction parts of a redox process. If you're having trouble, you may want to review the full discussion in Chapter 4 and the summary in Topic 5 of the Interchapter.

Half-Reaction Method for Balancing Redox Reactions

In Chapter 4, two methods for balancing redox reactions were mentioned—the oxidation number method and the half-reaction method—but only the first was discussed in detail (see Sample Problem 4.8, p. 154). The essential difference between the two methods is that the **half-reaction method** *divides the overall redox reaction into oxidation and reduction half-reactions.* Each half-reaction is balanced for atoms and charge. Then, one or both are multiplied by some integer to make electrons gained equal electrons lost, and the half-reactions are recombined to give the balanced redox equation. The half-reaction method offers several advantages for studying electrochemistry:

- It separates the oxidation and reduction steps, which reflects their actual physical separation in electrochemical cells.
- It makes it easier to balance redox reactions that take place in acidic or basic solution, which is common in these cells.
- It (usually) does *not* require assigning O.N.s. (In cases where the half-reactions are not obvious, we assign O.N.s to determine which atoms undergo a change and write half-reactions with the species that contain those atoms.)

In general, we begin with a "skeleton" ionic reaction, which shows only the species that are oxidized and reduced. *If the oxidized form of a species is on the left side of the skeleton reaction, the reduced form of that species is on the right, and vice versa.* Unless H_2O, H^+, and OH^- are being oxidized or reduced, they do not appear in the skeleton reaction. The following steps are used in balancing a redox reaction by the half-reaction method:

Step 1. Divide the skeleton reaction into two half-reactions, each of which contains the oxidized and reduced forms of one of the species. (Which half-reaction is the oxidation and which the reduction becomes clear after we balance the charges in the next step.)

Step 2. Balance the atoms and charges in each half-reaction.

- Atoms are balanced in order: atoms other than O and H, then O, and then H.
- Charge is balanced by *adding electrons* (e^-). They are added *to the left in the reduction half-reaction* because the reactant gains them; they are added *to the right in the oxidation half-reaction* because the reactant loses them.

Step 3. If necessary, multiply one or both half-reactions by an integer to make the number of e^- gained in the reduction equals the number lost in the oxidation.

Step 4. Add the balanced half-reactions, and include states of matter.

Step 5. Check that the atoms and charges are balanced.

We'll balance a redox reaction that occurs in acidic solution first and then go through Sample Problem 21.1 to balance one in basic solution.

Balancing Redox Reactions in Acidic Solution When a redox reaction occurs in acidic solution, H_2O molecules and H^+ ions are available for balancing. Even though we've used H_3O^+ to indicate the proton in water, we use H^+ in this chapter because it makes the balanced equations less complex. However, after using H^+ in this example, we'll balance the same equation with H_3O^+ just to show you that the only difference is in the number of water molecules needed.

Let's balance the redox reaction between dichromate ion and iodide ion to form chromium(III) ion and solid iodine, which occurs in acidic solution (Figure 21.2). The skeleton ionic reaction shows only the oxidized and reduced species:

$$Cr_2O_7^{2-}(aq) + I^-(aq) \longrightarrow Cr^{3+}(aq) + I_2(s) \qquad \text{[acidic solution]}$$

Step 1. Divide the reaction into half-reactions, each of which contains the oxidized and reduced forms of one species. The two chromium species make up one half-reaction, and the two iodine species make up the other:

$$Cr_2O_7^{2-} \longrightarrow Cr^{3+}$$
$$I^- \longrightarrow I_2$$

Step 2. Balance atoms and charges in each half-reaction. We use H_2O to balance O atoms, H^+ to balance H atoms, and e^- to balance positive charges.

- For the $Cr_2O_7^{2-}/Cr^{3+}$ half-reaction:

  a. *Balance atoms other than O and H.* We balance the two Cr on the left with a coefficient 2 on the right:

  $$Cr_2O_7^{2-} \longrightarrow 2Cr^{3+}$$

  b. *Balance O atoms by adding H_2O molecules.* Each H_2O has one O atom, so we add seven H_2O on the right to balance the seven O in $Cr_2O_7^{2-}$:

  $$Cr_2O_7^{2-} \longrightarrow 2Cr^{3+} + 7H_2O$$

  c. *Balance H atoms by adding H^+ ions.* Each H_2O contains two H, and we added seven H_2O, so we add 14 H^+ ions on the left:

  $$14H^+ + Cr_2O_7^{2-} \longrightarrow 2Cr^{3+} + 7H_2O$$

  d. *Balance charge by adding electrons.* Each H^+ ion has a 1+ charge, and 14 H^+ plus $Cr_2O_7^{2-}$ gives 12+ on the left. Two Cr^{3+} give 6+ on the right. There is an excess of 6+ on the left, so we add six e^- on the left:

  $$6e^- + 14H^+ + Cr_2O_7^{2-} \longrightarrow 2Cr^{3+} + 7H_2O$$

  This half-reaction is balanced, and we see it is the *reduction* because electrons appear on the *left, as reactants:* the reactant $Cr_2O_7^{2-}$ gains electrons (is reduced), so $Cr_2O_7^{2-}$ is the *oxidizing agent.* (Note that the O.N. of Cr decreases from +6 on the left to +3 on the right.)

- For the I^-/I_2 half-reaction:

  a. *Balance atoms other than O and H.* Two I atoms on the right require a coefficient 2 on the left:

  $$2I^- \longrightarrow I_2$$

  b. *Balance O atoms with H_2O.* Not needed; there are no O atoms.

  c. *Balance H atoms with H^+.* Not needed; there are no H atoms.

  d. *Balance charge with e^-.* To balance the 2− on the left, we add two e^- on the right:

  $$2I^- \longrightarrow I_2 + 2e^-$$

  This half-reaction is balanced, and it is the *oxidation* because electrons appear on the *right, as products:* the reactant I^- loses electrons (is oxidized), so I^- is the *reducing agent.* (Note that the O.N. of I increases from −1 to 0.)

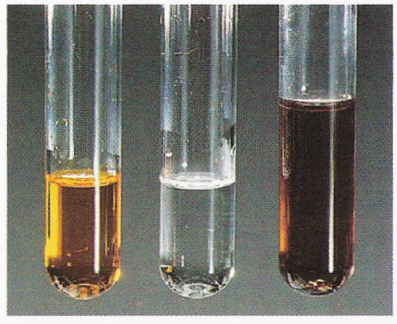

Figure 21.2 The redox reaction between dichromate ion and iodide ion. When $Cr_2O_7^{2-}$ (*left*) and I^- (*center*) are mixed in acid solution, they react to form Cr^{3+} and I_2 (*right*).

Step 3. Multiply each half-reaction, if necessary, by an integer so that the number of e^- lost in the oxidation equals the number of e^- gained in the reduction. Two e^- are lost in the oxidation and six e^- are gained in the reduction, so we multiply the oxidation by 3:

$$3(2I^- \longrightarrow I_2 + 2e^-)$$
$$6I^- \longrightarrow 3I_2 + 6e^-$$

Step 4. Add the half-reactions together, canceling substances that appear on both sides, and include states of matter. In this example, only the electrons cancel:

$$\cancel{6e^-} + 14H^+ + Cr_2O_7^{2-} \longrightarrow 2Cr^{3+} + 7H_2O$$
$$6I^- \longrightarrow 3I_2 + \cancel{6e^-}$$
$$\overline{6I^-(aq) + 14H^+(aq) + Cr_2O_7^{2-}(aq) \longrightarrow 3I_2(s) + 7H_2O(l) + 2Cr^{3+}(aq)}$$

Step 5. Check that atoms and charges balance:

Reactants (6I, 14H, 2Cr, 7O; 6+) ⟶ products (6I, 14H, 2Cr, 7O; 6+)

Balancing a Redox Reaction Using H_3O^+ Now let's balance the reduction half-reaction with H_3O^+ as the supplier of H atoms. In step 2, balancing Cr atoms and balancing O atoms with H_2O are the same as before, so we start with

$$Cr_2O_7^{2-} \longrightarrow 2Cr^{3+} + 7H_2O$$

Now we use H_3O^+ instead of H^+ to balance H atoms. Because each H_3O^+ is an H^+ bonded to an H_2O, we balance the 14 H on the right with 14 H_3O^+ on the left and immediately balance the H_2O that are part of those 14 H_3O^+ by adding 14 more H_2O on the right:

$$14H_3O^+ + Cr_2O_7^{2-} \longrightarrow 2Cr^{3+} + 7H_2O + 14H_2O$$

Simplifying the right side by taking the sum of the H_2O molecules gives

$$14H_3O^+ + Cr_2O_7^{2-} \longrightarrow 2Cr^{3+} + 21H_2O$$

None of this affects the redox change, so balancing the charge still requires six e^- on the left, and we obtain the balanced reduction half-reaction:

$$6e^- + 14H_3O^+ + Cr_2O_7^{2-} \longrightarrow 2Cr^{3+} + 21H_2O$$

Adding the balanced oxidation half-reaction gives the balanced redox equation:

$$6I^-(aq) + 14H_3O^+(aq) + Cr_2O_7^{2-}(aq) \longrightarrow 3I_2(s) + 21H_2O(l) + 2Cr^{3+}(aq)$$

Note, as mentioned earlier, that the only difference is the number of H_2O molecules: there are 14 more H_2O (21 instead of 7) from the 14 H_3O^+.

To depict the reaction even more accurately, we could show the metal ion in its hydrated form, which would also affect only the total number of H_2O:

$$6I^-(aq) + 14H_3O^+(aq) + Cr_2O_7^{2-}(aq) \longrightarrow 3I_2(s) + 9H_2O(l) + 2Cr(H_2O)_6^{3+}(aq)$$

Although these added steps present the species in solution more accurately, they change only the number of water molecules and make balancing more difficult; thus, they detract somewhat from the key chemical event—the redox change. Therefore, we'll employ the method that uses H^+ to balance H atoms.

Balancing Redox Reactions in Basic Solution As you just saw, in acidic solution, H_2O molecules and H^+ (or H_3O^+) ions are available for balancing. As Sample Problem 21.1 shows, in basic solution, H_2O molecules and OH^- ions are available. Only one additional step is needed to balance a redox equation that takes place in basic solution. It appears after both half-reactions have first been balanced *as if they took place in acidic solution* (steps 1 and 2), the e^- lost have been made equal to the e^- gained (step 3), and the half-reactions have been combined (step 4). At this point, *we add one OH^- ion* ***to both sides of the equation*** *for every H^+ ion present.* (We label this step "4 Basic.") The H^+ ions on one side are combined with the added OH^- ions to form H_2O, and OH^- ions appear on the other side of the equation. Excess H_2O molecules are canceled, and states of matter are identified. Finally, we check that atoms and charges balance (step 5).

SAMPLE PROBLEM 21.1 Balancing Redox Reactions by the Half-Reaction Method

Problem Permanganate ion is a strong oxidizing agent, and its deep purple color makes it useful as an indicator in redox titrations (see Figure 4.14, p. 156). It reacts in basic solution with the oxalate ion to form carbonate ion and solid manganese dioxide. Balance the skeleton ionic equation for the reaction between $NaMnO_4$ and $Na_2C_2O_4$ in basic solution:

$$MnO_4^-(aq) + C_2O_4^{2-}(aq) \longrightarrow MnO_2(s) + CO_3^{2-}(aq) \quad \text{[basic solution]}$$

Plan We proceed through step 4 as if this took place in acidic solution. Then, we add the appropriate number of OH^- ions and cancel excess H_2O molecules (step 4 Basic).

Solution

1. Divide into half-reactions.

$MnO_4^- \longrightarrow MnO_2$ $\qquad$ $C_2O_4^{2-} \longrightarrow CO_3^{2-}$

2. Balance.

a. Atoms other than O and H,
Not needed

b. O atoms with H_2O,
$MnO_4^- \longrightarrow MnO_2 + 2H_2O$

c. H atoms with H^+,
$4H^+ + MnO_4^- \longrightarrow MnO_2 + 2H_2O$

d. Charge with e^-,
$3e^- + 4H^+ + MnO_4^- \longrightarrow MnO_2 + 2H_2O$ [reduction]

a. Atoms other than O and H,
$C_2O_4^{2-} \longrightarrow 2CO_3^{2-}$

b. O atoms with H_2O,
$2H_2O + C_2O_4^{2-} \longrightarrow 2CO_3^{2-}$

c. H atoms with H^+,
$2H_2O + C_2O_4^{2-} \longrightarrow 2CO_3^{2-} + 4H^+$

d. Charge with e^-,
$2H_2O + C_2O_4^{2-} \longrightarrow 2CO_3^{2-} + 4H^+ + 2e^-$ [oxidation]

3. Multiply each half-reaction, if necessary, by some integer to make e^- lost equal e^- gained.

$2(3e^- + 4H^+ + MnO_4^- \longrightarrow MnO_2 + 2H_2O)$
$6e^- + 8H^+ + 2MnO_4^- \longrightarrow 2MnO_2 + 4H_2O$

$3(2H_2O + C_2O_4^{2-} \longrightarrow 2CO_3^{2-} + 4H^+ + 2e^-)$
$6H_2O + 3C_2O_4^{2-} \longrightarrow 6CO_3^{2-} + 12H^+ + 6e^-$

4. Add half-reactions, and cancel substances appearing on both sides.
The six e^- cancel, eight H^+ cancel to leave four H^+ on the right, and four H_2O cancel to leave two H_2O on the left:

$$\begin{array}{r} \cancel{6e^-} + \cancel{8H^+} + 2MnO_4^- \longrightarrow 2MnO_2 + \cancel{4H_2O} \\ 2\,\cancel{6H_2O} + 3C_2O_4^{2-} \longrightarrow 6CO_3^{2-} + 4\,\cancel{12H^+} + \cancel{6e^-} \\ \hline 2MnO_4^- + 2H_2O + 3C_2O_4^{2-} \longrightarrow 2MnO_2 + 6CO_3^{2-} + 4H^+ \end{array}$$

4 Basic. Add OH^- to both sides to neutralize H^+, and cancel H_2O.
Adding four OH^- to both sides forms four H_2O on the right, two of which cancel the two H_2O on the left, leaving two H_2O on the right:

$$2MnO_4^- + 2H_2O + 3C_2O_4^{2-} + 4OH^- \longrightarrow 2MnO_2 + 6CO_3^{2-} + [4H^+ + 4OH^-]$$
$$2MnO_4^- + \cancel{2H_2O} + 3C_2O_4^{2-} + 4OH^- \longrightarrow 2MnO_2 + 6CO_3^{2-} + 2\,\cancel{4H_2O}$$

Including states of matter gives the final balanced equation:

$$2MnO_4^-(aq) + 3C_2O_4^{2-}(aq) + 4OH^-(aq) \longrightarrow 2MnO_2(s) + 6CO_3^{2-}(aq) + 2H_2O(l)$$

5. Check that atoms and charges balance.

$$(2Mn, 24O, 6C, 4H; 12-) \longrightarrow (2Mn, 24O, 6C, 4H; 12-)$$

Comment As a final step, we can obtain the balanced *molecular* equation for this reaction by noting the number of moles of each anion in the balanced ionic equation and adding the correct number of moles of spectator ions (in this case, Na^+) to obtain neutral compounds. Thus, for instance, balancing the charge of 2 mol of MnO_4^- requires 2 mol of Na^+, so we have $2NaMnO_4$. The balanced molecular equation is

$$2NaMnO_4(aq) + 3Na_2C_2O_4(aq) + 4NaOH(aq) \longrightarrow 2MnO_2(s) + 6Na_2CO_3(aq) + 2H_2O(l)$$

FOLLOW-UP PROBLEM 21.1 Write a balanced molecular equation for the reaction between $KMnO_4$ and KI in basic solution. The skeleton ionic reaction is

$$MnO_4^-(aq) + I^-(aq) \longrightarrow MnO_4^{2-}(aq) + IO_3^-(aq) \quad \text{[basic solution]}$$

The half-reaction method reveals a great deal about redox processes and is essential to understanding electrochemical cells. The major points are

- Any redox reaction can be treated as the sum of a reduction and an oxidation half-reaction.
- Atoms and charge are conserved in each half-reaction.
- Electrons lost in one half-reaction are gained in the other.
- Although the half-reactions are treated separately, electron loss and electron gain occur simultaneously.

An Overview of Electrochemical Cells

We distinguish two types of electrochemical cells based on the general thermodynamic nature of the reaction:

1. A **voltaic cell** (or **galvanic cell**) uses a spontaneous reaction ($\Delta G < 0$) to generate electrical energy. In the cell reaction, the difference in chemical potential energy between higher energy reactants and lower energy products is converted into electrical energy. This energy is used to operate the load—flashlight bulb, CD player, car starter motor, or other electrical device. In other words, *the system does work on the surroundings*. All batteries contain voltaic cells.
2. An **electrolytic cell** uses electrical energy to drive a nonspontaneous reaction ($\Delta G > 0$). In the cell reaction, electrical energy from an external power supply converts lower energy reactants into higher energy products. Thus, *the surroundings do work on the system*. Electroplating and recovering metals from ores involve electrolytic cells.

The two types of cell have certain design features in common (Figure 21.3). Two **electrodes,** which conduct the electricity between cell and surroundings, are dipped into an **electrolyte,** a mixture of ions (usually in aqueous solution) that

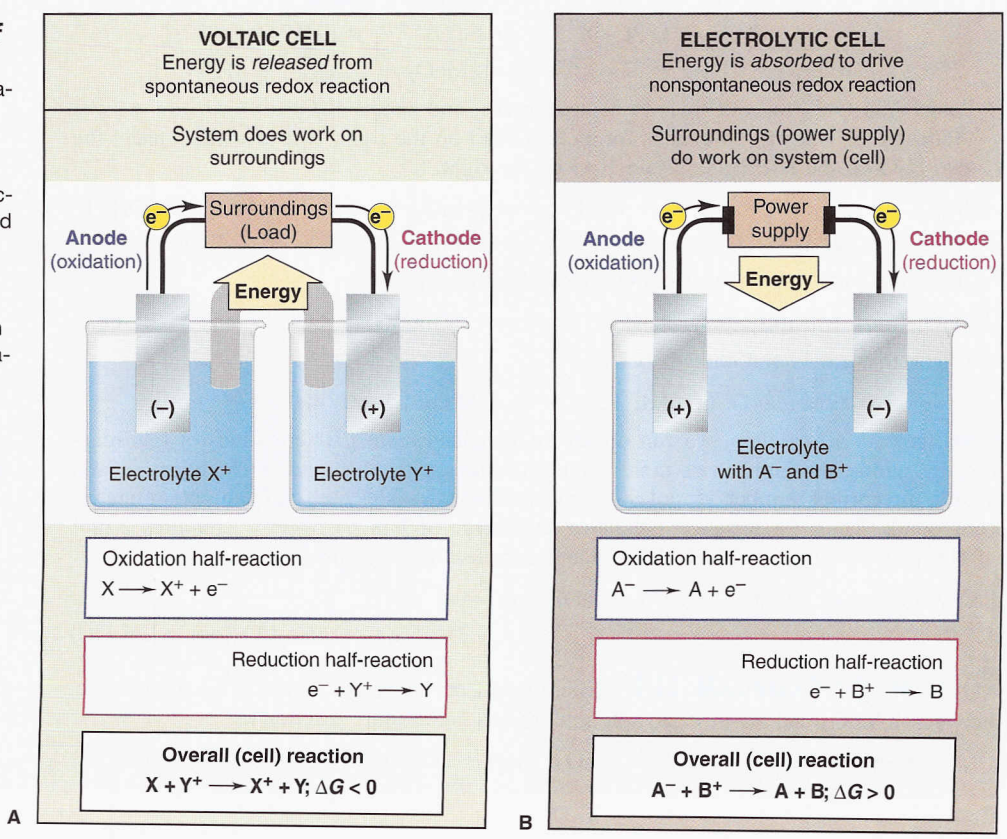

Figure 21.3 General characteristics of voltaic and electrolytic cells. A voltaic cell **(A)** generates energy from a spontaneous reaction ($\Delta G < 0$), whereas an electrolytic cell **(B)** requires energy to drive a nonspontaneous reaction ($\Delta G > 0$). In both types of cell, two electrodes dip into electrolyte solutions, and an external circuit provides the means for electrons to flow between them. Most important, notice that oxidation takes place at the anode and reduction takes place at the cathode, but the relative electrode charges are opposite in the two cells.

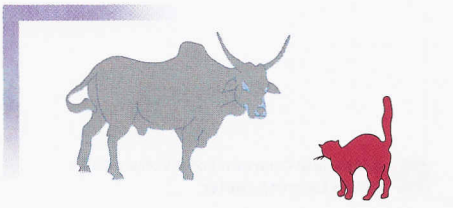
are involved in the reaction or that carry the charge. An electrode is identified as either **anode** or **cathode** depending on the half-reaction that takes place there:

- *The oxidation half-reaction occurs at the anode.* Electrons are lost by the substance being oxidized (reducing agent) and *leave the cell* at the anode.
- *The reduction half-reaction occurs at the cathode.* Electrons are gained by the substance being reduced (oxidizing agent) and *enter the cell* at the cathode.

As shown in Figure 21.3, the relative charges of the electrodes are *opposite* in the two types of cell. As you'll see in the following sections, these opposite charges result from the different phenomena that cause the electrons to flow.



Which Half-Reaction Occurs at Which Electrode? Here are some memory aids to help you remember which half-reaction occurs at which electrode:

1. The words *anode* and *oxidation* start with vowels; the words *cathode* and *reduction* start with consonants.
2. Alphabetically, the *A* in anode comes before the *C* in cathode, and the *O* in oxidation comes before the *R* in reduction.
3. Look at the first syllables and use your imagination:

ANode, OXidation; REDuction, CAThode
⇒ AN OX and a RED CAT

SECTION SUMMARY

An oxidation-reduction (redox) reaction involves the transfer of electrons from a reducing agent to an oxidizing agent. The half-reaction method of balancing divides the overall reaction into half-reactions that are balanced separately and then recombined. Both types of electrochemical cells are based on redox reactions. In a voltaic cell, a spontaneous reaction generates electricity and does work on the surroundings; in an electrolytic cell, the surroundings supply electricity that does work to drive a nonspontaneous reaction. In both types, two electrodes dip into electrolyte solutions; oxidation occurs at the anode, and reduction occurs at the cathode.

21.2 VOLTAIC CELLS: USING SPONTANEOUS REACTIONS TO GENERATE ELECTRICAL ENERGY

If you put a strip of zinc metal in a solution of Cu^{2+} ion, the blue color of the solution fades as a brown-black crust of Cu metal forms on the Zn strip (Figure 21.4). Judging from what we see, the reaction involves the reduction of Cu^{2+} ion to Cu metal, which must be accompanied by the oxidation of Zn metal to Zn^{2+} ion. The overall reaction consists of two half-reactions:

$$Cu^{2+}(aq) + 2e^- \longrightarrow Cu(s) \quad \text{[reduction]}$$
$$Zn(s) \longrightarrow Zn^{2+}(aq) + 2e^- \quad \text{[oxidation]}$$
$$Zn(s) + Cu^{2+}(aq) \longrightarrow Zn^{2+}(aq) + Cu(s) \quad \text{[overall reaction]}$$

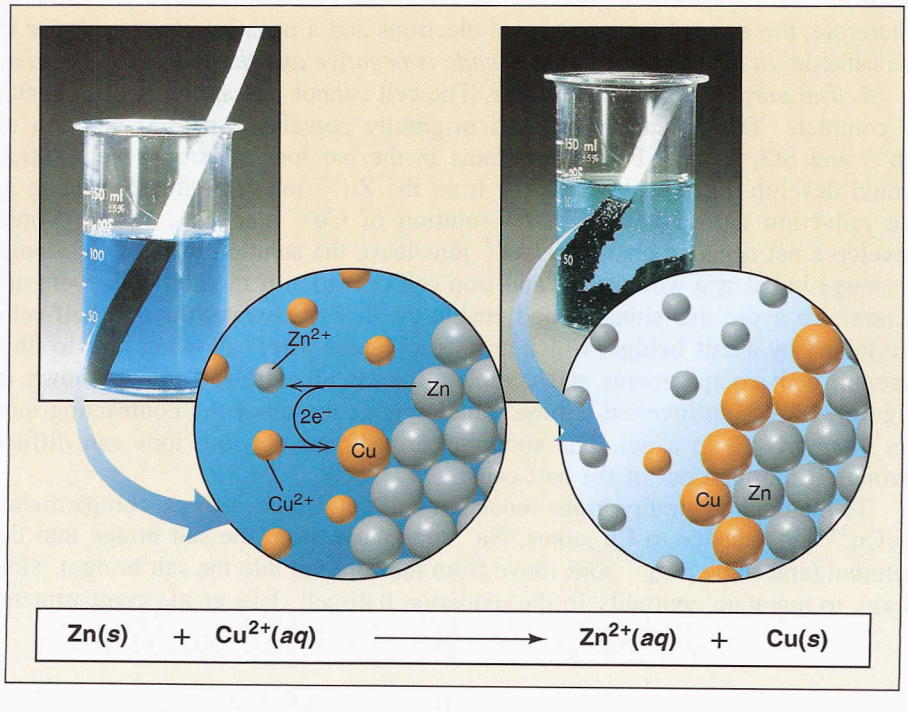


Figure 21.4 The spontaneous reaction between zinc and copper(II) ion. When a strip of zinc metal is placed in a solution of Cu^{2+} ion, a redox reaction begins (*left*), in which the zinc is oxidized to Zn^{2+} and the Cu^{2+} is reduced to copper metal. As the reaction proceeds (*right*), the deep blue color of the solution of hydrated Cu^{2+} ion lightens, and the Cu "plates out" on the Zn and falls off in chunks. (The Cu appears black because it is very finely divided.) At the atomic scale, each Zn atom loses two electrons, which are gained by a Cu^{2+} ion. The process is summarized with symbols in the balanced equation.

In the remainder of this section, we examine this spontaneous reaction as the basis of a voltaic (galvanic) cell.

Construction and Operation of a Voltaic Cell

Animation: Operation of a Voltaic Cell
Online Learning Center

Electrons are being transferred in the Zn/Cu^{2+} reaction (Figure 21.4), but the system does not generate electrical energy because the oxidizing agent (Cu^{2+}) and the reducing agent (Zn) are in the same beaker. If, however, the half-reactions are physically separated and connected by an external circuit, the electrons are transferred by traveling through the circuit, thus producing an electric current.

This separation of half-reactions is the essential idea behind a voltaic cell (Figure 21.5A). The components of each half-reaction are placed in a separate container, or **half-cell,** which consists of one electrode dipping into an electrolyte solution. The two half-cells are joined by the circuit, which consists of a wire and a salt bridge (the inverted U tube in the figure; we will discuss its function shortly). In order to measure the voltage generated by the cell, a voltmeter is inserted in the path of the wire connecting the electrodes. A switch (not shown) closes (completes) or opens (breaks) the circuit. By convention, *the oxidation half-cell (anode compartment) is shown on the left and the reduction half-cell (cathode compartment) on the right.* Here are the key points about the Zn/Cu^{2+} voltaic cell:

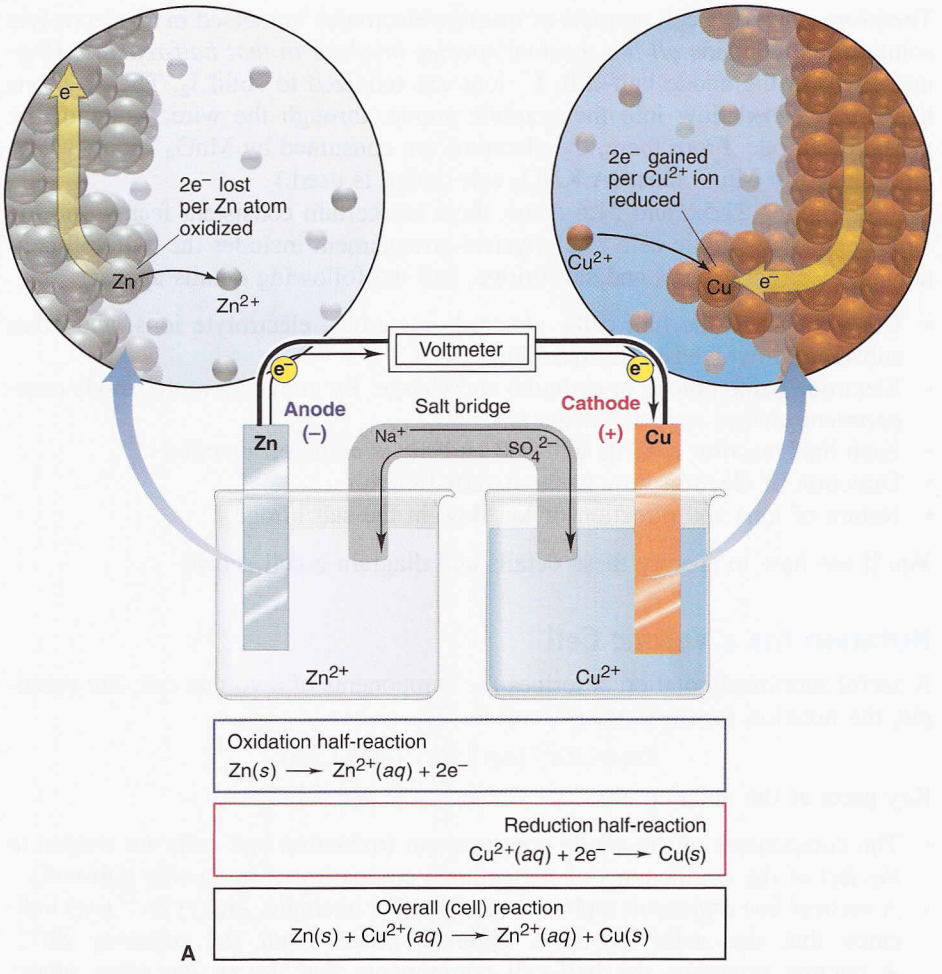
1. *The oxidation half-cell.* In this case, the anode compartment consists of a zinc bar (the anode) immersed in a Zn^{2+} electrolyte (such as a solution of zinc sulfate, $ZnSO_4$). The zinc bar is the reactant in the oxidation half-reaction, and it conducts the released electrons *out* of its half-cell.

2. *The reduction half-cell.* In this case, the cathode compartment consists of a copper bar (the cathode) immersed in a Cu^{2+} electrolyte [such as a solution of copper(II) sulfate, $CuSO_4$]. The copper bar is the product in the reduction half-reaction, and it conducts electrons *into* its half-cell.

3. *Relative charges on the electrodes.* The electrode charges are determined by the *source of electrons* and the *direction of electron flow* through the circuit. In this cell, zinc atoms are oxidized at the anode to Zn^{2+} ions and electrons. The Zn^{2+} ions enter the solution, while the electrons enter the bar and then the wire. *The electrons flow left to right* through the wire to the cathode, where Cu^{2+} ions in the solution accept them and are reduced to Cu atoms. As the cell operates, electrons are continuously generated at the anode and consumed at the cathode. Therefore, the anode has an excess of electrons and a negative charge *relative* to the cathode. *In any **voltaic** cell, the anode is negative and the cathode is positive.*

4. *The purpose of the salt bridge.* The cell cannot operate unless the circuit is complete. The oxidation half-cell originally contains a neutral solution of Zn^{2+} and SO_4^{2-} ions, but as Zn atoms in the bar lose electrons, the solution would develop a net positive charge from the Zn^{2+} ions entering. Similarly, in the reduction half-cell, the neutral solution of Cu^{2+} and SO_4^{2-} ions would develop a net negative charge as Cu^{2+} ions leave the solution to form Cu atoms. A charge imbalance would arise and stop cell operation if the half-cells were not neutral. To avoid this situation and enable the cell to operate, the two half-cells are joined by a **salt bridge,** which acts as a "liquid wire," allowing ions to flow through both compartments and complete the circuit. The salt bridge shown in Figure 21.5A is an inverted U tube containing a solution of the nonreacting ions Na^+ and SO_4^{2-} in a gel. The solution cannot pour out, but ions can diffuse through it into and out of the half-cells.

To maintain neutrality in the reduction half-cell (right; cathode compartment) as Cu^{2+} ions change to Cu atoms, Na^+ ions move from the salt bridge into the solution (and some SO_4^{2-} ions move from the solution into the salt bridge). Similarly, to maintain neutrality in the oxidation half-cell (left; anode compartment)



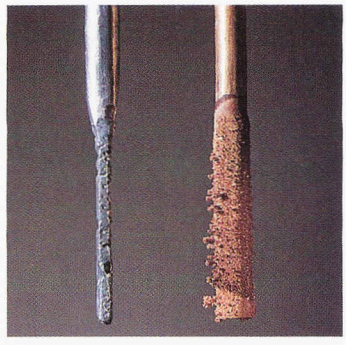


Figure 21.5 A voltaic cell based on the zinc-copper reaction. A, The anode half-cell (oxidation) consists of a Zn electrode dipping into a Zn^{2+} solution. The two electrons generated in the oxidation of each Zn atom move through the Zn bar and the wire, and into the Cu electrode, which dips into a Cu^{2+} solution in the cathode half-cell (reduction). There, the electrons reduce Cu^{2+} ions. Thus, electrons flow left to right through electrodes and wire. A salt bridge contains unreactive Na^+ and SO_4^{2-} ions that maintain neutral charge in the electrolyte solutions: anions in the salt bridge flow to the left, and cations flow to the right. The voltmeter registers the electrical output of the cell. **B,** After the cell runs for several hours, the Zn anode weighs less because Zn atoms have been oxidized to aqueous Zn^{2+} ions, and the Cu cathode weighs more because aqueous Cu^{2+} ions have been reduced to Cu metal.

as Zn atoms change to Zn^{2+} ions, SO_4^{2-} ions move from the salt bridge into that solution (and some Zn^{2+} ions move from the solution into the salt bridge). Thus, as Figure 21.5A shows, the circuit is completed *as electrons move left to right through the wire, while anions move right to left and cations move left to right through the salt bridge.*

5. *Active vs. inactive electrodes.* The electrodes in the Zn/Cu^{2+} cell are *active* because the metal bars themselves are components of the half-reactions. As the cell operates, the mass of the zinc electrode gradually decreases, and the $[Zn^{2+}]$ in the anode half-cell increases. At the same time, the mass of the copper electrode increases, and the $[Cu^{2+}]$ in the cathode half-cell decreases; we say that the Cu^{2+} "plates out" on the electrode. Look at Figure 21.5B to see how the electrodes look, removed from their half-cells, after several hours of operation.

For many redox reactions, there are no reactants or products capable of serving as electrodes, so *inactive* electrodes are used. Most commonly, inactive electrodes are rods of *graphite* or *platinum*: they conduct electrons into or out of the half-cells but cannot take part in the half-reactions. In a voltaic cell based on the following half-reactions, for instance, the reacting species cannot act as electrodes:

$$2I^-(aq) \longrightarrow I_2(s) + 2e^- \quad \text{[anode; oxidation]}$$

$$MnO_4^-(aq) + 8H^+(aq) + 5e^- \longrightarrow Mn^{2+}(aq) + 4H_2O(l) \quad \text{[cathode; reduction]}$$

Therefore, each half-cell consists of inactive electrodes immersed in an electrolyte solution that contains *all the reactant species involved in that half-reaction* (Figure 21.6). In the anode half-cell, I^- ions are oxidized to solid I_2. The electrons that are released flow into the graphite anode, through the wire, and into the graphite cathode. From there, the electrons are consumed by MnO_4^- ions, which are reduced to Mn^{2+} ions. (A KNO_3 salt bridge is used.)

As Figures 21.5A and 21.6 show, there are certain consistent features in the *diagram* of any voltaic cell. The physical arrangement includes the half-cell containers, electrodes, wire, and salt bridge, and the following details appear:

- Components of the half-cells: electrode materials, electrolyte ions, and other substances involved in the reaction
- Electrode name (anode or cathode) and charge. By convention, the anode compartment always appears *on the left*.
- Each half-reaction with its half-cell and the overall cell reaction
- Direction of electron flow in the external circuit
- Nature of ions and direction of ion flow in the salt bridge

You'll see how to specify these details and diagram a cell shortly.

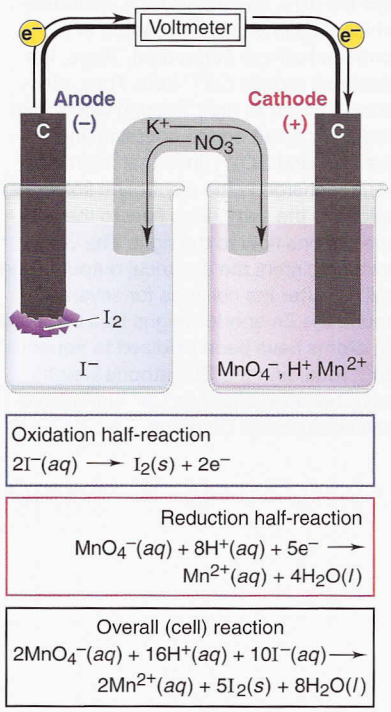

Figure 21.6 A voltaic cell using inactive electrodes. The reaction between I^- and MnO_4^- in acidic solution does not have species that can be used as electrodes, so inactive graphite (C) electrodes are used.

Notation for a Voltaic Cell

A useful shorthand notation describes the components of a voltaic cell. For example, the notation for the Zn/Cu^{2+} cell is

$$Zn(s) \mid Zn^{2+}(aq) \parallel Cu^{2+}(aq) \mid Cu(s)$$

Key parts of the notation are

- The components of the anode compartment (oxidation half-cell) are written *to the left* of the components of the cathode compartment (reduction half-cell).
- A vertical line represents a phase boundary. For example, $Zn(s) \mid Zn^{2+}(aq)$ indicates that the *solid* Zn is a *different* phase from the *aqueous* Zn^{2+}. A comma separates the half-cell components that are in the *same* phase. For example, the notation for the voltaic cell housing the reaction between I^- and MnO_4^- shown in Figure 21.6 is

  $$\text{graphite} \mid I^-(aq) \mid I_2(s) \parallel H^+(aq), MnO_4^-(aq), Mn^{2+}(aq) \mid \text{graphite}$$

  That is, in the cathode compartment, H^+, MnO_4^-, and Mn^{2+} ions are all in aqueous solution with solid graphite immersed in it. Often, we specify the concentrations of dissolved components; for example, if the concentrations of Zn^{2+} and Cu^{2+} are 1 *M*, we write

  $$Zn(s) \mid Zn^{2+}(1\ M) \parallel Cu^{2+}(1\ M) \mid Cu(s)$$

- Half-cell components usually appear in the same order as in the half-reaction, and electrodes appear at the far left and right of the notation.
- A double vertical line separates the half-cells and represents the phase boundary on either side of the salt bridge (the ions in the salt bridge are omitted because they are not part of the reaction).

SAMPLE PROBLEM 21.2 Diagramming Voltaic Cells

Problem Diagram, show balanced equations, and write the notation for a voltaic cell that consists of one half-cell with a Cr bar in a $Cr(NO_3)_3$ solution, another half-cell with an Ag bar in an $AgNO_3$ solution, and a KNO_3 salt bridge. Measurement indicates that the Cr electrode is negative relative to the Ag electrode.

Plan From the given contents of the half-cells, we can write the half-reactions. We must determine which is the anode compartment (oxidation) and which is the cathode (reduction). To do so, we must find the direction of the spontaneous redox reaction, which is

given by the relative electrode charges. Since electrons are released into the anode during oxidation, it has a negative charge. We are told that Cr is negative, so it must be the anode; and, therefore, Ag is the cathode.

Solution Writing the balanced half-reactions. Since the Ag electrode is positive, the half-reaction consumes e^-:

$$Ag^+(aq) + e^- \longrightarrow Ag(s) \qquad \text{[reduction; cathode]}$$

Since the Cr electrode is negative, the half-reaction releases e^-:

$$Cr(s) \longrightarrow Cr^{3+}(aq) + 3e^- \qquad \text{[oxidation; anode]}$$

Writing the balanced overall cell reaction. We triple the reduction half-reaction in order to balance e^-, and then we combine the half-reactions to obtain the overall spontaneous redox reaction:

$$Cr(s) + 3Ag^+(aq) \longrightarrow Cr^{3+}(aq) + 3Ag(s)$$

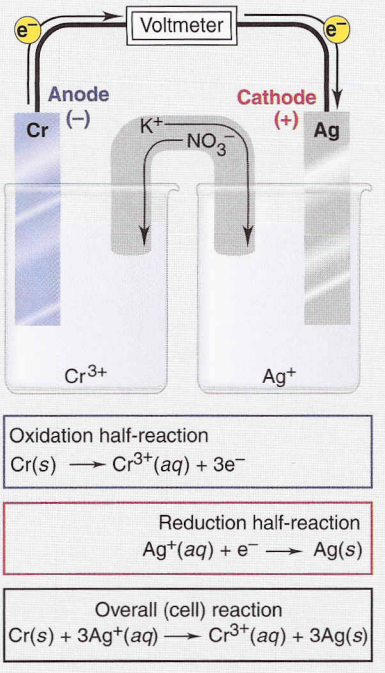
Determining direction of electron and ion flow. The released e^- in the Cr electrode (negative) flow through the external circuit to the Ag electrode (positive). As Cr^{3+} ions enter the anode electrolyte, NO_3^- ions enter from the salt bridge to maintain neutrality. As Ag^+ ions leave the cathode electrolyte and plate out on the Ag electrode, K^+ ions enter from the salt bridge to maintain neutrality. The diagram of this cell is shown in the margin.

Writing the cell notation:

$$Cr(s) \mid Cr^{3+}(aq) \parallel Ag^+(aq) \mid Ag(s)$$

Check Always be sure that the half-reactions and cell reaction are balanced, the half-cells contain *all* components of the half-reactions, and the electron and ion flow are shown. You should be able to write the half-reactions from the cell notation as a check.

Comment The key to diagramming a voltaic cell is to use the direction of the spontaneous reaction to identify the oxidation (anode) and reduction (cathode) half-reactions.



FOLLOW-UP PROBLEM 21.2 In one compartment of a voltaic cell, a graphite rod dips into an acidic solution of $K_2Cr_2O_7$ and $Cr(NO_3)_3$; in the other compartment, a tin bar dips into a $Sn(NO_3)_2$ solution. A KNO_3 salt bridge joins them. The tin electrode is negative relative to the graphite. Diagram the cell, write the balanced equations, and show the cell notation.

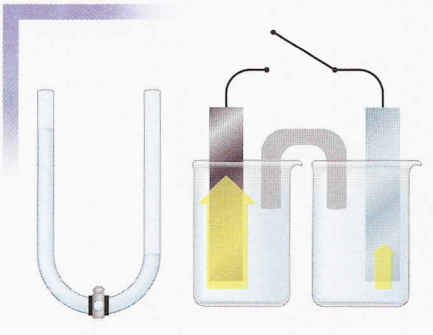
Why Does a Voltaic Cell Work?

By placing a lightbulb in the circuit or looking at the voltmeter, we can see that the Zn/Cu^{2+} cell generates electrical energy. But what principle explains *how* the reaction takes place, and *why* do electrons flow in the direction shown?

Let's examine what happens when the switch is open and no reaction is occurring. In each half-cell, we can consider the metal electrode to be in equilibrium with the metal ions in the electrolyte and the electrons residing in the metal:

$$Zn(s) \rightleftharpoons Zn^{2+}(aq) + 2e^-(\text{in Zn metal})$$
$$Cu(s) \rightleftharpoons Cu^{2+}(aq) + 2e^-(\text{in Cu metal})$$

From the direction of the overall spontaneous reaction, we know that Zn gives up its electrons more easily than Cu does; thus, Zn is a stronger reducing agent. Therefore, the equilibrium position of the Zn half-reaction lies farther to the right: Zn produces more electrons than Cu does. You might think of the electrons in the Zn electrode as being subject to a greater electron "pressure" than those in the Cu electrode, a greater potential energy (referred to as *electrical potential*) ready to "push" them through the circuit. Close the switch, and electrons flow from the Zn to the Cu electrode to equalize this difference in electrical potential. The flow disturbs the equilibrium at each electrode. The Zn half-reaction shifts to the right to restore the electrons flowing out, and the Cu half-reaction shifts to the left to remove the electrons flowing in. Thus, *the spontaneous reaction occurs as a result of the different abilities of these metals to give up their electrons and the ability of the electrons to flow through the circuit.*



Electron Flow and Water Flow Consider this analogy between electron "pressure" and water pressure. A U tube (cell) is separated into two arms (two half-cells) by a stopcock (switch), and the two arms contain water at different heights (the half-cells contain half-reactions with different electrical potentials). Open the stopcock (close the switch), and the different heights (potential difference) become equal as water flows (electrons flow and current is generated).

SECTION SUMMARY

A voltaic cell consists of oxidation (anode) and reduction (cathode) half-cells, connected by a wire to conduct electrons and a salt bridge to maintain charge neutrality as the cell operates. Electrons move from anode (left) to cathode (right), while cations move from the salt bridge into the cathode half-cell and anions from the salt bridge into the anode half-cell. The cell notation shows the species and their phases in each half-cell, as well as the direction of current flow. A voltaic cell operates because species in the two half-cells differ in their tendency to lose electrons.

21.3 CELL POTENTIAL: OUTPUT OF A VOLTAIC CELL

The purpose of a voltaic cell is to convert the free energy change of a spontaneous reaction into the kinetic energy of electrons moving through an external circuit (electrical energy). This electrical energy can do work and is proportional to the *difference in electrical potential between the two electrodes*. This difference in the electrical potential of the electrodes is the **cell potential (E_{cell}),** also called the **voltage** of the cell or the **electromotive force (emf).**

Electrons flow spontaneously from the negative to the positive electrode, that is, toward the electrode with the more positive electrical potential. Thus, when the cell operates *spontaneously,* the difference in the electrical potential of the electrodes is positive; that is, there is a *positive* cell potential:

$$E_{cell} > 0 \text{ for a spontaneous process} \qquad (21.1)$$

The more positive E_{cell} is, the more work the cell can do, and the farther the reaction proceeds to the right as written. A *negative* cell potential, on the other hand, is associated with a *nonspontaneous* cell reaction. If $E_{cell} = 0$, the reaction has reached equilibrium and the cell can do no more work. (There is a clear relationship between E_{cell}, K, and ΔG that we'll discuss in Section 21.4.)

How are the units of cell potential related to those of energy available to do work? As you've seen, work is done when charge moves between electrode compartments that differ in electrical potential. The SI unit of electrical potential is the **volt (V),** and the SI unit of electrical charge is the **coulomb (C).** By definition, for two electrodes that differ by 1 volt of electrical potential, 1 joule of energy is released (that is, 1 joule of work can be done) for each coulomb of charge that moves between the electrodes. Thus,

$$1 \text{ V} = 1 \text{ J/C} \qquad (21.2)$$

Table 21.1 lists the voltages of some commercial and natural voltaic cells. Let's see how to measure cell potential.

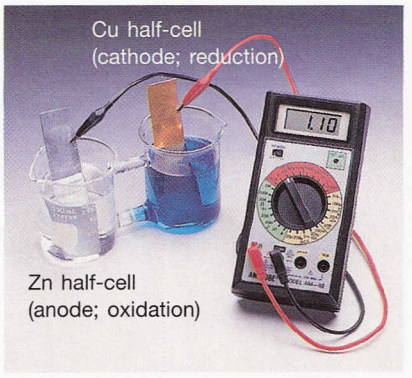
Table 21.1 Voltages of Some Voltaic Cells

Voltaic Cell	Voltage (V)
Common alkaline flashlight battery	1.5
Lead-acid car battery (6 cells = 12 V)	2.0
Calculator battery (mercury)	1.3
Lithium-ion laptop battery	3.7
Electric eel (~5000 cells in 6-ft eel = 750 V)	0.15
Nerve of giant squid (across cell membrane)	0.070

Standard Cell Potentials

The measured potential of a voltaic cell is affected by changes in concentration as the reaction proceeds and by energy losses due to heating of the cell and the external circuit. Therefore, in order to compare the output of different cells, we obtain a **standard cell potential (E^0_{cell}),** the potential measured at a specified temperature (usually 298 K) with no current flowing* and *all components in their standard states:* 1 atm for gases, 1 *M* for solutions, the pure solid for electrodes. When the zinc-copper cell that we diagrammed in Figure 21.5 begins operating under standard state conditions, that is, when $[Zn^{2+}] = [Cu^{2+}] = 1\ M$, the cell produces 1.10 V at 298 K (see photo):

$$Zn(s) + Cu^{2+}(aq;\ 1\ M) \longrightarrow Zn^{2+}(aq;\ 1\ M) + Cu(s) \qquad E^0_{cell} = 1.10\ V$$



The zinc-copper cell at 298 K under standard-state conditions.

Standard Electrode (Half-Cell) Potentials Just as each half-reaction makes up part of the overall reaction, the potential of each half-cell makes up a part of the overall cell potential. The **standard electrode potential ($E^0_{half\text{-}cell}$)** is the potential associated with a given half-reaction (electrode compartment) when all the components are in their standard states.

By convention, *a standard electrode potential always refers to the half-reaction written as a* ***reduction.*** For the zinc-copper reaction, for example, the standard electrode potentials for the zinc half-reaction (E^0_{zinc}, anode compartment) and for the copper half-reaction (E^0_{copper}, cathode compartment) refer to the processes written as reductions:

$$Zn^{2+}(aq) + 2e^- \longrightarrow Zn(s) \qquad E^0_{zinc}\ (E^0_{anode}) \qquad \text{[reduction]}$$
$$Cu^{2+}(aq) + 2e^- \longrightarrow Cu(s) \qquad E^0_{copper}\ (E^0_{cathode}) \qquad \text{[reduction]}$$

The overall cell reaction involves the *oxidation* of zinc at the anode, not the *reduction* of Zn^{2+}, so we reverse the zinc half-reaction:

$$Zn(s) \longrightarrow Zn^{2+}(aq) + 2e^- \qquad \text{[oxidation]}$$
$$Cu^{2+}(aq) + 2e^- \longrightarrow Cu(s) \qquad \text{[reduction]}$$

The overall redox reaction is the sum of these half-reactions:

$$Zn(s) + Cu^{2+}(aq) \longrightarrow Zn^{2+}(aq) + Cu(s)$$

Because electrons flow spontaneously toward the copper electrode (cathode), it must have a more positive $E^0_{half\text{-}cell}$ than the zinc electrode (anode). Therefore, to obtain a positive E^0_{cell}, we subtract E^0_{zinc} from E^0_{copper}:

$$E^0_{cell} = E^0_{copper} - E^0_{zinc}$$

We can generalize this result for any voltaic cell: *the standard cell potential is the difference between the standard electrode potential of the cathode (reduction) half-cell and the standard electrode potential of the anode (oxidation) half-cell:*

$$E^0_{cell} = E^0_{cathode\ (reduction)} - E^0_{anode\ (oxidation)} \qquad (21.3)$$

Determining $E^0_{half\text{-}cell}$: The Standard Hydrogen Electrode What portion of E^0_{cell} for the zinc-copper reaction is contributed by the anode half-cell (oxidation of Zn) and what portion by the cathode half-cell (reduction of Cu^{2+})? That is, how can we know half-cell potentials if we can only measure the potential of the complete cell? Half-cell potentials, such as E^0_{zinc} and E^0_{copper}, are not absolute quantities, but rather are values *relative* to that of a standard. *This standard reference half-cell has its standard electrode potential defined as zero ($E^0_{reference} \equiv 0.00\ V$).*

Animation: Galvanic Cell
Online Learning Center

*The current required to operate modern digital voltmeters makes a negligible difference in the value of E^0_{cell}.

The **standard reference half-cell** is a **standard hydrogen electrode,** which consists of a specially prepared platinum electrode immersed in a 1 *M* aqueous solution of a strong acid, $H^+(aq)$ [or $H_3O^+(aq)$], through which H_2 gas at 1 atm is bubbled. Thus, the reference half-reaction is

$$2H^+(aq;\ 1\ M) + 2e^- \rightleftharpoons H_2(g;\ 1\ \text{atm}) \qquad E^0_{\text{reference}} = 0.00\ \text{V}$$

Now we can construct a voltaic cell consisting of this reference half-cell and another half-cell whose potential we want to determine. With $E^0_{\text{reference}}$ defined as zero, the overall E^0_{cell} allows us to find the unknown standard electrode potential, E^0_{unknown}. When H_2 is oxidized, the reference half-cell is the anode, and so reduction occurs at the unknown half-cell:

$$E^0_{\text{cell}} = E^0_{\text{cathode}} - E^0_{\text{anode}} = E^0_{\text{unknown}} - E^0_{\text{reference}} = E^0_{\text{unknown}} - 0.00\ \text{V} = E^0_{\text{unknown}}$$

When H^+ is reduced, the reference half-cell is the cathode, and so oxidation occurs at the unknown half-cell:

$$E^0_{\text{cell}} = E^0_{\text{cathode}} - E^0_{\text{anode}} = E^0_{\text{reference}} - E^0_{\text{unknown}} = 0.00\ \text{V} - E^0_{\text{unknown}} = -E^0_{\text{unknown}}$$

Figure 21.7 shows a voltaic cell that has the Zn/Zn^{2+} half-reaction in one compartment and the H^+/H_2 (or H_3O^+/H_2) half-reaction in the other. The zinc electrode is negative relative to the hydrogen electrode, so we know that the zinc is being oxidized and is the anode. The measured E^0_{cell} is +0.76 V, and we use this value to find the unknown standard electrode potential, E^0_{zinc}:

$$2H^+(aq) + 2e^- \longrightarrow H_2(g) \qquad E^0_{\text{reference}} = 0.00\ \text{V} \qquad \text{[cathode; reduction]}$$
$$Zn(s) \longrightarrow Zn^{2+}(aq) + 2e^- \qquad E^0_{\text{zinc}} = ?\ \text{V} \qquad \text{[anode; oxidation]}$$
$$Zn(s) + 2H^+(aq) \longrightarrow Zn^{2+}(aq) + H_2(g) \qquad E^0_{\text{cell}} = 0.76\ \text{V}$$
$$E^0_{\text{cell}} = E^0_{\text{cathode}} - E^0_{\text{anode}} = E^0_{\text{reference}} - E^0_{\text{zinc}}$$
$$E^0_{\text{zinc}} = E^0_{\text{reference}} - E^0_{\text{cell}} = 0.00\ \text{V} - 0.76\ \text{V} = -0.76\ \text{V}$$

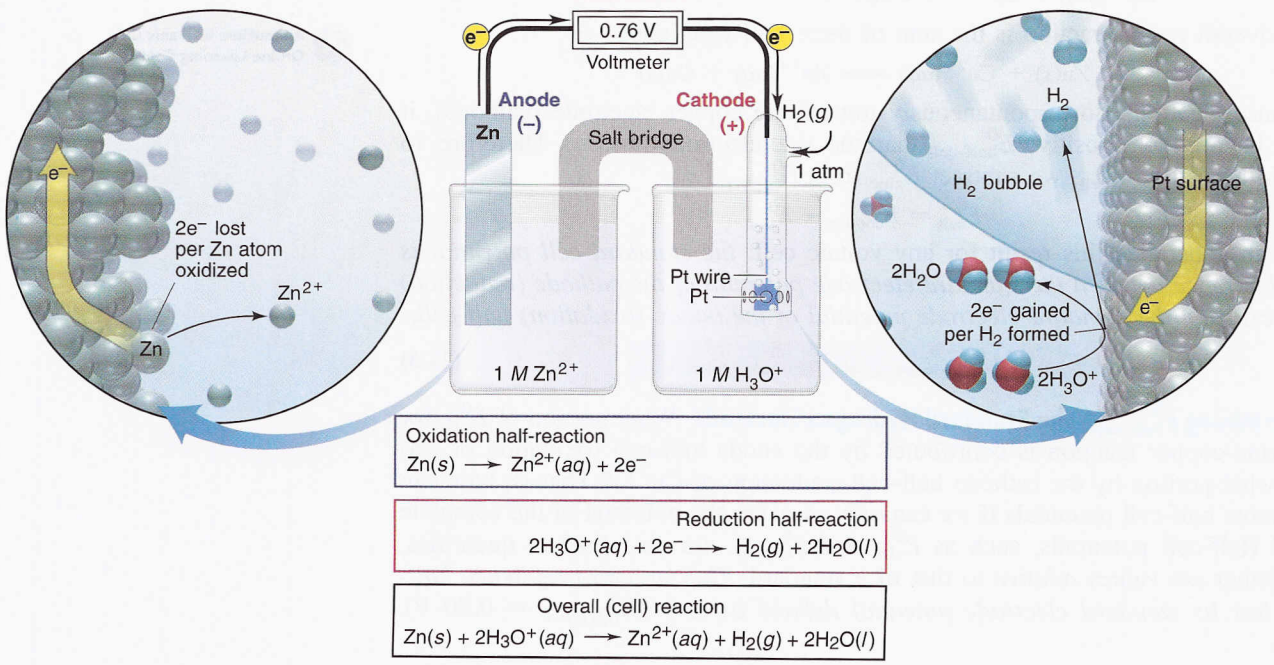


Figure 21.7 Determining an unknown $E^0_{\text{half-cell}}$ with the standard reference (hydrogen) electrode. A voltaic cell has the Zn half-reaction in one half-cell and the hydrogen reference half-reaction in the other. The magnified view of the hydrogen half-reaction shows two H_3O^+ ions being reduced to two H_2O molecules and an H_2 molecule, which enters the H_2 bubble. The Zn/Zn^{2+} half-cell potential is negative (anode), and the cell potential is 0.76 V. The potential of the standard reference electrode is defined as 0.00 V, so the cell potential equals the negative of the anode potential; that is,

$$0.76\ \text{V} = 0.00\ \text{V} - E^0_{\text{zinc}} \qquad \text{so} \qquad E^0_{\text{zinc}} = -0.76\ \text{V}$$

Now let's return to the zinc-copper cell and use the measured value of E^0_{cell} (1.10 V) and the value we just found for E^0_{zinc} to calculate E^0_{copper}:

$$E^0_{cell} = E^0_{cathode} - E^0_{anode} = E^0_{copper} - E^0_{zinc}$$
$$E^0_{copper} = E^0_{cell} + E^0_{zinc} = 1.10\ V + (-0.76\ V) = 0.34\ V$$

By continuing this process of constructing cells with one known and one unknown electrode potential, we can find many other standard electrode potentials. Let's go over these ideas once more with a sample problem.

SAMPLE PROBLEM 21.3 Calculating an Unknown $E^0_{half\text{-}cell}$ from E^0_{cell}

Problem A voltaic cell houses the reaction between aqueous bromine and zinc metal:

$$Br_2(aq) + Zn(s) \longrightarrow Zn^{2+}(aq) + 2Br^-(aq) \qquad E^0_{cell} = 1.83\ V$$

Calculate $E^0_{bromine}$, given $E^0_{zinc} = -0.76$ V.

Plan E^0_{cell} is positive, so the reaction is spontaneous as written. By dividing the reaction into half-reactions, we see that Br_2 is reduced and Zn is oxidized; thus, the zinc half-cell contains the anode. We use Equation 21.3 to find $E^0_{unknown}$ ($E^0_{bromine}$).

Solution Dividing the reaction into half-reactions:

$$Br_2(aq) + 2e^- \longrightarrow 2Br^-(aq) \qquad E^0_{unknown} = E^0_{bromine} = ?\ V$$
$$Zn(s) \longrightarrow Zn^{2+}(aq) + 2e^- \qquad E^0_{zinc} = -0.76\ V$$

Calculating $E^0_{bromine}$:

$$E^0_{cell} = E^0_{cathode} - E^0_{anode} = E^0_{bromine} - E^0_{zinc}$$
$$E^0_{bromine} = E^0_{cell} + E^0_{zinc} = 1.83\ V + (-0.76\ V) = 1.07\ V$$

Check A good check is to make sure that calculating $E^0_{bromine} - E^0_{zinc}$ gives E^0_{cell}: 1.07 V − (−0.76 V) = 1.83 V.

Comment Keep in mind that, whichever is the unknown half-cell, reduction is the cathode half-reaction and oxidation is the anode half-reaction. Always subtract E^0_{anode} from $E^0_{cathode}$ to get E^0_{cell}.

FOLLOW-UP PROBLEM 21.3 A voltaic cell based on the reaction between aqueous Br_2 and vanadium(III) ions has $E^0_{cell} = 1.39$ V:

$$Br_2(aq) + 2V^{3+}(aq) + 2H_2O(l) \longrightarrow 2VO^{2+}(aq) + 4H^+(aq) + 2Br^-(aq)$$

What is $E^0_{vanadium}$, the standard electrode potential for the reduction of VO^{2+} to V^{3+}?

Relative Strengths of Oxidizing and Reducing Agents

One of the things we can learn from measuring potentials of voltaic cells is the relative strengths of the oxidizing and reducing agents involved. Three oxidizing agents present in the voltaic cell just discussed are Cu^{2+}, H^+, and Zn^{2+}. We can rank their relative oxidizing strengths by writing each half-reaction as a gain of electrons (reduction), with its corresponding standard electrode potential:

$$Cu^{2+}(aq) + 2e^- \longrightarrow Cu(s) \qquad E^0 = 0.34\ V$$
$$2H^+(aq) + 2e^- \longrightarrow H_2(g) \qquad E^0 = 0.00\ V$$
$$Zn^{2+}(aq) + 2e^- \longrightarrow Zn(s) \qquad E^0 = -0.76\ V$$

The more positive the E^0 value, the more readily the reaction (as written) occurs; thus, Cu^{2+} gains two electrons more readily than H^+, which gains them more readily than Zn^{2+}. In terms of strength as an oxidizing agent, therefore, $Cu^{2+} > H^+ > Zn^{2+}$. Moreover, this listing also ranks the strengths of the reducing agents: $Zn > H_2 > Cu$. Notice that this list of half-reactions in order of *decreasing* half-cell potential shows, *from top to bottom*, the oxidizing agents (reactants) *decreasing* in strength and the reducing agents (products) *increasing* in strength; that is, Cu^{2+} (top left) is the strongest oxidizing agent, and Zn (bottom right) is the strongest reducing agent.

By combining many pairs of half-cells into voltaic cells, we can create a list of reduction half-reactions and arrange them in *decreasing* order of standard electrode potential (from most positive to most negative). Such a list, called an *emf series* or a *table of standard electrode potentials,* appears in Appendix D, with a few examples in Table 21.2. There are several key points to keep in mind:

- All values are relative to the standard hydrogen (reference) electrode:

$$2H^+(aq;\ 1\ M) + 2e^- \rightleftharpoons H_2(g;\ 1\ \text{atm}) \qquad E^0_{\text{reference}} = 0.00\ \text{V}$$

- By convention, the half-reactions are written as *reductions,* which means that *only reactants are oxidizing agents and only products are reducing agents.*
- The more positive the $E^0_{\text{half-cell}}$, the more readily the half-reaction occurs.
- Half-reactions are shown with an equilibrium arrow because each can occur as a reduction or an oxidation (that is, take place at the cathode or anode, respectively), depending on the $E^0_{\text{half-cell}}$ of the other half-reaction.
- As Appendix D (and Table 21.2) is arranged, the strength of the oxidizing agent (reactant) *increases going up (bottom to top),* and the strength of the reducing agent (product) *increases going down (top to bottom).*

Table 21.2 Selected Standard Electrode Potentials (298 K)

Half-Reaction	$E^0_{\text{half-cell}}$ (V)
$F_2(g) + 2e^- \rightleftharpoons 2F^-(aq)$	+2.87
$Cl_2(g) + 2e^- \rightleftharpoons 2Cl^-(aq)$	+1.36
$MnO_2(s) + 4H^+(aq) + 2e^- \rightleftharpoons Mn^{2+}(aq) + 2H_2O(l)$	+1.23
$NO_3^-(aq) + 4H^+(aq) + 3e^- \rightleftharpoons NO(g) + 2H_2O(l)$	+0.96
$Ag^+(aq) + e^- \rightleftharpoons Ag(s)$	+0.80
$Fe^{3+}(aq) + e^- \rightleftharpoons Fe^{2+}(aq)$	+0.77
$O_2(g) + 2H_2O(l) + 4e^- \rightleftharpoons 4OH^-(aq)$	+0.40
$Cu^{2+}(aq) + 2e^- \rightleftharpoons Cu(s)$	+0.34
$2H^+(aq) + 2e^- \rightleftharpoons H_2(g)$	0.00
$N_2(g) + 5H^+(aq) + 4e^- \rightleftharpoons N_2H_5^+(aq)$	−0.23
$Fe^{2+}(aq) + 2e^- \rightleftharpoons Fe(s)$	−0.44
$Zn^{2+}(aq) + 2e^- \rightleftharpoons Zn(s)$	−0.76
$2H_2O(l) + 2e^- \rightleftharpoons H_2(g) + 2OH^-(aq)$	−0.83
$Na^+(aq) + e^- \rightleftharpoons Na(s)$	−2.71
$Li^+(aq) + e^- \rightleftharpoons Li(s)$	−3.05

Strength of oxidizing agent ↑ Strength of reducing agent ↓

Thus, $F_2(g)$ is the strongest oxidizing agent (has the largest positive E^0), which means $F^-(aq)$ is the weakest reducing agent. Similarly, $Li^+(aq)$ is the weakest oxidizing agent (has the most negative E^0), which means $Li(s)$ is the strongest reducing agent. (You may have noticed an analogy to conjugate acid-base pairs: a strong acid forms a weak conjugate base, and vice versa, just as a *strong oxidizing agent forms a weak reducing agent,* and vice versa.)

If you forget the ranking in the table, just rely on your chemical knowledge of the elements. You know that F_2 is very electronegative and typically occurs as F^-. It is easily reduced (gains electrons), so it must be a strong oxidizing agent (high, positive E^0). Similarly, Li metal has a low ionization energy and typically occurs as Li^+. Therefore, it is easily oxidized (loses electrons), so it must be a strong reducing agent (low, negative E^0).

Writing Spontaneous Redox Reactions Appendix D can be used to write spontaneous redox reactions, which is useful for constructing voltaic cells.

Every redox reaction is the sum of two half-reactions, so there is a reducing agent and an oxidizing agent on each side. In the zinc-copper reaction, for

instance, Zn and Cu are the reducing agents, and Cu^{2+} and Zn^{2+} are the oxidizing agents. The stronger oxidizing and reducing agents react spontaneously to form the weaker oxidizing and reducing agents:

$$\underset{\substack{\text{stronger}\\\text{reducing agent}}}{Zn(s)} + \underset{\substack{\text{stronger}\\\text{oxidizing agent}}}{Cu^{2+}(aq)} \longrightarrow \underset{\substack{\text{weaker}\\\text{oxidizing agent}}}{Zn^{2+}(aq)} + \underset{\substack{\text{weaker}\\\text{reducing agent}}}{Cu(s)}$$

Here, too, note the similarity to acid-base chemistry. The stronger acid and base spontaneously form the weaker base and acid, respectively. The members of a conjugate acid-base pair differ by a proton: the acid has the proton and the base does not. The members of a redox pair, or *redox couple,* such as Zn and Zn^{2+}, differ by one or more electrons: the reduced form (Zn) has the electrons and the oxidized form (Zn^{2+}) does not. In acid-base reactions, we compare acid and base strength using K_a and K_b values. In redox reactions, we compare oxidizing and reducing strength using E^0 values.

Based on the order of the E^0 values in Appendix D, *the stronger oxidizing agent (species on the left) has a half-reaction with a larger (more positive or less negative) E^0 value, and the stronger reducing agent (species on the right) has a half-reaction with a smaller (less positive or more negative) E^0 value*. Therefore, a spontaneous reaction ($E^0_{cell} > 0$) will occur between an oxidizing agent and a reducing agent that lies *below* it in the list. For instance, Cu^{2+} (left) and Zn (right) react spontaneously, and Zn lies below Cu^{2+}. In other words, *for a spontaneous reaction to occur, the half-reaction higher in the list proceeds at the cathode as written, and the half-reaction lower in the list proceeds at the anode in reverse*. This pairing ensures that the stronger oxidizing agent (higher on the left) and stronger reducing agent (lower on the right) will be the reactants.

However, if we know the electrode potentials, we can write a spontaneous redox reaction even if Appendix D is not available. Let's choose a pair of half-reactions from the appendix and, without referring to their relative positions in the list, arrange them into a spontaneous redox reaction:

$$Ag^+(aq) + e^- \longrightarrow Ag(s) \qquad E^0_{silver} = 0.80\ V$$
$$Sn^{2+}(aq) + 2e^- \longrightarrow Sn(s) \qquad E^0_{tin} = -0.14\ V$$

There are two steps involved:

1. Reverse one of the half-reactions into an oxidation step such that the difference of the electrode potentials (cathode *minus* anode) gives a *positive* E^0_{cell}. Note that when we reverse the half-reaction, we do *not* reverse the sign of $E^0_{half\text{-}cell}$ because the minus sign in Equation 21.3 ($E^0_{cell} = E^0_{cathode} - E^0_{anode}$) will do that.
2. Add the rearranged half-reactions to obtain a balanced overall equation. Be sure to multiply by coefficients so that e^- lost equals e^- gained and to cancel species common to both sides.

(You may be tempted in this case to add the two half-reactions as written, because you obtain a positive E^0_{cell}, but you would then have two oxidizing agents forming two reducing agents, which cannot occur.)

We want to pair the stronger oxidizing and reducing agents as reactants. The larger (more positive) E^0 value for the silver half-reaction means that Ag^+ is a stronger oxidizing agent (gains electrons more readily) than Sn^{2+}, and the smaller (more negative) E^0 value for the tin half-reaction means that Sn is a stronger reducing agent (loses electrons more readily) than Ag. Therefore, we reverse the tin half-reaction (but *not* the sign of E^0_{tin}):

$$Sn(s) \longrightarrow Sn^{2+}(aq) + 2e^- \qquad E^0_{tin} = -0.14\ V$$

Subtracting $E^0_{half\text{-}cell}$ of the tin half-reaction (anode, oxidation) from $E^0_{half\text{-}cell}$ of the silver half-reaction (cathode, reduction) gives a positive E^0_{cell}; that is, $0.80\ V - (-0.14\ V) = 0.94\ V$.

With the half-reactions written in the correct direction, we must next make sure that the *number of electrons lost in the oxidation equals the number gained in the reduction*. In this case, we double the silver (reduction) half-reaction and add the half-reactions to obtain the balanced equation:

$$2Ag^+(aq) + 2e^- \longrightarrow 2Ag(s) \qquad E^0 = 0.80\ V \quad \text{[reduction]}$$
$$Sn(s) \longrightarrow Sn^{2+}(aq) + 2e^- \qquad E^0 = -0.14\ V \quad \text{[oxidation]}$$
$$Sn(s) + 2Ag^+(aq) \longrightarrow Sn^{2+}(aq) + 2Ag(s) \qquad E^0_{cell} = E^0_{silver} - E^0_{tin} = 0.94\ V$$

With the reaction spontaneous as written, the stronger oxidizing and reducing agents are reactants, which confirms that Sn is a stronger reducing agent than Ag, and Ag^+ is a stronger oxidizing agent than Sn^{2+}.

A very important point to note is that, when we doubled the coefficients of the silver half-reaction to balance the number of electrons, we did *not* double its E^0 value—it remained 0.80 V. That is, *changing the balancing coefficients of a half-reaction does* ***not*** *change its E^0 value*. The reason is that a standard electrode potential is an *intensive* property, one that does *not* depend on the amount of substance present. The potential is the *ratio* of energy to charge. When we change the coefficients, thus changing the amount of substance, the energy *and* the charge change proportionately, so their ratio stays the same. (Recall that density, which is also an intensive property, does not change with the amount of substance because the mass *and* the volume change proportionately.)

SAMPLE PROBLEM 21.4 Writing Spontaneous Redox Reactions and Ranking Oxidizing and Reducing Agents by Strength

Problem **(a)** Combine the following three half-reactions into three balanced equations (A, B, and C) for spontaneous reactions, and calculate E^0_{cell} for each. **(b)** Rank the relative strengths of the oxidizing and reducing agents.

(1) $NO_3^-(aq) + 4H^+(aq) + 3e^- \longrightarrow NO(g) + 2H_2O(l)$ $\quad E^0 = 0.96\ V$
(2) $N_2(g) + 5H^+(aq) + 4e^- \longrightarrow N_2H_5^+(aq)$ $\quad E^0 = -0.23\ V$
(3) $MnO_2(s) + 4H^+(aq) + 2e^- \longrightarrow Mn^{2+}(aq) + 2H_2O(l)$ $\quad E^0 = 1.23\ V$

Plan **(a)** To write the redox equations, we combine the possible pairs of half-reactions: (1) and (2), (1) and (3), and (2) and (3). They are all written as reductions, so the oxidizing agents appear as reactants and the reducing agents appear as products. In each pair, we reverse the reduction half-reaction that has the smaller (less positive or more negative) E^0 value to an oxidation to obtain a positive E^0_{cell}. We make e^- lost equal e^- gained, without changing the magnitude of the E^0 value, add the half-reactions together, and then apply Equation 21.3 to find E^0_{cell}. **(b)** Because each reaction is spontaneous as written, the stronger oxidizing and reducing agents are the reactants. To obtain the overall ranking, we first rank the relative strengths within each equation and then compare them.

Solution **(a)** Combining half-reactions (1) and (2) gives equation A. The E^0 value for half-reaction (1) is larger (more positive) than that for (2), so we reverse (2) to obtain a positive E^0_{cell}:

(1) $NO_3^-(aq) + 4H^+(aq) + 3e^- \longrightarrow NO(g) + 2H_2O(l)$ $\quad E^0 = 0.96\ V$
(rev 2) $N_2H_5^+(aq) \longrightarrow N_2(g) + 5H^+(aq) + 4e^-$ $\quad E^0 = -0.23\ V$

To make e^- lost equal e^- gained, we multiply (1) by four and the reversed (2) by three; then add half-reactions and cancel appropriate numbers of common species (H^+ and e^-):

$$4NO_3^-(aq) + 16H^+(aq) + 12e^- \longrightarrow 4NO(g) + 8H_2O(l) \qquad E^0 = 0.96\ V$$
$$3N_2H_5^+(aq) \longrightarrow 3N_2(g) + 15H^+(aq) + 12e^- \qquad E^0 = -0.23\ V$$

(A) $3N_2H_5^+(aq) + 4NO_3^-(aq) + H^+(aq) \longrightarrow 3N_2(g) + 4NO(g) + 8H_2O(l)$

$E^0_{cell} = 0.96\ V - (-0.23\ V) = 1.19\ V$

Combining half-reaction (1) and half-reaction (3) gives equation B. Half-reaction (1) must be reversed:

$$\text{(rev 1)}\quad NO(g) + 2H_2O(l) \longrightarrow NO_3^-(aq) + 4H^+(aq) + 3e^- \qquad E^0 = 0.96\ V$$
$$\text{(3)}\quad MnO_2(s) + 4H^+(aq) + 2e^- \longrightarrow Mn^{2+}(aq) + 2H_2O(l) \qquad E^0 = 1.23\ V$$

We multiply reversed (1) by two and (3) by three, then add and cancel:

$$2NO(g) + 4H_2O(l) \longrightarrow 2NO_3^-(aq) + 8H^+(aq) + 6e^- \qquad E^0 = 0.96\ V$$
$$3MnO_2(s) + 12H^+(aq) + 6e^- \longrightarrow 3Mn^{2+}(aq) + 6H_2O(l) \qquad E^0 = 1.23\ V$$

$$\text{(B)}\quad 3MnO_2(s) + 4H^+(aq) + 2NO(g) \longrightarrow 3Mn^{2+}(aq) + 2H_2O(l) + 2NO_3^-(aq)$$

$$E^0_{cell} = 1.23\ V - 0.96\ V = 0.27\ V$$

Combining half-reaction (2) and half-reaction (3) gives equation C. Half-reaction (2) must be reversed:

$$\text{(rev 2)}\quad N_2H_5^+(aq) \longrightarrow N_2(g) + 5H^+(aq) + 4e^- \qquad E^0 = -0.23\ V$$
$$\text{(3)}\quad MnO_2(s) + 4H^+(aq) + 2e^- \longrightarrow Mn^{2+}(aq) + 2H_2O(l) \qquad E^0 = 1.23\ V$$

We multiply reaction (3) by two, add the half-reactions, and cancel:

$$N_2H_5^+(aq) \longrightarrow N_2(g) + 5H^+(aq) + 4e^- \qquad E^0 = -0.23\ V$$
$$2MnO_2(s) + 8H^+(aq) + 4e^- \longrightarrow 2Mn^{2+}(aq) + 4H_2O(l) \qquad E^0 = 1.23\ V$$

$$\text{(C)}\quad N_2H_5^+(aq) + 2MnO_2(s) + 3H^+(aq) \longrightarrow N_2(g) + 2Mn^{2+}(aq) + 4H_2O(l)$$

$$E^0_{cell} = 1.23\ V - (-0.23\ V) = 1.46\ V$$

(b) Ranking the oxidizing and reducing agents within each equation:

Equation (A): Oxidizing agents: $NO_3^- > N_2$ Reducing agents: $N_2H_5^+ > NO$

Equation (B): Oxidizing agents: $MnO_2 > NO_3^-$ Reducing agents: $NO > Mn^{2+}$

Equation (C): Oxidizing agents: $MnO_2 > N_2$ Reducing agents: $N_2H_5^+ > Mn^{2+}$

Determining the overall ranking of oxidizing and reducing agents. Comparing the relative strengths from the three balanced equations gives

Oxidizing agents: $MnO_2 > NO_3^- > N_2$

Reducing agents: $N_2H_5^+ > NO > Mn^{2+}$

Check As always, check that atoms and charge balance on each side of the equation. A good way to check the ranking and equations is to list the given half-reactions in order of decreasing E^0 value:

$$MnO_2(s) + 4H^+(aq) + 2e^- \longrightarrow Mn^{2+}(aq) + 2H_2O(l) \qquad E^0 = 1.23\ V$$
$$NO_3^-(aq) + 4H^+(aq) + 3e^- \longrightarrow NO(g) + 2H_2O(l) \qquad E^0 = 0.96\ V$$
$$N_2(g) + 5H^+(aq) + 4e^- \longrightarrow N_2H_5^+(aq) \qquad E^0 = -0.23\ V$$

Then the oxidizing agents (reactants) decrease in strength going down the list, so the reducing agents (products) decrease in strength going up. Moreover, each of the three spontaneous reactions (A, B, and C) should combine a reactant with a product from lower down on this list.

FOLLOW-UP PROBLEM 21.4 Is the following reaction spontaneous as written?

$$3Fe^{2+}(aq) \longrightarrow Fe(s) + 2Fe^{3+}(aq)$$

If not, write the equation for the spontaneous reaction, calculate E^0_{cell}, and rank the three species of iron in order of decreasing reducing strength.

Relative Reactivities of Metals In Chapter 4, we discussed the activity series of the metals (see Figure 4.20, p. 163), which ranks metals by their ability to "displace" one another from aqueous solution. Now you'll see *why* this displacement occurs, as well as why many, but not all, metals react with acid to form H_2, and why a few metals form H_2 even in water.

1. *Metals that can displace H_2 from acid.* The standard hydrogen half-reaction represents the reduction of H^+ ions from an acid to H_2:

$$2H^+(aq) + 2e^- \longrightarrow H_2(g) \qquad E^0 = 0.00\ V$$

To see which metals reduce H^+ (referred to as "displacing H_2") from acids, choose a metal, write its half-reaction as an oxidation, combine this half-reaction with the hydrogen half-reaction, and see if E^0_{cell} is positive. What you find is that the metals Li through Pb, those that lie *below* the standard hydrogen (reference) half-reaction in Appendix D, give a positive E^0_{cell} when reducing H^+. Iron, for example, reduces H^+ from an acid to H_2:

$$\begin{array}{rll} Fe(s) \longrightarrow Fe^{2+}(aq) + 2e^- & E^0 = -0.44\ V & \text{[anode; oxidation]} \\ 2H^+(aq) + 2e^- \longrightarrow H_2(g) & E^0 = 0.00\ V & \text{[cathode; reduction]} \\ \hline Fe(s) + 2H^+(aq) \longrightarrow H_2(g) + Fe^{2+}(aq) & E^0_{cell} = 0.00\ V - (-0.44\ V) = 0.44\ V & \end{array}$$

The lower the metal in the list, the stronger it is as a reducing agent; therefore, the more positive its half-cell potential when the half-reaction is reversed, and the higher the E^0_{cell} for its reduction of H^+ to H_2. *If E^0_{cell} for the reduction of H^+ is more positive for metal A than it is for metal B, metal A is a stronger reducing agent than metal B and a more* ***active*** *metal.*

2. *Metals that cannot displace H_2 from acid.* Metals that are *above* the standard hydrogen (reference) half-reaction *cannot* reduce H^+ from acids. When we reverse the metal half-reaction, the E^0_{cell} is negative, so the reaction does not occur. For example, the coinage metals—copper, silver, and gold, which are in Group 1B(11)—are not strong enough reducing agents to reduce H^+ from acids:

$$\begin{array}{rll} Ag(s) \longrightarrow Ag^+(aq) + e^- & E^0 = 0.80\ V & \text{[anode; oxidation]} \\ 2H^+(aq) + 2e^- \longrightarrow H_2(g) & E^0 = 0.00\ V & \text{[cathode; reduction]} \\ \hline 2Ag(s) + 2H^+(aq) \longrightarrow 2Ag^+(aq) + H_2(g) & E^0_{cell} = 0.00\ V - 0.80\ V = -0.80\ V & \end{array}$$

The higher the metal in the list, the more negative is its E^0_{cell} for the reduction of H^+ to H_2, the lower is its reducing strength, and the less active it is. Thus, gold is less active than silver, which is less active than copper.

3. *Metals that can displace H_2 from water.* Metals active enough to displace H_2 from water lie *below the half-reaction for the reduction of water:*

$$2H_2O(l) + 2e^- \longrightarrow H_2(g) + 2OH^-(aq) \qquad E = -0.42\ V$$

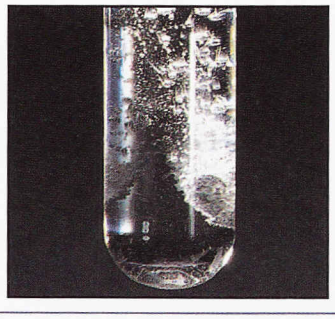
(The value shown here is the *nonstandard* electrode potential because, in pure water, $[OH^-]$ is 1.0×10^{-7} *M*, not the standard-state value of 1 *M*.) For example, consider the reaction of sodium in water (with the Na half-reaction reversed and doubled):

$$\begin{array}{rll} 2Na(s) \longrightarrow 2Na^+(aq) + 2e^- & E^0 = -2.71\ V & \text{[anode; oxidation]} \\ 2H_2O(l) + 2e^- \longrightarrow H_2(g) + 2OH^-(aq) & E = -0.42\ V & \text{[cathode; reduction]} \\ \hline 2Na(s) + 2H_2O(l) \longrightarrow 2Na^+(aq) + H_2(g) + 2OH^-(aq) & & \\ E_{cell} = -0.42\ V - (-2.71\ V) = 2.29\ V & & \end{array}$$

The alkali metals [Group 1A(1)] and the larger alkaline earth metals [Group 2A(2)] can displace H_2 from H_2O (Figure 21.8).

4. *Metals that can displace other metals from solution.* We can also predict whether one metal can reduce the aqueous ion of another metal. Any metal that is lower in the list in Appendix D can reduce the ion of a metal that is higher up, and thus displace that metal from solution. For example, zinc can displace iron from solution:

$$\begin{array}{rll} Zn(s) \longrightarrow Zn^{2+}(aq) + 2e^- & E^0 = -0.76\ V & \text{[anode; oxidation]} \\ Fe^{2+}(aq) + 2e^- \longrightarrow Fe(s) & E^0 = -0.44\ V & \text{[cathode; reduction]} \\ \hline Zn(s) + Fe^{2+}(aq) \longrightarrow Zn^{2+}(aq) + Fe(s) & E^0_{cell} = -0.44\ V - (-0.76\ V) = 0.32\ V & \end{array}$$



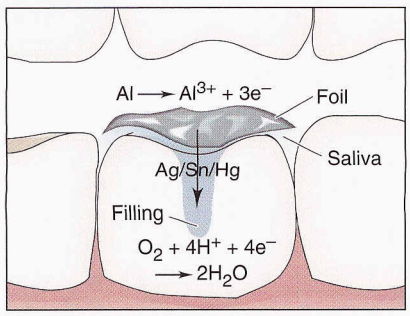
Oxidation half-reaction
$Ca(s) \longrightarrow Ca^{2+}(aq) + 2e^-$

Reduction half-reaction
$2H_2O(l) + 2e^- \longrightarrow H_2(g) + 2OH^-(aq)$

Overall (cell) reaction
$Ca(s) + 2H_2O(l) \longrightarrow Ca(OH)_2(aq) + H_2(g)$

Figure 21.8 The reaction of calcium in water. Calcium is one of the metals active enough to displace H_2 from H_2O.

This particular reaction has tremendous economic importance in protecting iron from rusting, as you'll see shortly. The reducing power of metals has other, more personal, consequences, as the margin note points out.



The Pain of a Dental Voltaic Cell
Have you ever felt a jolt of pain when biting down with a filled tooth on a scrap of foil left on a piece of food? Here's the reason. The aluminum foil acts as an active anode (E^0 of Al = −1.66 V), saliva as the electrolyte, and the filling (usually a silver/tin/mercury alloy) as an inactive cathode. O_2 is reduced to water, and the short circuit between the foil in contact with the filling creates a current that is sensed by the nerve of the tooth.

SECTION SUMMARY

The output of a cell is called the cell potential (E_{cell}) and is measured in volts (1 V = 1 J/C). When all substances are in their standard states, the output is the standard cell potential (E^0_{cell}). $E^0_{cell} > 0$ for a spontaneous reaction at standard-state conditions. By convention, a standard electrode potential ($E^0_{half\text{-}cell}$) refers to the *reduction* half-reaction. E^0_{cell} equals $E^0_{half\text{-}cell}$ of the cathode *minus* $E^0_{half\text{-}cell}$ of the anode. Using a standard hydrogen (reference) electrode, other $E^0_{half\text{-}cell}$ values can be measured and used to rank oxidizing (or reducing) agents (see Appendix D). Spontaneous redox reactions combine stronger oxidizing and reducing agents to form weaker ones. A metal can reduce another species (H^+, H_2O, or an ion of another metal) if E^0_{cell} for the reaction is positive.

21.4 FREE ENERGY AND ELECTRICAL WORK

In Chapter 20, we discussed the relationship of useful work, free energy, and the equilibrium constant. In this section, we examine this relationship in the context of electrochemical cells and see the effect of concentration on cell potential.

Standard Cell Potential and the Equilibrium Constant

As you know from Section 20.3, a spontaneous reaction has a *negative* free energy change ($\Delta G < 0$), and you've just seen that a spontaneous electrochemical reaction has a *positive* cell potential ($E_{cell} > 0$). Note that *the signs of ΔG and E_{cell} are opposite for a spontaneous reaction.* These two indications of spontaneity are proportional to each other:

$$\Delta G \propto -E_{cell}$$

Let's determine this proportionality constant by focusing on the electrical work done (w, in joules), which is the product of the potential (E_{cell}, in volts) and the amount of charge that flows (in coulombs):

$$w = E_{cell} \times \text{charge}$$

The value used for E_{cell} is measured with no current flowing and, therefore, no energy lost to heating the cell. Thus, E_{cell} is the maximum voltage the cell can generate, that is, the maximum work the system can do *on* the surroundings. Recall from Chapter 20 that *only a reversible process can do maximum work.* For no current to flow and the process to be reversible, E_{cell} must be opposed by an equal potential in the measuring circuit. (In this case, a reversible process means that, if the opposing potential is infinitesimally smaller, the cell reaction goes forward; if it is infinitesimally larger, the reaction goes backward.) Equation 20.9, p. 884, shows that the maximum work done *on* the surroundings is $-\Delta G$:

$$w_{max} = E_{cell} \times \text{charge} = -\Delta G \qquad \text{or} \qquad \Delta G = -E_{cell} \times \text{charge}$$

The charge that flows through the cell equals the number of moles of electrons (n) transferred times the charge of 1 mol of electrons (symbol F):

$$\text{Charge} = \text{moles of } e^- \times \frac{\text{charge}}{\text{mol } e^-} \qquad \text{or} \qquad \text{charge} = nF$$

The charge of 1 mol of electrons is the **Faraday constant (F),** named in honor of Michael Faraday, the 19th-century British scientist who pioneered the study of electrochemistry:

$$F = \frac{96{,}485 \text{ C}}{\text{mol } e^-}$$

Because 1 V = 1 J/C, we have 1 C = 1 J/V, and

$$F = 9.65\times10^4 \frac{\text{J}}{\text{V·mol e}^-} \quad (3 \text{ sf}) \tag{21.4}$$

Substituting for charge, the proportionality constant is nF:

$$\Delta G = -nFE_{\text{cell}} \tag{21.5}$$

When all of the components are in their standard states, we have

$$\Delta G^0 = -nFE^0_{\text{cell}} \tag{21.6}$$

Using this relationship, we can relate the standard cell potential to the equilibrium constant of the redox reaction. Recall that

$$\Delta G^0 = -RT \ln K$$

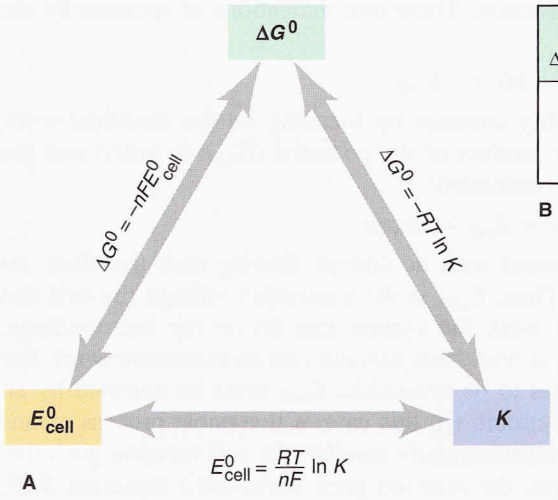
Substituting for ΔG^0 from Equation 21.6 gives

$$-nFE^0_{\text{cell}} = -RT \ln K$$

Solving for E^0_{cell} gives

$$E^0_{\text{cell}} = \frac{RT}{nF} \ln K \tag{21.7}$$

Figure 21.9 summarizes the interconnections among the standard free energy change, the equilibrium constant, and the standard cell potential. The procedures presented in Chapter 20 for determining K required that we know ΔG^0, either from ΔH^0 and ΔS^0 values or from ΔG^0_f values. For redox reactions, we now have a direct experimental method for determining K *and* ΔG^0: measure E^0_{cell}.



ΔG^0	K	E^0_{cell}	Reaction at standard-state conditions
<0	>1	>0	Spontaneous
0	1	0	At equilibrium
>0	<1	<0	Nonspontaneous

B

Figure 21.9 The interrelationship of ΔG^0, E^0_{cell}, and K. A, Any one of these three central thermodynamic parameters can be used to find the other two. **B,** The signs of ΔG^0 and E^0_{cell} determine the reaction direction at standard-state conditions.

It is common practice to simplify Equation 21.7 in calculations by

- Substituting the known value of 8.314 J/(mol rxn·K) for the constant R
- Substituting the known value of 9.65×10^4 J/(V·mol e$^-$) for the constant F
- Substituting the standard temperature of 298.15 K for T, but keeping in mind that the cell can run at other temperatures.
- Multiplying by 2.303 to convert from natural to common (base-10) logarithms. This conversion shows that a *10-fold change in K makes E^0_{cell} change by 1,* which arises from the close connection between cell voltage and pH.

Thus, when n moles of e^- are transferred per mole of reaction in the balanced equation, this simplified relation between E^0_{cell} and K gives

$$E^0_{cell} = \frac{RT}{nF}\ln K = 2.303\frac{RT}{nF}\log K = 2.303 \times \frac{8.314\ \frac{\cancel{J}}{\cancel{mol\ rxn \cdot K}} \times 298.15\ \cancel{K}}{\frac{n\ \cancel{mol\ e^-}}{\cancel{mol\ rxn}}\left(9.65\times10^4\ \frac{\cancel{J}}{V\cdot\cancel{mol\ e^-}}\right)}\log K$$

And, we have

$$E^0_{cell} = \frac{0.0592\ V}{n}\log K \quad \text{or} \quad \log K = \frac{nE^0_{cell}}{0.0592\ V} \quad \text{(at 298 K)} \qquad \textbf{(21.8)}$$

SAMPLE PROBLEM 21.5 Calculating K and ΔG^0 from E^0_{cell}

Problem Lead can displace silver from solution:

$$Pb(s) + 2Ag^+(aq) \longrightarrow Pb^{2+}(aq) + 2Ag(s)$$

As a consequence, silver is a valuable by-product in the industrial extraction of lead from its ore. Calculate K and ΔG^0 at 298 K for this reaction.

Plan We divide the spontaneous redox equation into the half-reactions and use values from Appendix D to calculate E^0_{cell}. Then, we substitute this result into Equation 21.8 to find K and into Equation 21.6 to find ΔG^0.

Solution Writing the half-reactions and their E^0 values:

(1) $Ag^+(aq) + e^- \longrightarrow Ag(s)$ $\quad E^0 = 0.80$ V

(2) $Pb^{2+}(aq) + 2e^- \longrightarrow Pb(s)$ $\quad E^0 = -0.13$ V

Calculating E^0_{cell}: We double (1), reverse (2), add the half-reactions, and subtract E^0_{lead} from E^0_{silver}:

$2Ag^+(aq) + 2e^- \longrightarrow 2Ag(s)$ $\quad E^0 = 0.80$ V

$Pb(s) \longrightarrow Pb^{2+}(aq) + 2e^-$ $\quad E^0 = -0.13$ V

$Pb(s) + 2Ag^+(aq) \longrightarrow Pb^{2+}(aq) + 2Ag(s)$ $\quad E^0_{cell} = 0.80\ V - (-0.13\ V) = 0.93\ V$

Calculating K with Equations 21.7 and 21.8:

$$E^0_{cell} = \frac{RT}{nF}\ln K = 2.303\frac{RT}{nF}\log K$$

The adjusted half-reactions show that 2 mol of e^- are transferred per mole of reaction as written, so $n = 2$. Then, performing the substitutions for R and F that we just discussed with the cell running at 25°C (298 K), we have

$$E^0_{cell} = \frac{0.0592\ V}{2}\log K = 0.93\ V$$

So, $$\log K = \frac{0.93\ V \times 2}{0.0592\ V} = 31.42 \quad \text{and} \quad K = 2.6\times10^{31}$$

Calculating ΔG^0 (Equation 21.6):

$$\Delta G^0 = -nFE^0_{cell} = -\frac{2\ mol\ e^-}{mol\ rxn} \times \frac{96.5\ kJ}{V\cdot mol\ e^-} \times 0.93\ V = -1.8\times10^2\ kJ/mol\ rxn$$

Check The three variables are consistent with the reaction being spontaneous at standard-state conditions: $E^0_{cell} > 0$, $\Delta G^0 < 0$, and $K > 1$. Be sure to round and check the order of magnitude: in the ΔG^0 calculation, for instance, $\Delta G^0 \approx -2 \times 100 \times 1 = -200$, so the overall math seems right. Another check would be to obtain ΔG^0 directly from its relation with K:

$$\Delta G^0 = -RT\ln K = -8.314\ J/mol\ rxn\cdot K \times 298\ K \times \ln(2.6\times10^{31})$$
$$= -1.8\times10^5\ J/mol\ rxn = -1.8\times10^2\ kJ/mol\ rxn$$

FOLLOW-UP PROBLEM 21.5 When cadmium metal reduces Cu^{2+} in solution, Cd^{2+} forms in addition to copper metal. If $\Delta G^0 = -143$ kJ, calculate K at 25°C. What is E^0_{cell} of a voltaic cell that uses this reaction?

The Effect of Concentration on Cell Potential

So far, we've considered cells with all components in their standard states and found standard cell potential (E^0_{cell}) from standard half-cell potentials ($E^0_{half\text{-}cell}$). However, most cells do not start with all components in their standard states, and even if they did, the concentrations change after a few moments of operation. Moreover, in all practical voltaic cells, such as batteries, reactant concentrations are far from standard-state values. Clearly, we must be able to determine E_{cell}, the cell potential under nonstandard conditions.

To do so, let's derive an expression for the relation between cell potential and concentration based on the relation between free energy and concentration. Recall from Chapter 20 (Equation 20.13) that ΔG equals ΔG^0 (the free energy change when the system moves from standard-state concentrations to equilibrium) *plus* $RT \ln Q$ (the free energy change when the system moves from nonstandard-state to standard-state concentrations):

$$\Delta G = \Delta G^0 + RT \ln Q$$

ΔG is related to E_{cell} and ΔG^0 to E^0_{cell} (Equations 21.5 and 21.6), so we substitute for them and get

$$-nFE_{cell} = -nFE^0_{cell} + RT \ln Q$$

Dividing both sides by $-nF$, we obtain the **Nernst equation,** developed by the German chemist Walther Hermann Nernst in 1889:

$$E_{cell} = E^0_{cell} - \frac{RT}{nF} \ln Q \qquad (21.9)$$

The Nernst equation says that a cell potential under any conditions depends on the potential at standard-state concentrations *and* a term for the potential at nonstandard-state concentrations. How do changes in Q affect cell potential? From Equation 21.9, we see that

- When $Q < 1$ and thus [reactant] > [product], $\ln Q < 0$, so $E_{cell} > E^0_{cell}$.
- When $Q = 1$ and thus [reactant] = [product], $\ln Q = 0$, so $E_{cell} = E^0_{cell}$.
- When $Q > 1$ and thus [reactant] < [product], $\ln Q > 0$, so $E_{cell} < E^0_{cell}$.

As before, to obtain a simplified form of the Nernst equation for use in calculations, let's substitute known values of R and F, operate the cell at 298.15 K, and convert to common (base-10) logarithms:

$$E_{cell} = E^0_{cell} - \frac{RT}{nF} \ln Q = E^0_{cell} - 2.303 \frac{RT}{nF} \log Q$$

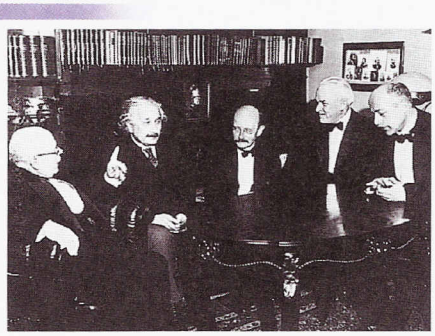
$$= E^0_{cell} - 2.303 \times \frac{8.314 \dfrac{\cancel{\text{J}}}{\text{mol rxn}\cdot\cancel{\text{K}}} \times 298.15\ \cancel{\text{K}}}{\dfrac{n\ \text{mol}\ \cancel{e^-}}{\text{mol rxn}} \left(9.65\times10^4 \dfrac{\cancel{\text{J}}}{\text{V}\cdot\text{mol}\ \cancel{e^-}}\right)} \log Q$$

And we obtain:

$$E_{cell} = E^0_{cell} - \frac{0.0592\ \text{V}}{n} \log Q \quad \text{(at 298 K)} \qquad (21.10)$$

Remember that the expression for Q *contains only those species with concentrations (and/or pressures) that can vary;* thus, solids do not appear, even when they are the electrodes. For example, in the reaction between cadmium and silver ion, the Cd and Ag electrodes do not appear in the expression for Q:

$$Cd(s) + 2Ag^+(aq) \longrightarrow Cd^{2+}(aq) + 2Ag(s) \qquad Q = \frac{[Cd^{2+}]}{[Ag^+]^2}$$



Walther Hermann Nernst (1864–1941)
This great German physical chemist was only 25 years old when he developed the equation for the relationship between cell voltage and concentration. His career, which culminated in the Nobel Prize in chemistry in 1920, included formulating the third law of thermodynamics, establishing the principle of the solubility product, and contributing key ideas to photochemistry and the Haber process. He is shown here in later years making a point to a few of his celebrated colleagues: from left to right, Nernst, Albert Einstein, Max Planck, Robert Millikan, and Max von Laue.

SAMPLE PROBLEM 21.6 Using the Nernst Equation to Calculate E_{cell}

Problem In a test of a new reference electrode, a chemist constructs a voltaic cell consisting of a Zn/Zn^{2+} half-cell and an H_2/H^+ half-cell under the following conditions:

$$[Zn^{2+}] = 0.010\ M \qquad [H^+] = 2.5\ M \qquad P_{H_2} = 0.30\ \text{atm}$$

Calculate E_{cell} at 298 K.

Plan To apply the Nernst equation and determine E_{cell}, we must know E^0_{cell} and Q. We write the spontaneous reaction, calculate E^0_{cell} from standard electrode potentials (Appendix D), and use the given pressure and concentrations to find Q. (Recall that the ideal gas law allows us to use P at constant T as another way of writing concentration, n/V.) Then we substitute into Equation 21.10.

Solution Determining the cell reaction and E^0_{cell}:

$$2H^+(aq) + 2e^- \longrightarrow H_2(g) \qquad E^0 = 0.00\ \text{V}$$
$$Zn(s) \longrightarrow Zn^{2+}(aq) + 2e^- \qquad E^0 = -0.76\ \text{V}$$
$$2H^+(aq) + Zn(s) \longrightarrow H_2(g) + Zn^{2+}(aq) \qquad E^0_{cell} = 0.00\ \text{V} - (-0.76\ \text{V}) = 0.76\ \text{V}$$

Calculating Q:

$$Q = \frac{P_{H_2} \times [Zn^{2+}]}{[H^+]^2} = \frac{0.30 \times 0.010}{2.5^2} = 4.8\times10^{-4}$$

Solving for E_{cell} at 25°C (298 K), with $n = 2$:

$$E_{cell} = E^0_{cell} - 2.303\frac{RT}{nF}\log Q = E^0_{cell} - \frac{0.0592\ \text{V}}{n}\log Q$$
$$= 0.76\ \text{V} - \left[\frac{0.0592\ \text{V}}{2}\log(4.8\times10^{-4})\right] = 0.76\ \text{V} - (-0.0982\ \text{V}) = 0.86\ \text{V}$$

Check After you check the arithmetic, reason through the answer: $E_{cell} > E^0_{cell}$ $(0.86 > 0.76)$ because the log Q term was negative, which is consistent with $Q < 1$; that is, the amounts of products, P_{H_2} and $[Zn^{2+}]$, are smaller than the amount of reactant, $[H^+]$.

FOLLOW-UP PROBLEM 21.6 Consider a voltaic cell based on the following reaction: $Fe(s) + Cu^{2+}(aq) \longrightarrow Fe^{2+}(aq) + Cu(s)$. If $[Cu^{2+}] = 0.30\ M$, what must $[Fe^{2+}]$ be to increase E_{cell} by 0.25 V above E^0_{cell} at 25°C?

Changes in Potential During Cell Operation

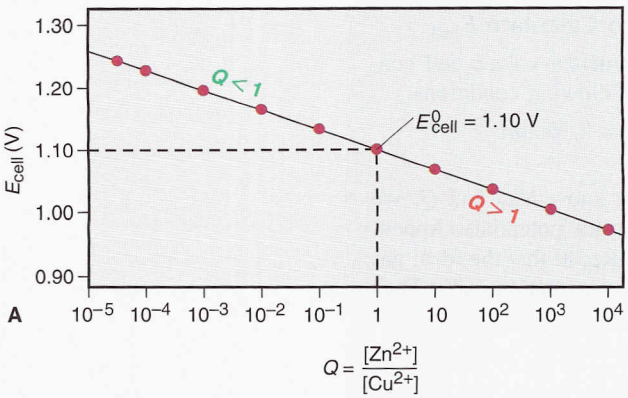
Let's see how the potential of the zinc-copper cell changes as concentrations change during cell operation. In this case, the only concentrations that change are [reactant] = $[Cu^{2+}]$ and [product] = $[Zn^{2+}]$:

$$Zn(s) + Cu^{2+}(aq) \longrightarrow Zn^{2+}(aq) + Cu(s) \qquad Q = \frac{[Zn^{2+}]}{[Cu^{2+}]}$$

The positive E^0_{cell} (1.10 V) means that this reaction proceeds *spontaneously* from standard-state conditions, at which $[Zn^{2+}] = [Cu^{2+}] = 1\ M$ $(Q = 1)$, to some point at which $[Zn^{2+}] > [Cu^{2+}]$ $(Q > 1)$. Now, suppose that we start the cell when $[Zn^{2+}] < [Cu^{2+}]$ $(Q < 1)$, for example, when $[Zn^{2+}] = 1.0\times10^{-4}\ M$ and $[Cu^{2+}] = 2.0\ M$. Thus, the cell potential is *higher* than the standard cell potential:

$$E_{cell} = E^0_{cell} - \frac{0.0592\ \text{V}}{2}\log\frac{[Zn^{2+}]}{[Cu^{2+}]} = 1.10\ \text{V} - \left(\frac{0.0592\ \text{V}}{2}\log\frac{1.0\times10^{-4}}{2.0}\right)$$
$$= 1.10\ \text{V} - \left[\frac{0.0592\ \text{V}}{2}(-4.30)\right] = 1.10\ \text{V} + 0.127\ \text{V} = 1.23\ \text{V}$$

As the cell operates, $[Zn^{2+}]$ increases (as the Zn electrode deteriorates) and $[Cu^{2+}]$ decreases (as Cu plates out on the Cu electrode). Although the changes during this process occur smoothly, if we keep Equation 21.10 in mind, we can



A

Changes in E_{cell} and Concentration

Stage in cell operation	Q	Relative [P] and [R]	$\frac{0.0592\ V}{n} \log Q$
1. $E > E^0$	<1	[P] < [R]	<0
2. $E = E^0$	=1	[P] = [R]	=0
3. $E < E^0$	>1	[P] > [R]	>0
4. $E = 0$	$=K$	[P] ≫ [R]	$=E^0$

B

Figure 21.10 The relation between E_{cell} and log Q for the zinc-copper cell. A, A plot of E_{cell} vs. Q (on a logarithmic scale) for the zinc-copper cell shows a linear decrease. When $Q < 1$ (*left*), [reactant] is relatively high, and the cell can do relatively more work. When $Q = 1$, $E_{cell} = E^0_{cell}$. When $Q > 1$ (*right*), [reactant] is relatively low, and the cell can do relatively less work. **B,** A summary of the changes in E_{cell} as the cell operates, including the changes in $[Zn^{2+}]$, denoted [P] for [product], and $[Cu^{2+}]$, denoted [R] for [reactant].

identify four general stages of operation. Figure 21.10A shows the first three. The main point to note is *as the cell operates, its potential decreases:*

Stage 1. $E_{cell} > E^0_{cell}$ when $Q < 1$: When the cell begins operation, $[Cu^{2+}] > [Zn^{2+}]$, so the $[(0.0592\ V/n) \log Q]$ term < 0 and $E_{cell} > E^0_{cell}$.

As cell operation continues, $[Zn^{2+}]$ increases and $[Cu^{2+}]$ decreases; thus, Q becomes larger, the $[(0.0592\ V/n) \log Q]$ term becomes less negative (more positive), and E_{cell} decreases.

Stage 2. $E_{cell} = E^0_{cell}$ when $Q = 1$: At the point when $[Cu^{2+}] = [Zn^{2+}]$, $Q = 1$, so the $[(0.0592\ V/n) \log Q]$ term $= 0$ and $E_{cell} = E^0_{cell}$.

Stage 3. $E_{cell} < E^0_{cell}$ when $Q > 1$: As the $[Zn^{2+}]/[Cu^{2+}]$ ratio continues to increase, the $[(0.0592\ V/n) \log Q]$ term > 0, so $E_{cell} < E^0_{cell}$.

Stage 4. $E_{cell} = 0$ when $Q = K$: Eventually, the $[(0.0592\ V/n) \log Q]$ term becomes so large that it equals E^0_{cell}, which means that E_{cell} is zero. This occurs *when the system reaches* ***equilibrium:*** *no more free energy is released, so the cell can do no more work.* At this point, we say that a battery is "dead."

Figure 21.10B summarizes these four key stages in the operation of a voltaic cell.

Let's find K for the zinc-copper cell. At equilibrium, Equation 21.10 becomes

$$0 = E^0_{cell} - \left(\frac{0.0592\ V}{n}\right) \log K, \text{ which rearranges to } E^0_{cell} = \frac{0.0592\ V}{n} \log K$$

Note that this result is identical to Equation 21.8, which we obtained from ΔG^0. Solving for K of the zinc-copper cell ($E^0_{cell} = 1.10$ V),

$$\log K = \frac{2 \times E^0_{cell}}{0.0592\ V}, \qquad \text{so} \qquad K = 10^{(2\times 1.10\ V)/0.0592\ V} = 10^{37.16} = 1.4\times 10^{37}$$

Thus, the zinc-copper cell does work until the $[Zn^{2+}]/[Cu^{2+}]$ ratio is *very* high.

To conclude, let's examine cell potential in terms of the *starting* Q/K ratio:

- If $Q/K < 1$, E_{cell} is positive for the reaction *as written*. The smaller the Q/K ratio, the greater the value of E_{cell}, and the more electrical work the cell can do.
- If $Q/K = 1$, $E_{cell} = 0$. The cell is at equilibrium and can no longer do work.
- If $Q/K > 1$, E_{cell} is negative for the reaction as written. The reverse reaction will take place, and the cell will do work until Q/K equals 1 at equilibrium.

Concentration Cells

If you mix a concentrated solution and a dilute solution of a salt, you know that the final concentration equals some intermediate value. A **concentration cell** employs this phenomenon to generate electrical energy. The two solutions are in separate half-cells, so they do not mix; rather, their concentrations become equal as the cell operates.

How a Concentration Cell Works Suppose both compartments of a voltaic cell house the Cu/Cu^{2+} half-reaction. The cell reaction is the sum of identical half-reactions, written in opposite directions, so the *standard* half-cell potentials cancel ($E^0_{copper} - E^0_{copper}$) and E^0_{cell} is zero. This occurs because standard electrode potentials are based on concentrations of 1 *M*. *In a concentration cell, however, the half-reactions are the same but the* ***concentrations*** *are different.* As a result, even though E^0_{cell} equals zero, the *nonstandard* cell potential, E_{cell}, does *not* equal zero because it depends on the ratio of concentrations.

In Figure 21.11A, a concentration cell has 0.10 *M* Cu^{2+} in the anode half-cell and 1.0 *M* Cu^{2+}, a 10-fold higher concentration, in the cathode half-cell:

$$Cu(s) \longrightarrow Cu^{2+}(aq;\ 0.10\ M) + 2e^- \qquad \text{[anode; oxidation]}$$

$$Cu^{2+}(aq;\ 1.0\ M) + 2e^- \longrightarrow Cu(s) \qquad \text{[cathode; reduction]}$$

The overall cell reaction is the sum of the half-reactions:

$$Cu^{2+}(aq;\ 1.0\ M) \longrightarrow Cu^{2+}(aq;\ 0.10\ M) \qquad E_{cell} = ?$$

The cell potential at the initial concentrations of 0.10 *M* (dilute) and 1.0 *M* (concentrated), with $n = 2$, is obtained from the Nernst equation:

$$E_{cell} = E^0_{cell} - \frac{0.0592\ V}{2} \log \frac{[Cu^{2+}]_{dil}}{[Cu^{2+}]_{conc}} = 0\ V - \left(\frac{0.0592\ V}{2} \log \frac{0.10\ M}{1.0\ M}\right)$$

$$= 0\ V - \left[\frac{0.0592\ V}{2}(-1.00)\right] = 0.0296\ V$$

As you can see, because E^0_{cell} for a concentration cell equals zero, E_{cell} for nonstandard conditions depends entirely on the $[(0.0592\ V/n) \log Q]$ term.

What is actually going on as this cell operates? In the half-cell with dilute electrolyte (anode), the Cu atoms in the electrode give up electrons and become Cu^{2+} ions, which enter the solution and make it *more* concentrated. The electrons released at the anode flow to the cathode compartment. There, Cu^{2+} ions in the concentrated solution pick up the electrons and become Cu atoms, which plate out on the electrode, so that solution becomes *less* concentrated. As in any voltaic cell, E_{cell} decreases until equilibrium is attained, which happens when $[Cu^{2+}]$ is the same in both half-cells (Figure 21.11B). The same final concentration would result if we mixed the two solutions, but no electrical work would be done.

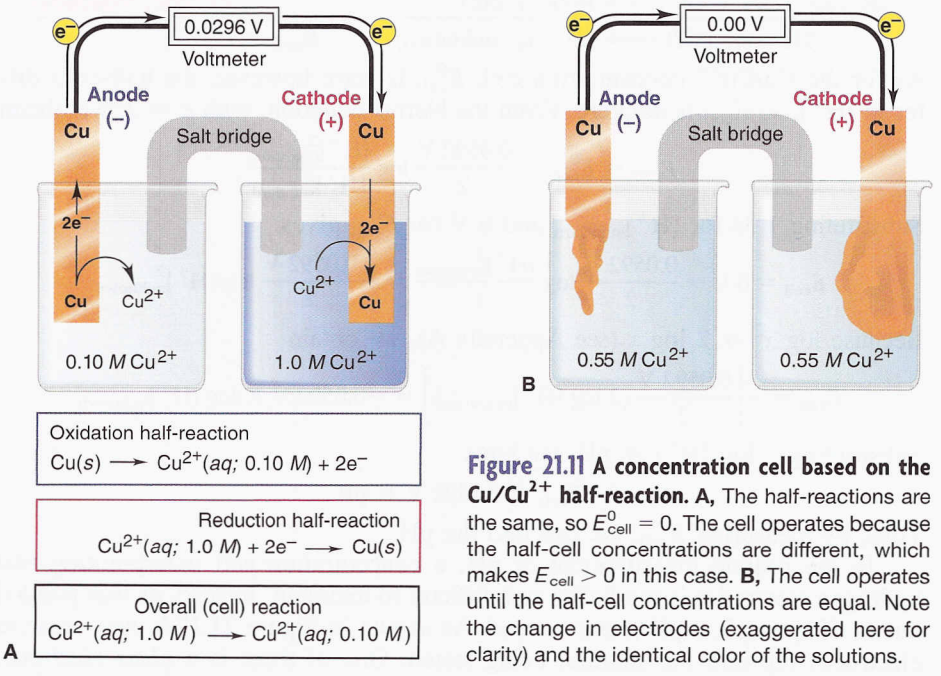


Figure 21.11 A concentration cell based on the Cu/Cu^{2+} half-reaction. A, The half-reactions are the same, so $E^0_{cell} = 0$. The cell operates because the half-cell concentrations are different, which makes $E_{cell} > 0$ in this case. **B,** The cell operates until the half-cell concentrations are equal. Note the change in electrodes (exaggerated here for clarity) and the identical color of the solutions.

SAMPLE PROBLEM 21.7 Calculating the Potential of a Concentration Cell

Problem A concentration cell consists of two Ag/Ag^+ half-cells. In half-cell A, electrode A dips into 0.010 M $AgNO_3$; in half-cell B, electrode B dips into 4.0×10^{-4} M $AgNO_3$. What is the cell potential at 298 K? Which electrode has a positive charge?

Plan The standard half-cell reactions are identical, so E^0_{cell} is zero, and we calculate E_{cell} from the Nernst equation. Because half-cell A has a higher $[Ag^+]$, Ag^+ ions will be reduced and plate out on electrode A. In half-cell B, Ag will be oxidized and Ag^+ ions will enter the solution. As in all voltaic cells, reduction occurs at the cathode, which is positive.

Solution Writing the spontaneous reaction: The $[Ag^+]$ decreases in half-cell A and increases in half-cell B, so the spontaneous reaction is

$$Ag^+(aq;\ 0.010\ M)\ \text{[half-cell A]} \longrightarrow Ag^+(aq;\ 4.0\times10^{-4}\ M)\ \text{[half-cell B]}$$

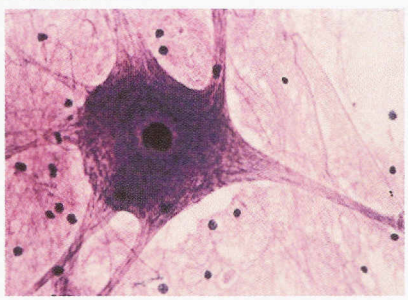
Calculating E_{cell}, with $n = 1$:

$$E_{cell} = E^0_{cell} - \frac{0.0592\ \text{V}}{1}\log\frac{[Ag^+]_{dil}}{[Ag^+]_{conc}} = 0\ \text{V} - \left(0.0592\ \text{V}\log\frac{4.0\times10^{-4}}{0.010}\right)$$

$$= 0.0828\ \text{V}$$

Reduction occurs at the cathode, electrode A: $Ag^+(aq;\ 0.010\ M) + e^- \longrightarrow Ag(s)$. Thus, electrode A has a positive charge due to a relative electron deficiency.

FOLLOW-UP PROBLEM 21.7 A concentration cell is built using two Au/Au^{3+} half-cells. In half-cell A, $[Au^{3+}] = 7.0\times10^{-4}$ M, and in half-cell B, $[Au^{3+}] = 2.5\times10^{-2}$ M. What is E_{cell}, and which electrode is negative?



Concentration Cells in Your Nerve Cells The nerve cells that mediate every thought, movement, and other bodily process function by the principle of a concentration cell. The nerve membrane is imbedded with a host of specialized enzyme "gates" that use energy from ATP hydrolysis to separate an *interior* solution of low $[Na^+]$ and high $[K^+]$ from an *exterior* solution of high $[Na^+]$ and low $[K^+]$. As a result of the differences in $[Na^+]$ and $[K^+]$, the membrane is more positive outside than inside. One third of the body's ATP is used to create and maintain these concentration differences. (The 1997 Nobel Prize in chemistry was shared by Jens C. Skou for elucidation of this enzyme mechanism.) When the nerve membrane is stimulated, Na^+ ions spontaneously rush in, and in 0.001 s, the inside of the membrane becomes more positive than the outside. This event is followed by K^+ ions spontaneously rushing out; after another 0.001 s, the membrane is again more positive outside. These large changes in charge in one region of the membrane stimulate the neighboring region and the electrical impulse moves down the length of the cell.

Applications of Concentration Cells Chemists, biologists, and environmental scientists apply the principle of a concentration cell in a host of applications. The most important is the measurement of unknown ion concentrations, particularly $[H^+]$. Suppose we construct a concentration cell based on the H_2/H^+ half-reaction, in which the cathode compartment houses the standard hydrogen electrode and the anode compartment has the same apparatus dipping into an unknown $[H^+]$ in solution. The half-reactions and overall reaction are

$$H_2(g;\ 1\ \text{atm}) \longrightarrow 2H^+(aq;\ \text{unknown}) + 2e^- \quad \text{[anode; oxidation]}$$

$$2H^+(aq;\ 1\ M) + 2e^- \longrightarrow H_2(g;\ 1\ \text{atm}) \quad \text{[cathode; reduction]}$$

$$2H^+(aq;\ 1\ M) \longrightarrow 2H^+(aq;\ \text{unknown}) \qquad E_{cell} = ?$$

As for the Cu/Cu^{2+} concentration cell, E^0_{cell} is zero; however, the half-cells differ in $[H^+]$, so E_{cell} is *not* zero. From the Nernst equation, with $n = 2$, we obtain

$$E_{cell} = E^0_{cell} - \frac{0.0592\ \text{V}}{2}\log\frac{[H^+]^2_{unknown}}{[H^+]^2_{standard}}$$

Substituting 1 M for $[H^+]_{standard}$ and 0 V for E^0_{cell} gives

$$E_{cell} = 0\ \text{V} - \frac{0.0592\ \text{V}}{2}\log\frac{[H^+]^2_{unknown}}{1^2} = -\frac{0.0592\ \text{V}}{2}\log[H^+]^2_{unknown}$$

Because $\log x^2 = 2\log x$ (see Appendix A), we obtain

$$E_{cell} = -\left[\frac{0.0592\ \text{V}}{2}(2\log[H^+]_{unknown})\right] = -0.0592\ \text{V}\times\log[H^+]_{unknown}$$

Substituting $-\log[H^+] = \text{pH}$, we have

$$E_{cell} = 0.0592\ \text{V}\times\text{pH}$$

Thus, by measuring E_{cell}, we can find the pH.

In the routine measurement of pH, a concentration cell incorporating two hydrogen electrodes is too bulky and difficult to maintain. Instead, as was pointed out in Chapter 18, a pH meter is used. As shown in Figure 21.12A, two separate electrodes dip into the solution being tested. One of them is a *glass electrode*,

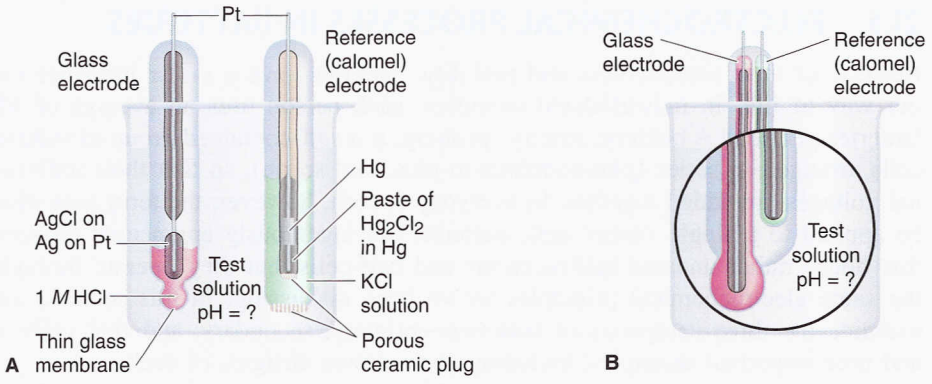


Figure 21.12 The laboratory measurement of pH. A, The glass electrode (*left*) is a self-contained Ag/AgCl half-cell immersed in an HCl solution of known concentration and enclosed by a thin glass membrane. It monitors the external $[H^+]$ in the solution relative to its fixed internal $[H^+]$. The saturated calomel electrode (*right*) acts as a reference. **B,** Most modern laboratories use a combination electrode, which houses both the glass and reference electrodes in one tube.

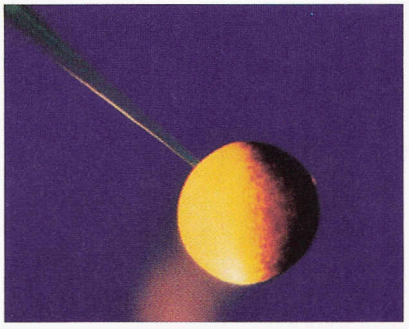
which consists of an Ag/AgCl half-reaction immersed in an HCl solution of fixed concentration (usually 1.000 *M*) and enclosed by a thin (~0.05 mm) membrane made of a special glass that is highly sensitive to the presence of H^+ ions. The other electrode is a reference electrode, typically a *saturated calomel electrode*. It consists of a platinum wire immersed in a paste of Hg_2Cl_2 (calomel), liquid Hg, and saturated KCl solution. The glass electrode monitors the solution's $[H^+]$ relative to its own fixed internal $[H^+]$, and the instrument converts the potential difference between the glass and reference electrodes into a measure of pH. In modern instruments, a combination electrode is used, which houses both electrodes in one tube (Figure 21.12B).

The pH electrode is one example of an *ion-selective (or ion-specific) electrode*. Electrodes have been designed with highly specialized membranes in order to selectively measure the concentrations of many different ions in industrial, environmental, and biological samples. Recent advances allow measurement in the picomolar-to-femtomolar (10^{-12}–10^{-15} *M*) range. Table 21.3 shows a few of the many ions for which ion-selective electrodes are available.

Table 21.3 Some Ions Measured with Ion-Specific Electrodes

Species Detected	Typical Sample
NH_3/NH_4^+	Industrial wastewater, seawater
CO_2/HCO_3^-	Blood, groundwater
F^-	Drinking water, urine, soil, industrial stack gases
Br^-	Grain, plant tissue
I^-	Milk, pharmaceuticals
NO_3^-	Soil, fertilizer, drinking water
K^+	Blood serum, soil, wine
H^+	Laboratory solutions, soil, natural waters



Minimicroanalysis Electronic miniaturization has greatly broadened the applications of electrochemistry. Environmental chemists use pocket-sized pH meters in the field to study natural waters and soil. Physiologists and biochemists employ electrodes so small that they can be surgically implanted in a single biological cell to study ion channels and receptors. In the photo, a microelectrode (filled with a fluorescent dye for better visibility) is shown penetrating an egg cell from the African toad *Xenopus laevis*.

SECTION SUMMARY

A spontaneous process is indicated by a negative ΔG or a positive E_{cell}, which are related: $\Delta G = -nFE_{cell}$. The ΔG of the cell reaction represents the maximum amount of electrical work the cell can do. Because the standard free energy change, ΔG^0, is related to E^0_{cell} and to *K*, we can use E^0_{cell} to determine *K*. At nonstandard conditions, the Nernst equation shows that E_{cell} depends on E^0_{cell} and a correction term based on *Q*. E_{cell} is high when *Q* is small (high [reactant]), and it decreases as the cell operates. At equilibrium, ΔG and E_{cell} are zero, which means that $Q = K$. Concentration cells have identical half-reactions, but solutions of differing concentration; thus they generate electrical energy as the concentrations become equal. Ion-specific electrodes, such as the pH electrode, measure the concentration of one species.

21.5 ELECTROCHEMICAL PROCESSES IN BATTERIES

Because of their compactness and mobility, batteries have a major influence on our way of life. In industrialized countries, each person uses an average of 10 batteries per year! A **battery,** strictly speaking, is a self-contained group of voltaic cells arranged in series (plus-to-minus-to-plus, and so on), so that their individual voltages are added together. In everyday speech, however, the term may also be applied to a single voltaic cell. Batteries are ingeniously engineered devices that house rather unusual half-reactions and half-cells, but they operate through the same electrochemical principles we've been discussing. In this section, we examine the three categories of batteries—primary, secondary, and fuel cells—and note important examples, including some newer designs, of each.

Primary (Nonrechargeable) Batteries

A *primary battery* cannot be recharged, so it is discarded when the components have reached their equilibrium concentrations, that is, when the cell is "dead." We'll discuss the alkaline battery, with a brief historical reference to the dry cell, the mercury and silver "button" batteries, and the primary lithium battery.

Alkaline Battery The precursor of today's ubiquitous alkaline battery, the common dry cell, or *Leclanché cell,* was invented in the 1860s and became a familiar household item during the first three-quarters of the 20th century. The anode of the dry cell was a zinc can that housed a mixture of MnO_2 and a weakly acidic electrolyte paste, consisting of NH_4Cl, $ZnCl_2$, H_2O, and starch. Powdered graphite was used to improve conductivity, and the cathode was an inactive graphite rod. Even today, the cathode half-reaction is not completely understood, but it involved the reduction of $MnO_2(s)$ to $Mn_2O_3(s)$ and an acid-base reaction between NH_4^+ and OH^-. At a high current drain, this reaction generated ammonia gas, which could build up and cause a serious voltage drop. Moreover, because the zinc anode reacted with the acidic NH_4^+ ions, dry cells had a short shelf life.

Although more expensive than the dry cell, the alkaline battery avoids these drawbacks. The same electrode materials, zinc and manganese dioxide, are used, but the electrolyte is a paste of KOH and water. The half-reactions are essentially the same, but use of the KOH paste eliminates the NH_3 gas buildup and maintains the Zn electrode (Figure 21.13):

Anode (oxidation): $$Zn(s) + 2OH^-(aq) \longrightarrow ZnO(s) + H_2O(l) + 2e^-$$

Cathode (reduction): $$MnO_2(s) + 2H_2O(l) + 2e^- \longrightarrow Mn(OH)_2(s) + 2OH^-(aq)$$

Overall (cell) reaction:

$$Zn(s) + MnO_2(s) + H_2O(l) \longrightarrow ZnO(s) + Mn(OH)_2(s) \qquad E_{cell} = 1.5\ V$$

Like the dry cell, the alkaline battery powers portable radios, toys, flashlights, and so on, is safe, and comes in many sizes. It has no voltage drop, longer shelf life, and better performance in terms of power capability and stored energy.

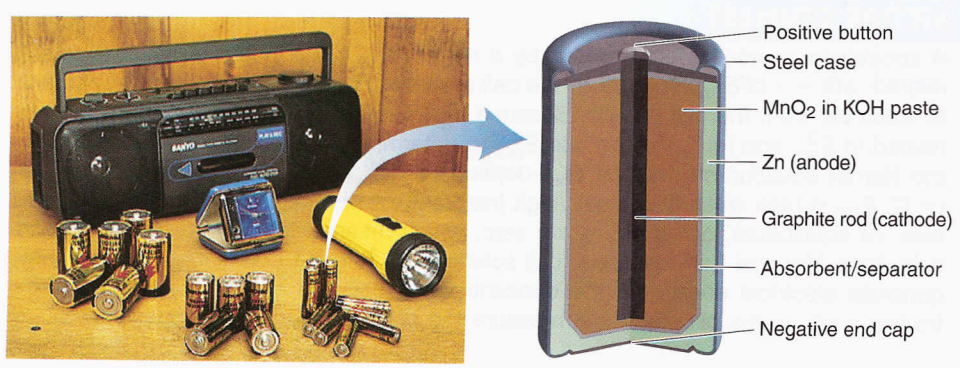


Figure 21.13 Alkaline battery.

Mercury and Silver (Button) Batteries Mercury and silver batteries are quite similar. Both use a zinc container as the anode (reducing agent) in a basic medium. The mercury battery employs HgO as the oxidizing agent, the silver uses Ag_2O, and both use a steel can around the cathode. The solid reactants are compacted with KOH and separated with moist paper. The half-reactions are

Anode (oxidation): $Zn(s) + 2OH^-(aq) \longrightarrow ZnO(s) + H_2O(l) + 2e^-$

Cathode (reduction) (mercury): $HgO(s) + H_2O(l) + 2e^- \longrightarrow Hg(l) + 2OH^-(aq)$

Cathode (reduction) (silver): $Ag_2O(s) + H_2O(l) + 2e^- \longrightarrow 2Ag(s) + 2OH^-(aq)$

Overall (cell) reaction (mercury):

$$Zn(s) + HgO(s) \longrightarrow ZnO(s) + Hg(l) \qquad E_{cell} = 1.3\ V$$

Overall (cell) reaction (silver):

$$Zn(s) + Ag_2O(s) \longrightarrow ZnO(s) + 2Ag(s) \qquad E_{cell} = 1.6\ V$$

Both cells are manufactured as small button-sized batteries. The mercury cell is used in calculators (Figure 21.14). Because of its very steady output, the silver cell is used in watches, cameras, heart pacemakers, and hearing aids. Their major disadvantages are toxicity of discarded mercury and high cost of silver cells.

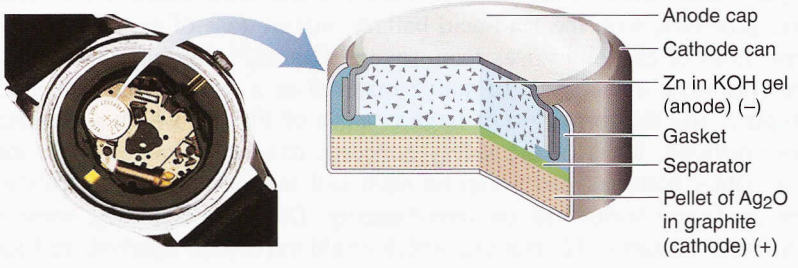

Figure 21.14 Silver button battery.

Primary Lithium Batteries The primary lithium battery is widely used in watches and implanted medical devices. It offers an extremely high energy/mass ratio, producing 1 mol of e^- (1 F) from less than 7 g of metal ($\mathcal{M}$ of Li = 6.941 g/mol). The anode is lithium metal foil, which requires a nonaqueous electrolyte. The cathode is one of several metal oxides in which lithium ions lie between oxide layers. Some implantable medical devices have a silver vanadium oxide (SVO; $AgV_2O_{5.5}$) cathode and can provide power for several years, but at a low rate because energy storage is limited (Figure 21.15). The half-reactions are

Anode (oxidation): $3.5Li(s) \longrightarrow 3.5Li^+ + 3.5e^-$

Cathode (reduction): $AgV_2O_{5.5} + 3.5Li^+ + 3.5e^- \longrightarrow Li_{3.5}AgV_2O_{5.5}$

Overall (cell) reaction: $AgV_2O_{5.5} + 3.5Li(s) \longrightarrow Li_{3.5}AgV_2O_{5.5}$

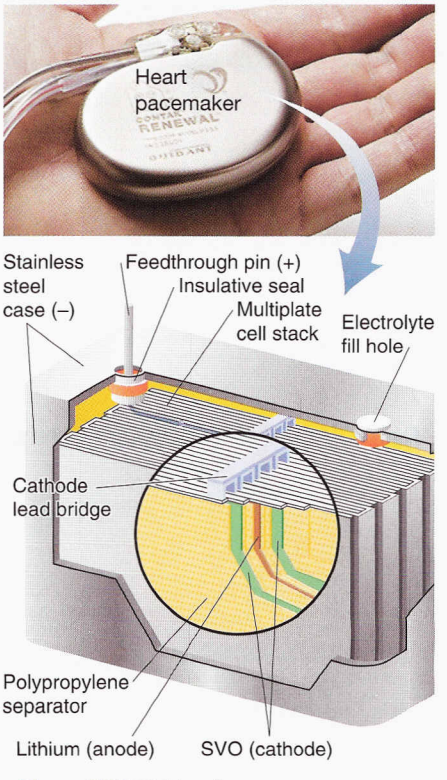

Figure 21.15 Lithium battery.

Secondary (Rechargeable) Batteries

In contrast to primary batteries, a *secondary,* or *rechargeable, battery* is recharged when it runs down *by supplying electrical energy to reverse the cell reaction* and re-form reactant. In other words, in this type of battery, the voltaic cells are periodically converted to electrolytic cells to restore *nonequilibrium* concentrations of the cell components. By far the most widely used secondary battery is the common car battery. Two newer types are the nickel–metal hydride battery and the lithium-ion battery, a secondary version of a lithium battery.

Lead-Acid Battery A typical lead-acid car battery has six cells connected in series, each of which delivers about 2.1 V for a total of about 12 V. Each cell contains two lead grids loaded with the electrode materials: high-surface-area Pb in the anode and high-surface-area PbO_2 in the cathode. The grids are immersed in an

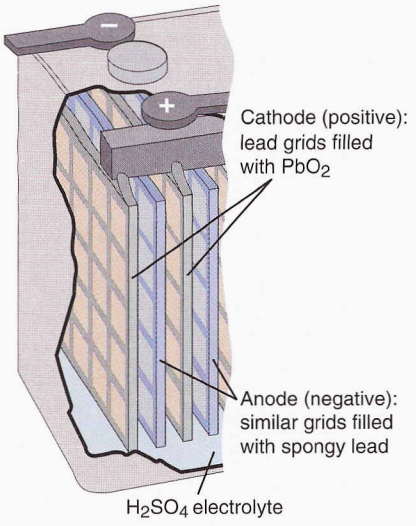

Figure 21.16 Lead-acid battery.

electrolyte solution of ~4.5 *M* H_2SO_4. Fiberglass sheets between the grids prevent shorting due to physical contact (Figure 21.16). When the cell discharges, it generates electrical energy as a voltaic cell:

Anode (oxidation): $Pb(s) + HSO_4^-(aq) \longrightarrow PbSO_4(s) + H^+ + 2e^-$

Cathode (reduction):

$$PbO_2(s) + 3H^+(aq) + HSO_4^-(aq) + 2e^- \longrightarrow PbSO_4(s) + 2H_2O(l)$$

Notice that both half-reactions produce Pb^{2+} ions, one through the oxidation of Pb, the other through the reduction of PbO_2. The Pb^{2+} forms $PbSO_4(s)$ at both electrodes by reacting with HSO_4^-.

Overall (cell) reaction (discharge):

$$PbO_2(s) + Pb(s) + 2H_2SO_4(aq) \longrightarrow 2PbSO_4(s) + 2H_2O(l) \qquad E_{cell} = 2.1\ V$$

When the cell is recharged, it uses electrical energy as an electrolytic cell, and the half-cell and overall reactions are reversed.

Overall (cell) reaction (recharge):

$$2PbSO_4(s) + 2H_2O(l) \longrightarrow PbO_2(s) + Pb(s) + 2H_2SO_4(aq)$$

For more than a century, car and truck owners have relied on the lead-acid battery to provide the large burst of current to the starter motor needed to start the engine—and to do so for years in both hot and cold weather. Nevertheless, there are problems with the lead-acid battery, mainly loss of capacity and safety concerns. Loss of capacity arises from several factors, including corrosion of the positive (Pb) grid, detachment of active material as a result of normal mechanical bumping, and the formation of large crystals of $PbSO_4$, which make recharging more difficult. Most of the safety concerns have been remedied in modern batteries. Older batteries had a cap on each cell for monitoring electrolyte density and replacing water lost on overcharging. During recharging, some water could be electrolyzed to H_2 and O_2, which could explode if sparked, and splatter H_2SO_4. Modern batteries are sealed, so they don't require addition of water during normal operation, and they use flame attenuators to reduce the explosion hazard.

Nickel–Metal Hydride (Ni-MH) Battery Concerns about the toxicity of the nickel-cadmium (nicad) battery are leading to its replacement by the nickel–metal hydride battery. The anode half-reaction oxidizes the hydrogen absorbed within a metal alloy (designated M; e.g., $LaNi_5$) in a basic (KOH) electrolyte, while nickel(III) in the form of NiO(OH) is reduced at the cathode (Figure 21.17):

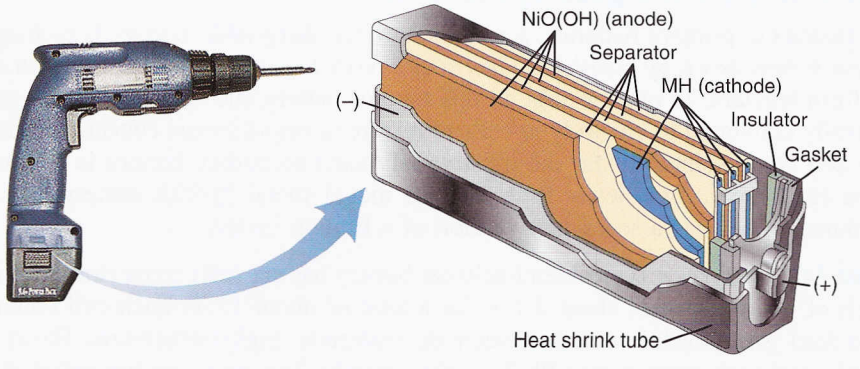
Anode (oxidation): $MH(s) + OH^-(aq) \longrightarrow M(s) + H_2O(l) + e^-$

Cathode (reduction): $NiO(OH)(s) + H_2O(l) + e^- \longrightarrow Ni(OH)_2(s) + OH^-(aq)$

Overall (cell) reaction: $MH(s) + NiO(OH)(s) \longrightarrow M(s) + Ni(OH)_2(s) \qquad E_{cell} = 1.4\ V$

The cell reaction is reversed during recharging. The Ni-MH battery is common in cordless razors, camera flash units, and power tools. It is lightweight, has high power, and is nontoxic, but it may discharge excessively during long-term storage.

Figure 21.17 Nickel–metal hydride battery.



Lithium-Ion Battery Like its primary cousin, the secondary lithium-ion battery has an anode of Li, but the atoms lie between sheets of graphite (designated Li_xC_6). The cathode is a lithium metal oxide, such as $LiMn_2O_4$ or $LiCoO_2$, and a typical electrolyte is 1 *M* $LiPF_6$ in an organic solvent, such as a mixture of dimethyl carbonate and methylethyl carbonate. Electrons flow through the circuit, while solvated Li^+ ions flow from anode to cathode within the cell (Figure 21.18). The cell reactions are

Anode (oxidation): $Li_xC_6 \longrightarrow xLi^+ + xe^- + C_6(s)$

Cathode (reduction): $Li_{1-x}Mn_2O_4(s) + xLi^+ + xe^- \longrightarrow LiMn_2O_4(s)$

Overall (cell) reaction: $Li_xC_6 + Li_{1-x}Mn_2O_4(s) \longrightarrow LiMn_2O_4(s) + C_6(s)$

$E_{cell} = 3.7$ V

The cell reaction is reversed during recharging. Although not as powerful as the primary lithium battery, the lithium-ion battery powers countless laptop computers, cell phones, and camcorders. Its key drawbacks are expense and the flammability of the organic solvent.

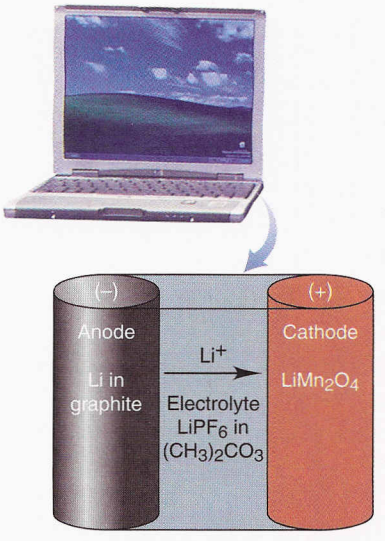


Figure 21.18 Lithium-ion battery.

Fuel Cells

In contrast to primary and secondary batteries, a **fuel cell,** sometimes called a *flow battery,* is not self-contained. The reactants (usually a combustible fuel and oxygen) enter the cell, and the products leave, generating electricity through the controlled oxidation of the fuel. In other words, *fuel cells use combustion to produce electricity*. The fuel does not burn because, as in other batteries, the half-reactions are separated, and the electrons are transferred through an external circuit.

The most common fuel cell being developed for use in cars is the *proton exchange membrane (PEM) cell,* which uses H_2 as the fuel and has an operating temperature of around 80°C (Figure 21.19). The cell reactions are

Anode (oxidation): $2H_2(g) \longrightarrow 4H^+(aq) + 4e^-$

Cathode (reduction): $O_2(g) + 4H^+(aq) + 4e^- \longrightarrow 2H_2O(g)$

Overall (cell) reaction: $2H_2(g) + O_2(g) \longrightarrow 2H_2O(g)$ $E_{cell} = 1.2$ V

The reactions in fuel cells have much lower rates than those in other batteries, so they require an *electrocatalyst* to decrease the activation energy (Section 16.8). The PEM cell electrodes are composites consisting of nanoparticles of a Pt-based catalyst deposited on graphite. These are embedded in a polymer electrolyte membrane having a perfluoroethylene backbone ($-[F_2C-CF_2]_n-$) with attached sulfonic acid groups (RSO_3^-) that play a key role in ferrying protons from anode to cathode. At the anode, two H_2 molecules adsorb onto the catalyst and are split and oxidized. From each H_2, two e^- travel through the wire to the cathode, while two H^+ become hydrated and migrate through the electrolyte as H_3O^+. According to a proposed multistep mechanism, at the cathode, an O_2 molecule adsorbs onto the catalyst, which provides an e^- to form O_2^-. One H_3O^+ donates its H^+ to the O_2^-, forming HO_2 (that is, HO—O). The O—O bond stretches and breaks as another H_3O^+ gives its H^+ and the catalyst provides another e^-: the first H_2O has formed. In similar fashion, a third H^+ and e^- attach to the freed O atom to form OH, and a fourth H^+ and e^- are transferred to form the second H_2O. Both water molecules desorb and leave the cell.

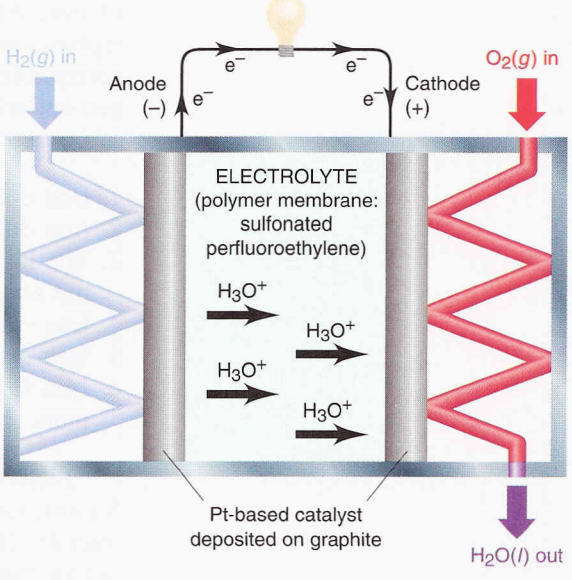

Figure 21.19 Hydrogen fuel cell.

Hydrogen fuel cells have been used for years to provide electricity and pure water during space flights. In the very near future, similar ones will supply electric power for transportation, residential, and commercial needs. Already, every major car manufacturer has a fuel-cell prototype. By themselves, these cells produce no pollutants, and they convert about 75% of the fuel's bond energy into

useable power, in contrast to 40% for a coal-fired power plant and 25% for a gasoline-powered car engine. Of course, their overall environmental impact will depend on how the H_2 is obtained; for example, electrolyzing water with solar power will have a negligible impact, whereas electrolyzing it with electricity from a coal-fired plant will have a sizeable one. Despite steady progress, current fuel-cell research remains focused on lowering costs by improving membrane conductivity and developing more efficient electrocatalysts.

SECTION SUMMARY

Batteries contain several voltaic cells in series and are classified as primary (e.g., alkaline, mercury, silver, and lithium), secondary (e.g., lead-acid, nickel–metal hydride, and lithium-ion), or fuel cell. Supplying electricity to a rechargeable (secondary) battery reverses the redox reaction, forming more reactant for further use. Fuel cells generate a current through the controlled oxidation of a fuel, such as H_2.

21.6 CORROSION: A CASE OF ENVIRONMENTAL ELECTROCHEMISTRY

By now, you may be thinking that spontaneous electrochemical processes are always beneficial, but consider the problem of **corrosion,** the natural redox process that oxidizes metals to their oxides and sulfides. In chemical terms, corrosion is the reverse of isolating a metal from its oxide or sulfide ore; in electrochemical terms, the process shares many similarities with the operation of a voltaic cell. Damage from corrosion to cars, ships, buildings, and bridges runs into tens of billions of dollars annually, so it is a major problem in much of the world. Although we focus here on the corrosion of iron, many other metals, such as copper and silver, also corrode.

The Corrosion of Iron

The most common and economically destructive form of corrosion is the rusting of iron. About 25% of the steel produced in the United States is made just to replace steel already in use that has corroded. Contrary to the simplified equation presented earlier, rust is *not* a direct product of the reaction between iron and oxygen but arises through a complex electrochemical process. Let's look at the facts of iron corrosion and then use the features of a voltaic cell to explain them:

1. Iron does not rust in dry air: moisture must be present.
2. Iron does not rust in air-free water: oxygen must be present.
3. The loss of iron and the depositing of rust often occur at *different* places on the *same* object.
4. Iron rusts more quickly at low pH (high $[H^+]$).
5. Iron rusts more quickly in contact with ionic solutions.
6. Iron rusts more quickly in contact with a less active metal (such as Cu) and more slowly in contact with a more active metal (such as Zn).

Picture the magnified surface of a piece of iron or steel (Figure 21.20). Strains, ridges, and dents in contact with water are typically the sites of iron loss (fact 1). These sites are called *anodic regions* because the following half-reaction occurs there:

$$Fe(s) \longrightarrow Fe^{2+}(aq) + 2e^- \quad \text{[anodic region; oxidation]}$$

Once the iron atoms lose electrons, the damage to the object has been done, and a pit forms where the iron is lost.

The freed electrons move through the external circuit—the piece of iron itself—until they reach a region of relatively high O_2 concentration (fact 2), near

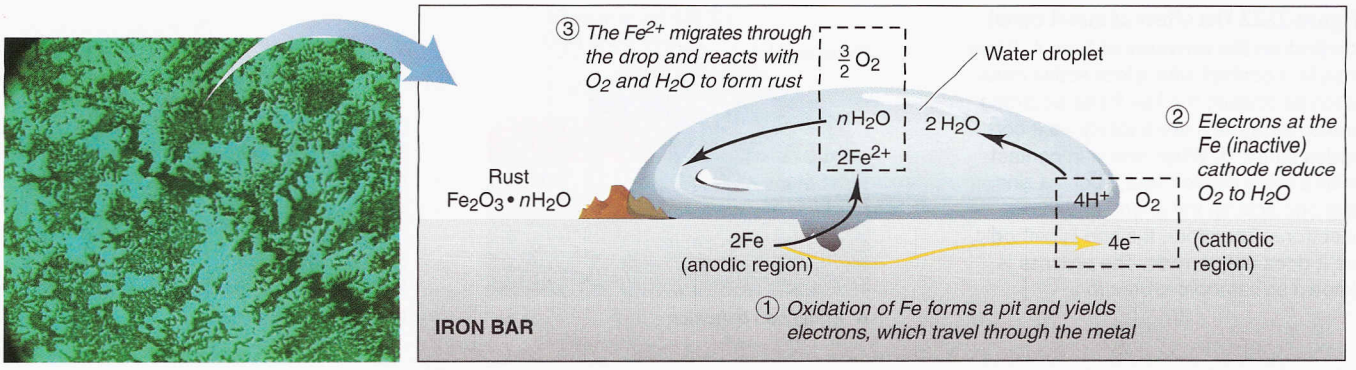

Figure 21.20 The corrosion of iron. A, A close-up view of an iron surface. Corrosion usually occurs at a surface irregularity. **B,** A schematic depiction of a small area of the surface, showing the steps in the corrosion process.

the surface of a surrounding water droplet, for instance. At this *cathodic region,* the electrons released from the iron atoms reduce O_2 molecules:

$$O_2(g) + 4H^+(aq) + 4e^- \longrightarrow 2H_2O(l) \qquad \text{[cathodic region; reduction]}$$

Notice that this overall redox process is complete; thus, the iron loss has occurred without any rust forming:

$$2Fe(s) + O_2(g) + 4H^+(aq) \longrightarrow 2Fe^{2+}(aq) + 2H_2O(l)$$

Rust forms through another redox reaction in which the reactants make direct contact. The Fe^{2+} ions formed originally at the anodic region disperse through the surrounding water and react with O_2, often at some distance from the pit (fact 3). The overall reaction for this step is

$$2Fe^{2+}(aq) + \tfrac{1}{2}O_2(g) + (2+n)H_2O(l) \longrightarrow Fe_2O_3 \cdot nH_2O(s) + 4H^+(aq)$$

[The inexact coefficient n for H_2O in the above equation appears because rust, $Fe_2O_3 \cdot nH_2O$, is a form of iron(III) oxide with a variable number of waters of hydration.] The rust deposit is really incidental to the damage caused by loss of iron—a chemical insult added to the original injury.

Adding the previous two equations together shows the overall equation for the rusting of iron:

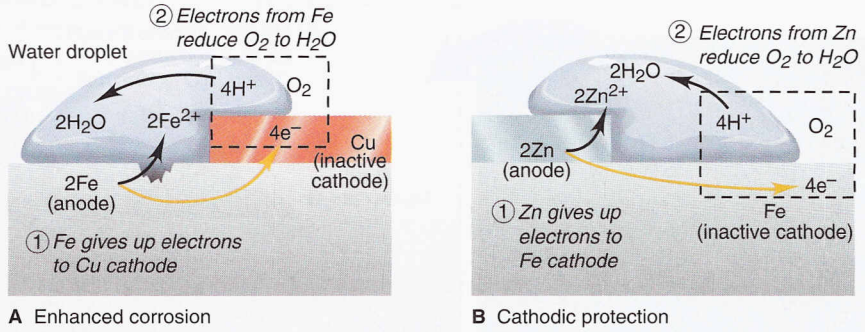
$$2Fe(s) + \tfrac{3}{2}O_2(g) + nH_2O(l) + \cancel{4H^+(aq)} \longrightarrow Fe_2O_3 \cdot nH_2O(s) + \cancel{4H^+(aq)}$$

The canceled H^+ ions are shown to emphasize that they act as a catalyst; that is, they speed the process as they are used up in one step of the overall reaction and created in another. As a result of this action, rusting is faster at low pH (high $[H^+]$) (fact 4). Ionic solutions speed rusting by improving the conductivity of the aqueous medium near the anodic and cathodic regions (fact 5). The effect of ions is especially evident on ocean-going vessels (Figure 21.21) and on the underbodies and around the wheel wells of cars driven in cold climates, where salts are used to melt ice on slippery roads.

In many ways, the components of the corrosion process resemble those of a voltaic cell:

- Anodic and cathodic regions are separated in space.
- The regions are connected via an external circuit through which the electrons travel.
- In the anodic region, iron behaves like an active electrode, whereas in the cathodic region, it is inactive.
- The moisture surrounding the pit functions somewhat like a salt bridge, a means for ions to ferry back and forth and keep the solution neutral.

Figure 21.21 Enhanced corrosion at sea. The high ion concentration of seawater leads to its high conductivity, which enhances the corrosion of iron in the hulls and anchors of ocean-going vessels.



A Enhanced corrosion **B** Cathodic protection

Figure 21.22 The effect of metal-metal contact on the corrosion of iron. A, When iron is in contact with a less active metal, such as copper, the iron loses electrons more readily (is more anodic), so it corrodes faster. **B,** When iron is in contact with a more active metal, such as zinc, the zinc acts as the anode and loses electrons. Therefore, the iron is cathodic, so it does not corrode. The process is known as *cathodic protection.*

Protecting Against the Corrosion of Iron

A common approach to preventing or limiting corrosion is to eliminate contact with the corrosive factors. The simple act of washing off road salt removes the ionic solution from auto bodies. Iron objects are frequently painted to keep out O_2 and moisture, but if the paint layer chips, rusting proceeds. More permanent coatings include chromium plated on plumbing fixtures. In the "blueing" of gun barrels, wood stoves, and other steel objects, an adherent coating of Fe_3O_4 (magnetite) is bonded to the surface.

The only fact regarding corrosion that we have not yet addressed concerns the relative activity of other metals in contact with iron (fact 6), which leads to the most effective way to prevent corrosion. The essential idea is that *iron functions as both anode and cathode in the rusting process, but it is lost only at the anode.* Therefore, it makes sense that anything that makes iron behave more like the anode increases corrosion. As you can see in Figure 21.22A, when iron is in contact with a *less* active metal (weaker reducing agent), such as copper, its anodic function is enhanced. As a result, when iron plumbing is connected directly to copper plumbing with no electrical insulation between them, the iron pipe corrodes rapidly.

On the other hand, anything that makes iron behave more like the cathode prevents corrosion. Application of this principle is called *cathodic protection.* For example, if the iron makes contact with a *more* active metal (stronger reducing agent), such as zinc, the iron becomes cathodic and remains intact, while the zinc acts as the anode and loses electrons (Figure 21.22B). Coating steel with a "sacrificial" layer of zinc is the basis of the *galvanizing* process. In addition to blocking physical contact with H_2O and O_2, the zinc is "sacrificed" (oxidized) instead of the iron.

Sacrificial anodes are employed to protect iron and steel structures (pipes, tanks, oil rigs, and so on) in marine and moist underground environments. The metals most frequently used for this purpose are magnesium and aluminum; because these elements are much more active than iron, they act as the anode while iron acts as the cathode (Figure 21.23). Another advantage of these metals is that they form adherent oxide coatings, which slows their own corrosion.

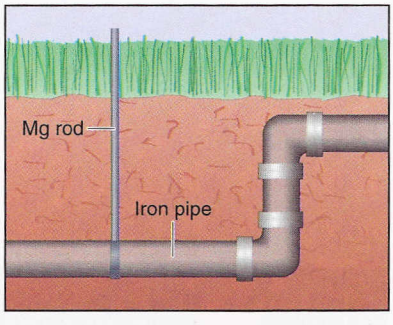


Figure 21.23 The use of sacrificial anodes to prevent iron corrosion. In cathodic protection, an active metal, such as magnesium or aluminum, is connected to underground iron pipes to prevent their corrosion. The active metal is sacrificed instead of the iron.

SECTION SUMMARY

Corrosion damages metal structures through a natural electrochemical change. Iron corrosion occurs in the presence of oxygen and moisture and is increased by high $[H^+]$, high [ion], or contact with a less active metal, such as Cu. Fe is oxidized and O_2 is reduced in one redox reaction, while rust (hydrated form of Fe_2O_3) is formed in another reaction that often takes place at a different location. Because Fe functions as both anode and cathode in the process, an iron or steel object can be protected by physically covering its surface or joining it to a more active metal (such as Zn, Mg, or Al), which acts as the anode in place of the Fe.

21.7 ELECTROLYTIC CELLS: USING ELECTRICAL ENERGY TO DRIVE NONSPONTANEOUS REACTIONS

Up to now, we've been considering voltaic cells, those that generate electrical energy from a spontaneous redox reaction. The principle of an electrolytic cell is exactly the opposite: *electrical energy from an external source drives a nonspontaneous reaction.*

Construction and Operation of an Electrolytic Cell

Let's examine the operation of an electrolytic cell by constructing one from a voltaic cell. Consider the tin-copper voltaic cell in Figure 21.24A. The Sn anode will gradually become oxidized to Sn^{2+} ions, and the Cu^{2+} ions will gradually be reduced and plate out on the Cu cathode because the cell reaction is spontaneous in that direction:

For the voltaic cell

$$Sn(s) \longrightarrow Sn^{2+}(aq) + 2e^- \quad \text{[anode; oxidation]}$$
$$Cu^{2+}(aq) + 2e^- \longrightarrow Cu(s) \quad \text{[cathode; reduction]}$$
$$Sn(s) + Cu^{2+}(aq) \longrightarrow Sn^{2+}(aq) + Cu(s) \quad E^0_{cell} = 0.48\ V \text{ and } \Delta G^0 = -93\ kJ$$

Therefore, the *reverse* cell reaction is *non*spontaneous and never happens of its own accord, as the negative E^0_{cell} and positive ΔG^0 indicate:

$$Cu(s) + Sn^{2+}(aq) \longrightarrow Cu^{2+}(aq) + Sn(s) \quad E^0_{cell} = -0.48\ V \text{ and } \Delta G^0 = 93\ kJ$$

However, we can make this process happen by supplying from an external source an electric potential *greater than* E^0_{cell}. In effect, we have converted the voltaic cell into an electrolytic cell and changed the nature of the electrodes—anode is now cathode, and cathode is now anode (Figure 21.24B):

For the electrolytic cell

$$Cu(s) \longrightarrow Cu^{2+}(aq) + 2e^- \quad \text{[anode; oxidation]}$$
$$Sn^{2+}(aq) + 2e^- \longrightarrow Sn(s) \quad \text{[cathode; reduction]}$$
$$Cu(s) + Sn^{2+}(aq) \longrightarrow Cu^{2+}(aq) + Sn(s) \quad \text{[overall (cell) reaction]}$$

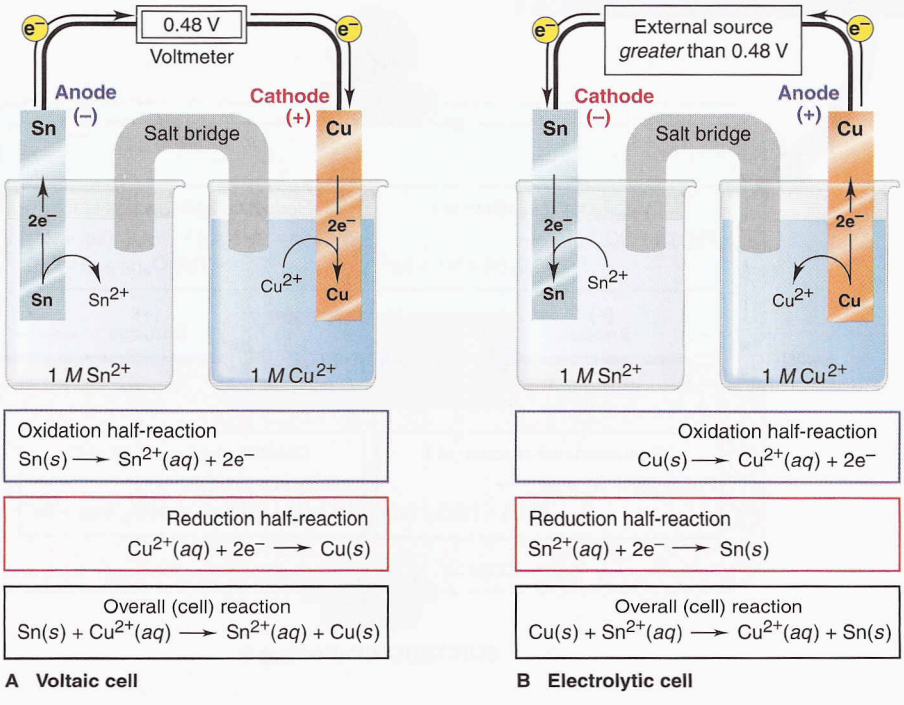

Figure 21.24 The tin-copper reaction as the basis of a voltaic and an electrolytic cell. A, The spontaneous reaction between Sn and Cu^{2+} generates 0.48 V in a voltaic cell. **B,** If more than 0.48 V is supplied, the same apparatus becomes an electrolytic cell, and the nonspontaneous reaction between Cu and Sn^{2+} occurs. Note the changes in electrode charges and direction of electron flow.

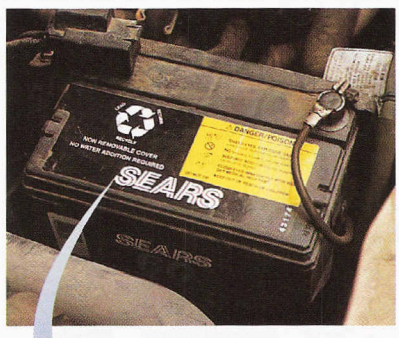
Note that in an electrolytic cell, as in a voltaic cell, *oxidation takes place at the anode and reduction takes place at the cathode, but the direction of electron flow and the signs of the electrodes are reversed.*

To understand these changes, keep in mind the *cause* of the electron flow:

- In a voltaic cell, electrons are generated at the anode, so it is negative, and electrons are consumed at the cathode, so it is positive.
- In an electrolytic cell, the electrons come from the external power source, which *supplies* them *to* the cathode, so it is negative, and *removes* them *from* the anode, so it is positive.

A rechargeable battery functions as a voltaic cell when it is discharging and as an electrolytic cell when it is recharging, so it provides a good way to compare these two cell types and the changes in the processes and charges of the electrodes. Figure 21.25 shows these changes in the lead-acid battery. In the discharge mode (voltaic cell), oxidation occurs at electrode I, thus making the *negative* electrode the anode. In the recharge mode (electrolytic cell), oxidation occurs at electrode II, thus making the *positive* electrode the anode. Similarly, the cathode is *positive* during discharge (electrode II) and *negative* during recharge (electrode I). To reiterate, regardless of whether the cell is discharging or recharging, oxidation occurs at the anode and reduction occurs at the cathode.



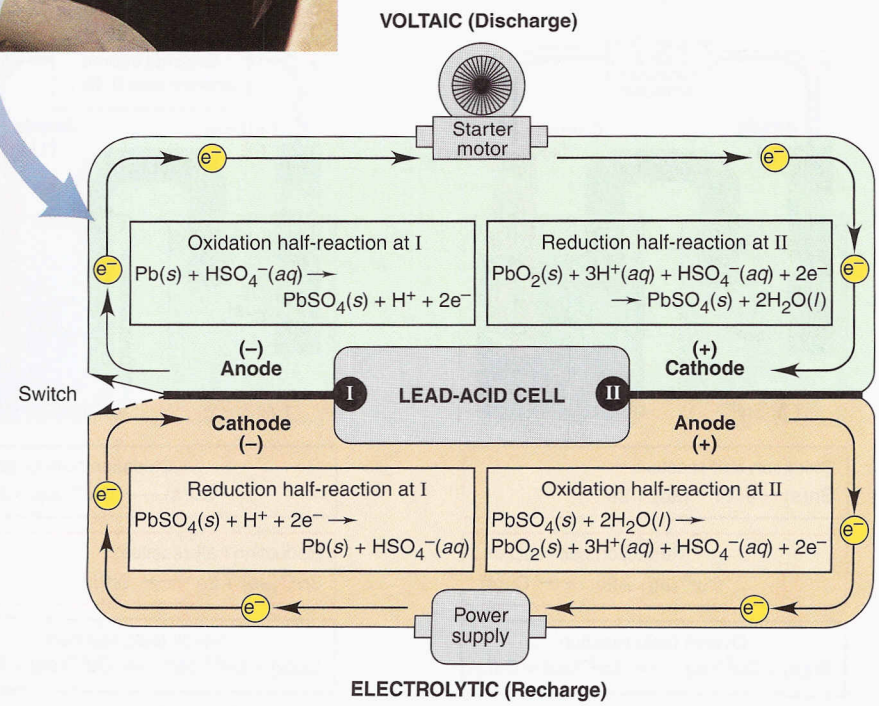


Figure 21.25 The processes occurring during the discharge and recharge of a lead-acid battery. When the lead-acid battery is discharging (*top*), it behaves like a voltaic cell: the anode is negative (electrode I), and the cathode is positive (electrode II). When it is recharging (*bottom*), it behaves like an electrolytic cell: the anode is positive (electrode II), and the cathode is negative (electrode I).

Table 21.4 Comparison of Voltaic and Electrolytic Cells

			Electrode		
Cell Type	ΔG	E_{cell}	Name	Process	Sign
Voltaic	<0	>0	Anode	Oxidation	−
Voltaic	<0	>0	Cathode	Reduction	+
Electrolytic	>0	<0	Anode	Oxidation	+
Electrolytic	>0	<0	Cathode	Reduction	−

Table 21.4 summarizes the processes and signs in the two types of electrochemical cells.

Predicting the Products of Electrolysis

Electrolysis, the splitting (lysing) of a substance by the input of electrical energy, is often used to decompose a compound into its elements. Electrolytic cells are involved in key industrial production steps for some of the most commercially important elements, including chlorine, aluminum, and copper, as you'll see in the next chapter. The first laboratory electrolysis of H_2O to H_2 and O_2 was performed in 1800, and the process is still used to produce these gases in ultrahigh purity. The electrolyte in an electrolytic cell can be the pure compound (such as H_2O or a molten salt), a mixture of molten salts, or an aqueous solution of a salt. The products obtained depend on atomic properties and several other factors, so let's examine some actual cases.

Electrolysis of Pure Molten Salts Many electrolytic applications involve isolating a metal or nonmetal from a molten salt. Predicting the product at each electrode is simple if the salt is pure because *the cation will be reduced and the anion oxidized.* The electrolyte is the molten salt itself, and the ions move through the cell because they are attracted by the oppositely charged electrodes.

Consider the electrolysis of molten (fused) calcium chloride. The two species present are Ca^{2+} and Cl^-, so Ca^{2+} ion is reduced and Cl^- ion is oxidized:

$$2Cl^-(l) \longrightarrow Cl_2(g) + 2e^- \quad \text{[anode; oxidation]}$$
$$Ca^{2+}(l) + 2e^- \longrightarrow Ca(s) \quad \text{[cathode; reduction]}$$
$$Ca^{2+}(l) + 2Cl^-(l) \longrightarrow Ca(s) + Cl_2(g) \quad \text{[overall]}$$

Metallic calcium is prepared industrially this way, as are several other active metals, such as Na and Mg, and the halogens Cl_2 and Br_2. We examine the details of these and several other electrolytic processes in Chapter 22.

Electrolysis of Mixed Molten Salts More typically, the electrolyte is a mixture of molten salts, which is then electrolyzed to obtain a particular metal. When we have a choice of product, how can we tell which species will react at which electrode? The general rule for all electrolytic cells is that *the more easily oxidized species (stronger reducing agent) reacts at the anode, and the more easily reduced species (stronger oxidizing agent) reacts at the cathode.*

It's important to realize that for electrolysis of mixtures of molten salts, we *cannot* use tabulated E^0 values to tell the relative strength of the oxidizing and reducing agents. Those values refer to the *change from aqueous ion to free element,* $M^{n+}(aq) + ne^- \longrightarrow M(s)$, under standard-state conditions, but there are no aqueous ions in a molten salt. Instead, we rely on our knowledge of periodic atomic trends to predict which of the ions present gains or loses electrons more easily (Sections 8.4 and 9.5).

SAMPLE PROBLEM 21.8 Predicting the Electrolysis Products of a Molten Salt Mixture

Problem A chemical engineer melts a naturally occurring mixture of NaBr and $MgCl_2$ and decomposes it in an electrolytic cell. Predict the substance formed at each electrode, and write balanced half-reactions and the overall cell reaction.

Plan We have to determine which metal and nonmetal will form more easily at the electrodes. We first list the ions as oxidizing or reducing agents. If one metal holds its electrons more tightly than another, it has a higher ionization energy (IE). Therefore, as a cation, it gains electrons more easily; it is the stronger oxidizing agent and is reduced at the cathode. Similarly, if one nonmetal holds its electrons less tightly than another, it has a lower electronegativity (EN). Therefore, as an anion, it loses electrons more easily; it is the stronger reducing agent and is oxidized at the anode.

Solution Listing the ions as oxidizing or reducing agents:

The possible oxidizing agents are Na^+ and Mg^{2+}.

The possible reducing agents are Br^- and Cl^-.

Determining the cathode product (more easily reduced cation): Mg is to the right of Na in Period 3. IE increases from left to right, so Mg has a higher IE. It takes more energy to remove an e^- from Mg than from Na, so it follows that Mg^{2+} has a greater attraction for e^- and thus is more easily reduced (stronger oxidizing agent):

$$Mg^{2+}(l) + 2e^- \longrightarrow Mg(l) \qquad \text{[cathode; reduction]}$$

Determining the anode product (more easily oxidized anion): Br is below Cl in Group 7A(17). EN decreases down the group, so Br has a lower EN than Cl. Therefore, it follows that Br^- holds its e^- less tightly than Cl^-, so Br^- is more easily oxidized (stronger reducing agent):

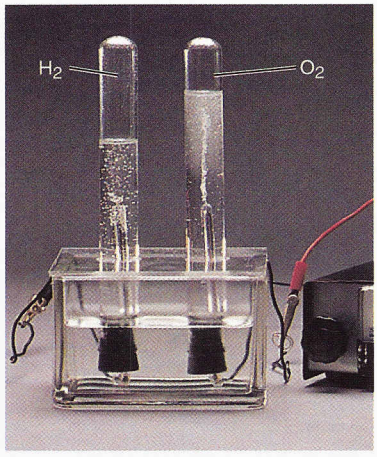
$$2Br^-(l) \longrightarrow Br_2(g) + 2e^- \qquad \text{[anode; oxidation]}$$

Writing the overall cell reaction:

$$Mg^{2+}(l) + 2Br^-(l) \longrightarrow Mg(l) + Br_2(g) \qquad \text{[overall]}$$

Comment The cell temperature must be high enough to keep the salt mixture molten. In this case, the temperature is greater than the melting point of Mg, so it appears as a liquid in the equation, and greater than the boiling point of Br_2, so it appears as a gas.

FOLLOW-UP PROBLEM 21.8 A sample of $AlBr_3$ contaminated with KF is melted and electrolyzed. Determine the electrode products and write the overall cell reaction.



Oxidation half-reaction
$2H_2O(l) \longrightarrow O_2(g) + 4H^+(aq) + 4e^-$

Reduction half-reaction
$2H_2O(l) + 2e^- \longrightarrow H_2(g) + 2OH^-(aq)$

Overall (cell) reaction
$2H_2O(l) \longrightarrow 2H_2(g) + O_2(g)$

Figure 21.26 The electrolysis of water. A certain volume of oxygen forms through the oxidation of H_2O at the anode (*right*), and twice that volume of hydrogen forms through the reduction of H_2O at the cathode (*left*).

Electrolysis of Water and Nonstandard Half-Cell Potentials Before we can analyze the electrolysis products of aqueous salt solutions, we must examine the electrolysis of water itself. Extremely pure water is difficult to electrolyze because very few ions are present to conduct a current. If we add a small amount of a salt that cannot be electrolyzed in water (such as Na_2SO_4), however, electrolysis proceeds rapidly. A glass electrolytic cell with separated gas compartments is used to keep the H_2 and O_2 gases from mixing (Figure 21.26). At the anode, water is oxidized as the O.N. of O changes from −2 to 0:

$$2H_2O(l) \longrightarrow O_2(g) + 4H^+(aq) + 4e^- \qquad E = 0.82\ V \qquad \text{[anode; oxidation]}$$

At the cathode, water is reduced as the O.N. of H changes from +1 to 0:

$$2H_2O(l) + 2e^- \longrightarrow H_2(g) + 2OH^-(aq) \qquad E = -0.42\ V \qquad \text{[cathode; reduction]}$$

After doubling the cathode half-reaction to equate e^- loss and gain, adding the half-reactions (which involves combining the H^+ and OH^- into H_2O and canceling e^- and excess H_2O), and calculating E_{cell}, the overall reaction is

$$2H_2O(l) \longrightarrow 2H_2(g) + O_2(g) \qquad E_{cell} = -0.42\ V - 0.82\ V = -1.24\ V \qquad \text{[overall]}$$

Notice that these electrode potentials are not written with a superscript zero because they are *not* standard electrode potentials. The $[H^+]$ and $[OH^-]$ are

1.0×10^{-7} M rather than the standard-state value of 1 M. These E values are obtained by applying the Nernst equation. For example, the calculation for the anode potential (with $n = 4$) is

$$E_{cell} = E^0_{cell} - \frac{0.0592\text{ V}}{4}\log\left(P_{O_2} \times [H^+]^4\right)$$

The standard potential for the *oxidation* of water is -1.23 V (from Appendix D) and $P_{O_2} \approx 1$ atm in the half-cell, so we have

$$E_{cell} = -1.23\text{ V} - \left\{\frac{0.0592\text{ V}}{4} \times [\log 1 + 4\log(1.0\times10^{-7})]\right\} = -0.82\text{ V}$$

In aqueous ionic solutions, $[H^+]$ and $[OH^-]$ are approximately 10^{-7} M also, so we use these nonstandard E_{cell} values to predict electrode products.

Electrolysis of Aqueous Ionic Solutions and the Phenomenon of Overvoltage

Aqueous salt solutions are mixtures of ions *and* water, so we have to compare the various electrode potentials to predict the electrode products. When two half-reactions are possible at an electrode,

- *The reduction with the less negative (more positive) electrode potential occurs.*
- *The oxidation with the less positive (more negative) electrode potential occurs.*

What happens, for instance, when a solution of potassium iodide is electrolyzed? The possible oxidizing agents are K^+ and H_2O, and their reduction half-reactions are

$$K^+(aq) + e^- \longrightarrow K(s) \qquad E^0 = -2.93\text{ V}$$
$$2H_2O(l) + 2e^- \longrightarrow H_2(g) + 2OH^-(aq) \qquad E = -0.42\text{ V} \quad \text{[reduction]}$$

The less *negative* electrode potential for water means that it is much easier to reduce than K^+, so H_2 forms at the cathode. The possible reducing agents are I^- and H_2O, and their oxidation half-reactions are

$$2I^-(aq) \longrightarrow I_2(s) + 2e^- \qquad E^0 = 0.53\text{ V} \quad \text{[oxidation]}$$
$$2H_2O(l) \longrightarrow O_2(g) + 4H^+(aq) + 4e^- \qquad E = 0.82\text{ V}$$

The less *positive* electrode potential for I^- means that a lower potential is needed to oxidize it than to oxidize H_2O, so I_2 forms at the anode.

However, the products predicted from this type of comparison of electrode potentials are not always the actual products. For gases such as $H_2(g)$ and $O_2(g)$ to be produced at metal electrodes, an additional voltage is required. This increment above the expected voltage is called the **overvoltage,** and it is 0.4 to 0.6 V for these gases. The overvoltage results from kinetic factors, such as the large activation energy (Section 16.5) required for gases to form at the electrode.

Overvoltage has major practical significance. A multibillion-dollar example is the industrial production of chlorine from concentrated NaCl solution. Water is easier to reduce than Na^+, so H_2 forms at the cathode even with an overvoltage of 0.6 V:

$$Na^+(aq) + e^- \longrightarrow Na(s) \qquad E^0 = -2.71\text{ V}$$
$$2H_2O(l) + 2e^- \longrightarrow H_2(g) + 2OH^-(aq) \qquad E = -0.42\text{ V } (\approx -1\text{ V with overvoltage})$$
[reduction]

But Cl_2 forms at the anode, even though the electrode potentials themselves would lead us to predict that O_2 should form:

$$2H_2O(l) \longrightarrow O_2(g) + 4H^+(aq) + 4e^- \qquad E = 0.82\text{ V} \quad (\sim 1.4\text{ V with overvoltage})$$
$$2Cl^-(aq) \longrightarrow Cl_2(g) + 2e^- \qquad E^0 = 1.36\text{ V} \quad \text{[oxidation]}$$

An overvoltage of $\sim$0.6 V makes the potential needed to form O_2 slightly above that for Cl_2. Keeping the $[Cl^-]$ high also favors Cl_2 formation. Thus, chlorine, which is one of the 10 most heavily produced industrial chemicals, can be formed from plentiful natural sources of aqueous sodium chloride (see Chapter 22).

From these and other examples, we can determine which elements can be prepared electrolytically from aqueous solutions of their salts:

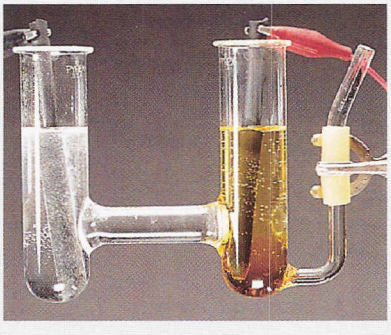
1. Cations of less active metals *are* reduced to the metal, including gold, silver, copper, chromium, platinum, and cadmium.
2. Cations of more active metals *are not* reduced, including those in Groups 1A(1) and 2A(2), and Al from 3A(13). Water is reduced to H_2 and OH^- instead.
3. Anions that *are* oxidized, because of overvoltage from O_2 formation, include the halides ($[Cl^-]$ must be high), except for F^-.
4. Anions that *are not* oxidized include F^- and common oxoanions, such as SO_4^{2-}, CO_3^{2-}, NO_3^-, and PO_4^{3-}, because the central nonmetal in these oxoanions is already in its highest oxidation state. Water is oxidized to O_2 and H^+ instead.

SAMPLE PROBLEM 21.9 Predicting the Electrolysis Products of Aqueous Ionic Solutions

Problem What products form during electrolysis of aqueous solutions of the following salts: **(a)** KBr; **(b)** $AgNO_3$; **(c)** $MgSO_4$?

Plan We identify the reacting ions and compare their electrode potentials with those of water, taking the 0.4 to 0.6 V overvoltage into consideration. The reduction half-reaction with the less negative electrode potential occurs at the cathode, and the oxidation half-reaction with the less positive electrode potential occurs at the anode.

Solution



Electrolysis of aqueous KBr.

(a)
$$K^+(aq) + e^- \longrightarrow K(s) \qquad E^0 = -2.93\ V$$
$$2H_2O(l) + 2e^- \longrightarrow H_2(g) + 2OH^-(aq) \qquad E = -0.42\ V$$

Despite the overvoltage, which makes E for the reduction of water between -0.8 and -1.0 V, H_2O is still easier to reduce than K^+, so $H_2(g)$ forms at the cathode.

$$2Br^-(aq) \longrightarrow Br_2(l) + 2e^- \qquad E^0 = 1.07\ V$$
$$2H_2O(l) \longrightarrow O_2(g) + 4H^+(aq) + 4e^- \qquad E = 0.82\ V$$

Because of the overvoltage, which makes E for the oxidation of water between 1.2 and 1.4 V, Br^- is easier to oxidize than water, so $Br_2(l)$ forms at the anode (see photo).

(b)
$$Ag^+(aq) + e^- \longrightarrow Ag(s) \qquad E^0 = 0.80\ V$$
$$2H_2O(l) + 2e^- \longrightarrow H_2(g) + 2OH^-(aq) \qquad E = -0.42\ V$$

As the cation of an inactive metal, Ag^+ is a better oxidizing agent than H_2O, so Ag forms at the cathode. NO_3^- cannot be oxidized, because N is already in its highest (+5) oxidation state. Thus, O_2 forms at the anode:

$$2H_2O(l) \longrightarrow O_2(g) + 4H^+(aq) + 4e^-$$

(c)
$$Mg^{2+}(aq) + 2e^- \longrightarrow Mg(s) \qquad E^0 = -2.37\ V$$

Like K^+ in part (a), Mg^{2+} cannot be reduced in the presence of water, so H_2 forms at the cathode. The SO_4^{2-} ion cannot be oxidized because S is in its highest (+6) oxidation state. Thus, H_2O is oxidized, and O_2 forms at the anode:

$$2H_2O(l) \longrightarrow O_2(g) + 4H^+(aq) + 4e^-$$

FOLLOW-UP PROBLEM 21.9 Write half-reactions showing the products you predict will form in the electrolysis of aqueous $AuBr_3$.

The Stoichiometry of Electrolysis: The Relation Between Amounts of Charge and Product

As you've seen, the charge flowing through an electrolytic cell yields products at the electrodes. In the electrolysis of molten NaCl, for example, the power source supplies electrons to the cathode, where Na^+ ions migrate to pick them up and

become Na metal. At the same time, the power source pulls from the anode the electrons that Cl^- ions release as they become Cl_2 gas. It follows that the more electrons picked up by Na^+ ions and released by Cl^- ions, the greater the amounts of Na and Cl_2 that form. This relationship was first determined experimentally by Michael Faraday and is referred to as *Faraday's law of electrolysis: the amount of substance produced at each electrode is directly proportional to the quantity of charge flowing through the cell.*

Each balanced half-reaction shows the amounts (mol) of reactant, electrons, and product involved in the change, so it contains the information we need to answer such questions as "How much material will form as a result of a given quantity of charge?" or, conversely, "How much charge is needed to produce a given amount of material?" To apply Faraday's law,

1. Balance the half-reaction to find the number of moles of electrons needed per mole of product.
2. Use the Faraday constant ($F = 9.65\times10^4$ C/mol e^-) to find the corresponding charge.
3. Use the molar mass to find the charge needed for a given mass of product.

In practice, to supply the correct amount of electricity, we need some means of finding the charge flowing through the cell. We cannot measure charge directly, but we *can* measure current, the charge flowing per unit time. The SI unit of current is the **ampere (A),** which is defined as 1 coulomb flowing through a conductor in 1 second:

$$1 \text{ ampere} = 1 \text{ coulomb/second} \quad \text{or} \quad 1 \text{ A} = 1 \text{ C/s} \tag{21.11}$$

Thus, the current multiplied by the time gives the charge:

$$\text{Current} \times \text{time} = \text{charge} \quad \text{or} \quad \text{A} \times \text{s} = \frac{\text{C}}{\text{s}} \times \text{s} = \text{C}$$

Therefore, we find the charge by measuring the current *and* the time during which the current flows. This, in turn, relates to the amount of product formed. Figure 21.27 summarizes these relationships.

The Father of Electrochemistry and Much More The investigations by Michael Faraday (1791–1867) into the mass of an element that is equivalent to a given amount of charge established electrochemistry as a quantitative science, but his breakthroughs in physics are even more celebrated. In 1821, Faraday developed the precursor of the electric motor, and his later studies of currents induced by electric and magnetic fields eventually led to the electric generator and the transformer. After his death, this self-educated blacksmith's son was rated by Albert Einstein as the peer of Newton, Galileo, and Maxwell. He is shown here delivering one of his famous lectures on the "Chemical History of a Candle."

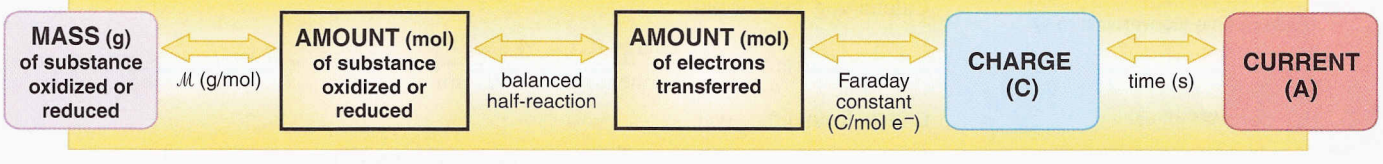


Figure 21.27 **A summary diagram for the stoichiometry of electrolysis.**

Problems based on Faraday's law often ask you to calculate current, mass of material, or time. The electrode half-reaction provides the key to solving these problems because it is related to the mass for a certain quantity of charge.

As an example, let's consider a typical problem in practical electrolysis: how long does it take to produce 3.0 g of $Cl_2(g)$ by electrolysis of aqueous NaCl using a power supply with a current of 12 A? The problem asks for the time needed to produce a certain mass, so let's first relate mass to number of moles of electrons to find the charge needed. Then, we'll relate the charge to the current to find the time.

We know the mass of Cl_2 produced, so we can find the amount (mol) of Cl_2. The half-reaction tells us that the loss of 2 mol of electrons produces 1 mol of chlorine gas:

$$2Cl^-(aq) \longrightarrow Cl_2(g) + 2e^-$$

We use this relationship as a conversion factor, and multiplying by the Faraday constant gives us the total charge:

$$\text{Charge (C)} = 3.0 \text{ g } Cl_2 \times \frac{1 \text{ mol } Cl_2}{70.90 \text{ g } Cl_2} \times \frac{2 \text{ mol } e^-}{1 \text{ mol } Cl_2} \times \frac{9.65\times10^4 \text{ C}}{1 \text{ mol } e^-} = 8.2\times10^3 \text{ C}$$

Now we use the relationship between charge and current to find the time needed:

$$\text{Time (s)} = \frac{\text{charge (C)}}{\text{current (A, or C/s)}} = 8.2\times10^3 \text{ C} \times \frac{1 \text{ s}}{12 \text{ C}} = 6.8\times10^2 \text{ s } (\sim 11 \text{ min})$$

Note that the entire calculation follows Figure 21.27 until the last step:

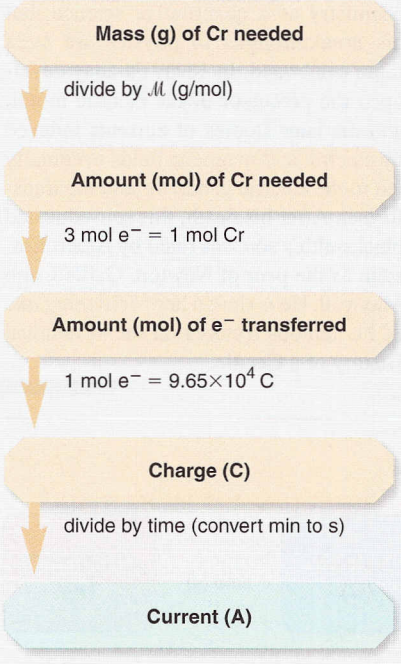
grams of Cl_2 ⇒ moles of Cl_2 ⇒ moles of e^- ⇒ coulombs ⇒ seconds

Sample Problem 21.10 demonstrates the steps as they appear in Figure 21.27.

SAMPLE PROBLEM 21.10 Applying the Relationship Among Current, Time, and Amount of Substance

Problem A technician is plating a faucet with 0.86 g of chromium from an electrolytic bath containing aqueous $Cr_2(SO_4)_3$. If 12.5 min is allowed for the plating, what current is needed?

Plan To find the current, we divide the charge by the time; therefore, we need to find the charge. First we write the half-reaction for Cr^{3+} reduction. From it, we know the number of moles of e^- required per mole of Cr. As the roadmap shows, to find the charge, we convert the mass of Cr needed (0.86 g) to amount (mol) of Cr. The balanced half-reaction gives the amount (mol) of e^- transferred. Then, we use the Faraday constant (9.65×10^4 C/mol e^-) to find the charge and divide by the time (12.5 min, converted to seconds) to obtain the current.



Solution Writing the balanced half-reaction:

$$Cr^{3+}(aq) + 3e^- \longrightarrow Cr(s)$$

Combining steps to find amount (mol) of e^- transferred for mass of Cr needed:

$$\text{Moles of } e^- \text{ transferred} = 0.86 \text{ g Cr} \times \frac{1 \text{ mol Cr}}{52.00 \text{ g Cr}} \times \frac{3 \text{ mol } e^-}{1 \text{ mol Cr}} = 0.050 \text{ mol } e^-$$

Calculating the charge:

$$\text{Charge (C)} = 0.050 \text{ mol } e^- \times \frac{9.65\times10^4 \text{ C}}{1 \text{ mol } e^-} = 4.8\times10^3 \text{ C}$$

Calculating the current:

$$\text{Current (A)} = \frac{\text{charge (C)}}{\text{time (s)}} = \frac{4.8\times10^3 \text{ C}}{12.5 \text{ min}} \times \frac{1 \text{ min}}{60 \text{ s}} = 6.4 \text{ C/s} = 6.4 \text{ A}$$

Check Rounding gives

$$(\sim 0.9 \text{ g})(1 \text{ mol Cr}/50 \text{ g})(3 \text{ mol } e^-/1 \text{ mol Cr}) = 5\times10^{-2} \text{ mol } e^-$$

then $$(5\times10^{-2} \text{ mol } e^-)(\sim 1\times10^5 \text{ C/mol } e^-) = 5\times10^3 \text{ C}$$

and $$(5\times10^3 \text{ C}/12 \text{ min})(1 \text{ min}/60 \text{ s}) = 7 \text{ A}$$

Comment For the sake of introducing Faraday's law, the details of the electroplating process have been simplified here. Actually, electroplating chromium is only 30% to 40% efficient and must be run at a particular temperature range for the plate to appear bright. Nearly 10,000 metric tons (2×10^8 mol) of chromium is used annually for electroplating.

FOLLOW-UP PROBLEM 21.10 Using a current of 4.75 A, how many minutes does it take to plate onto a sculpture 1.50 g of Cu from a $CuSO_4$ solution?

The following Chemical Connections essay links several themes of this chapter in the setting of a living cell.

Cellular Electrochemistry and the Production of ATP

Biological cells apply the principles of electrochemical cells to generate energy. The complex multistep process can be divided into two parts:

1. Bond energy in food is used to generate an electrochemical potential.
2. The potential is used to create the bond energy of the high-energy molecule adenosine triphosphate (ATP; see Chemical Connections, pp. 889–890).

The redox species that accomplish these steps are part of the *electron-transport chain* (ETC), which lies on the inner membranes of *mitochondria,* the subcellular particles that produce the cell's energy (Figure B21.1).

The ETC is a series of large molecules (mostly proteins), each of which contains a *redox couple* (the oxidized and reduced forms of a species), such as Fe^{3+}/Fe^{2+}, that passes electrons down the chain. At three points along the chain, large potential differences supply enough free energy to convert adenosine diphosphate (ADP) into ATP.

Bond Energy to Electrochemical Potential

Cells utilize the energy in food by releasing it in controlled steps rather than all at once. The reaction that ultimately powers the ETC is the oxidation of hydrogen to form water:

$$H_2 + \tfrac{1}{2}O_2 \longrightarrow H_2O$$

However, instead of H_2 gas, which does not occur in organisms, the hydrogen takes the form of two H^+ ions and two e^-. A biological oxidizing agent called NAD^+ (*n*icotinamide *a*denine *d*inucleotide) acquires these protons and electrons in the process of oxidizing the molecules in food. To show this process, we use the following half-reaction (without canceling an H^+ on both sides):

$$NAD^+(aq) + 2H^+(aq) + 2e^- \longrightarrow NADH(aq) + H^+(aq)$$

At the mitochondrial inner membrane, the NADH and H^+ transfer the two e^- to the first redox couple of the ETC and release the two H^+. The electrons are transported down the chain of redox couples, where they finally reduce O_2 to H_2O. The overall process, with standard electrode potentials,* is

$$NADH(aq) + H^+(aq) \longrightarrow NAD^+(aq) + 2H^+(aq) + 2e^- \qquad E^{0'} = -0.315\ V$$

$$\tfrac{1}{2}O_2(aq) + 2e^- + 2H^+(aq) \longrightarrow H_2O(l) \qquad E^{0'} = 0.815\ V$$

$$NADH(aq) + H^+(aq) + \tfrac{1}{2}O_2(aq) \longrightarrow NAD^+(aq) + H_2O(l)$$

$$E^{0'}_{overall} = 0.815\ V - (-0.315\ V) = 1.130\ V$$

Thus, for each mole of NADH that enters the ETC, the free-energy equivalent of 1.14 V is available:

$$\Delta G^{0'} = -nFE^{0'}$$
$$= -(2\ mol\ e^-/mol\ NADH)(96.5\ kJ/V{\cdot}mol\ e^-)(1.130\ V)$$
$$= -218\ kJ/mol\ NADH$$

(continued)

*In biological systems, standard potentials are designated $E^{0'}$ and the standard states include a pH of 7.0 ($[H^+] = 1\times10^{-7}\ M$).

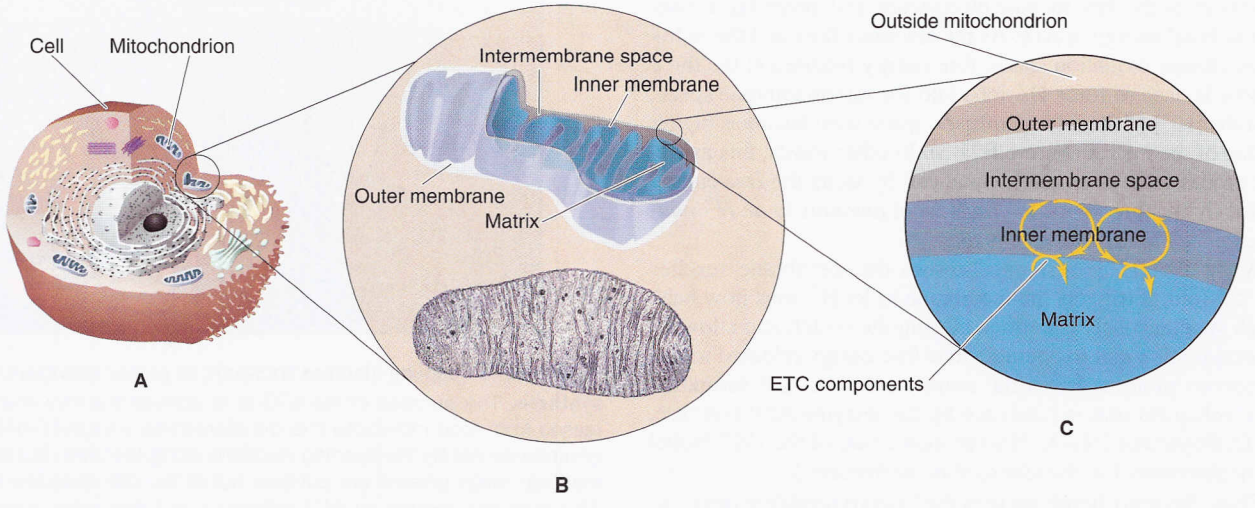


Figure B21.1 The mitochondrion. A, Mitochondria are subcellular particles outside the cell nucleus. **B,** They have a smooth outer membrane and a highly folded inner membrane, shown schematically and in an electron micrograph. **C,** The components of the electron-transport chain are attached to the inner membrane.

Note that this aspect of the process functions like a voltaic cell: a spontaneous reaction, the reduction of O_2 to H_2O, is used to generate a potential. In contrast to a laboratory voltaic cell, in which the overall process occurs in one step, this process occurs in many small steps. Figure B21.2 is a greatly simplified diagram of the three key steps in the ETC that generate the high potential to produce ATP.

In the cell, each of these steps is part of a complex consisting of several components, most of which are proteins. Electrons are passed from one redox couple to the next down the chain, such that the reduced form of the first couple reduces the oxidized form of the second, and so forth. Most of the ETC components are iron-containing proteins, and the redox change consists of the oxidation of Fe^{2+} to Fe^{3+} in one component accompanied by the reduction of Fe^{3+} to Fe^{2+} in another:

$$Fe^{2+}\ (\text{in A}) + Fe^{3+}\ (\text{in B}) \longrightarrow Fe^{3+}\ (\text{in A}) + Fe^{2+}\ (\text{in B})$$

In other words, metal ions within the ETC proteins are the actual species undergoing the redox reactions.

Electrochemical Potential to Bond Energy

At the three points shown in Figure B21.2, the large potential difference is used to form ATP:

$$ADP^{3-}(aq) + HPO_4^{2-}(aq) + H^+(aq) \longrightarrow ATP^{4-}(aq) + H_2O(l)$$
$$\Delta G^{0'} = 30.5\ \text{kJ/mol}$$

Note that the free energy that is *released* at each of the three ATP-producing points exceeds 30.5 kJ, the free energy that must be *absorbed* to form ATP. Thus, just as in an electrolytic cell, an electrochemical potential is supplied to drive a nonspontaneous reaction.

So far, we've followed the flow of *electrons* through the members of the ETC, but where have the released *protons* gone? The answer is the key to *how* electrochemical potential is converted to bond energy in ATP. As the electrons flow and the redox couples change oxidation states, free energy released at the three key steps is used to force H^+ ions into the intermembrane space, so that the $[H^+]$ of the intermembrane space soon becomes higher than that of the matrix (Figure B21.3). In other words, this aspect of the process acts as an electrolytic cell by using the free energy supplied by the three steps to *create what amounts to an H^+ concentration cell across the membrane.*

When the $[H^+]$ difference across the membrane reaches about 2.5-fold, it triggers the membrane to let H^+ ions flow back through spontaneously (in effect, closing the switch and allowing the concentration cell to operate). The free energy released in this spontaneous process drives the nonspontaneous ATP formation via a mechanism that is catalyzed by the enzyme ATP synthase. (Paul D. Boyer and John E. Walker shared half of the 1997 Nobel Prize in chemistry for elucidating this mechanism.)

Thus, the mitochondrion uses the "electron-motive force" of redox couples on the membrane to generate a "proton-motive force" across the membrane, which converts a potential difference to bond energy.

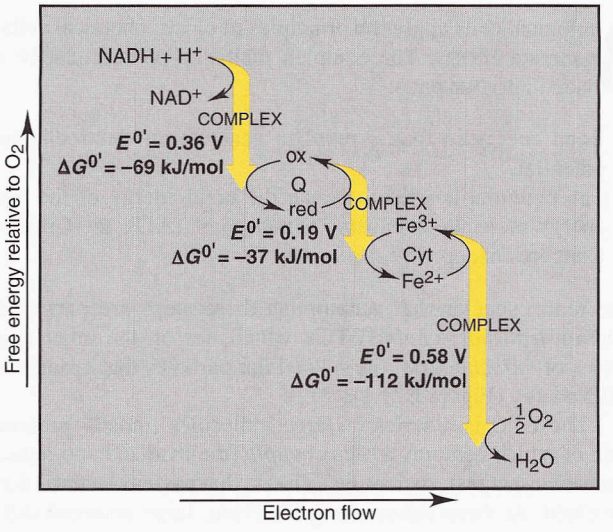

Figure B21.2 The main energy-yielding steps in the electron-transport chain (ETC). The electron carriers in the ETC undergo oxidation and reduction as they pass electrons to one another along the chain. At the three points shown, the difference in potential $E^{0'}$ (or free energy, $\Delta G^{0'}$) is large enough to be used for ATP production. (A complex consists of many components, mostly proteins; Q is a large organic molecule; and Cyt is the abbreviation for a cytochrome, a protein that contains a metal-ion redox couple, such as Fe^{3+}/Fe^{2+}, which is the actual electron carrier.)

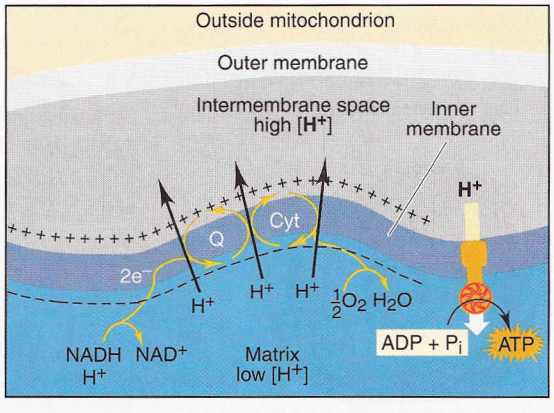

Figure B21.3 Coupling electron transport to proton transport to ATP synthesis. The purpose of the ETC is to convert the free energy released from food molecules into the stored free energy of ATP. It accomplishes this by transporting electrons along the chain (*curved yellow line*), while protons are pumped out of the mitochondrial matrix. This pumping creates an $[H^+]$ difference and generates a potential across the inner membrane (in effect, a concentration cell). When this potential reaches a "trigger" value, H^+ flows back into the inner space, and the free energy released drives the formation of ATP.

SECTION SUMMARY

An electrolytic cell uses electrical energy to drive a nonspontaneous reaction. Oxidation occurs at the anode and reduction at the cathode, but the direction of electron flow and the charges of the electrodes are opposite those in voltaic cells. When two products can form at each electrode, the more easily oxidized substance reacts at the anode and the more easily reduced at the cathode; that is, the half-reaction with the less negative (more positive) E^0 occurs. The reduction or oxidation of water takes place at nonstandard conditions. Overvoltage causes the actual voltage to be unexpectedly high and can affect the electrode product that forms. The amount of product that forms depends on the quantity of charge flowing through the cell, which is related to the magnitude of the current and the time it flows. Cellular redox systems combine aspects of voltaic, concentration, and electrolytic cells to convert bond energy in food into electrochemical potential and then into the bond energy of ATP.

Chapter Perspective

The field of electrochemistry is one of the many areas in which the principles of thermodynamics lead to practical benefits. As you've seen, electrochemical cells can use a reaction to generate energy or use energy to drive a reaction. Such processes are central not only to our mobile way of life, but also to our biological existence. In Chapter 22, we examine the electrochemical (and other) methods used by industry to convert raw natural resources into some of the materials modern society finds indispensable.

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. The meanings of *oxidation* and *reduction;* why an oxidizing agent is reduced and a reducing agent is oxidized (Section 21.1; also Section 4.5)
2. How the half-reaction method is used to balance redox reactions in acidic or basic solution (Section 21.1)
3. The distinction between voltaic and electrolytic cells in terms of the sign of ΔG (Section 21.1)
4. How voltaic cells use a spontaneous reaction to release electrical energy (Section 21.2)
5. The physical makeup of a voltaic cell: arrangement and composition of half-cells, relative charges of electrodes, and purpose of a salt bridge (Section 21.2)
6. How the difference in reducing strength of the electrodes determines the direction of electron flow (Section 21.2)
7. The correspondence between a positive E_{cell} and a spontaneous cell reaction (Section 21.3)
8. The usefulness and significance of standard electrode potentials ($E^0_{half\text{-}cell}$) (Section 21.3)
9. How $E^0_{half\text{-}cell}$ values are combined to give E^0_{cell} (Section 21.3)
10. How the standard reference electrode is used to find an unknown $E^0_{half\text{-}cell}$ (Section 21.3)
11. How an emf series (e.g., Table 21.2 or Appendix D) is used to write spontaneous redox reactions (Section 21.3)
12. How the relative reactivity of a metal is determined by its reducing power and is related to the negative of its $E^0_{half\text{-}cell}$ (Section 21.3)
13. How E_{cell} (the nonstandard cell potential) is related to ΔG (maximum work) and the charge (moles of electrons times the Faraday constant) flowing through the cell (Section 21.4)
14. The interrelationship of ΔG^0, E^0_{cell}, and K (Section 21.4)
15. How E_{cell} changes as the cell operates (Q changes) (Section 21.4)
16. Why a voltaic cell can do work until $Q = K$ (Section 21.4)
17. How a concentration cell does work until the half-cell concentrations are equal (Section 21.4)
18. The distinction between primary (nonrechargeable) and secondary (rechargeable) batteries (Section 21.5)
19. How corrosion occurs and is prevented; the similarities between a corroding metal and a voltaic cell (Section 21.6)
20. How electrolytic cells use nonspontaneous redox reactions driven by an external source of electricity (Section 21.7)
21. How atomic properties (ionization energy and electronegativity) determine the products of the electrolysis of molten salt mixtures (Section 21.7)
22. How the electrolysis of water influences the products of aqueous electrolysis; the importance of overvoltage (Section 21.7)
23. The relationship between the quantity of charge flowing through the cell and the amount of product formed (Section 21.7)

Learning Objectives *(continued)*

Master These Skills

1. Balancing redox reactions by the half-reaction method (Section 21.1 and SP 21.1)
2. Diagramming and notating a voltaic cell (Section 21.2 and SP 21.2)
3. Combining $E^0_{\text{half-cell}}$ values to obtain E^0_{cell} (Section 21.3)
4. Using E^0_{cell} and a known $E^0_{\text{half-cell}}$ to find an unknown $E^0_{\text{half-cell}}$ (SP 21.3)
5. Manipulating half-reactions to write a spontaneous redox reaction and calculate its E^0_{cell} (SP 21.4)
6. Ranking the relative strengths of oxidizing and reducing agents in a redox reaction (SP 21.4)
7. Predicting whether a metal can displace hydrogen or another metal from solution (Section 21.3)
8. Using the interrelationship of ΔG^0, E^0_{cell}, and K to calculate one of the three given the other two (Section 21.4 and SP 21.5)
9. Using the Nernst equation to calculate the nonstandard cell potential (E_{cell}) (SP 21.6)
10. Calculating E_{cell} of a concentration cell (SP 21.7)
11. Predicting the products of the electrolysis of a mixture of molten salts (SP 21.8)
12. Predicting the products of the electrolysis of aqueous salt solutions (SP 21.9)
13. Calculating the current (or time) needed to produce a given amount of product by electrolysis (SP 21.10)

Key Equations and Relationships

21.1 Relating a spontaneous process to the sign of the cell potential (914):

$$E_{\text{cell}} > 0 \text{ for a spontaneous process}$$

21.2 Relating electric potential to energy and charge in SI units (914):

$$\text{Potential} = \text{energy/charge} \quad \text{or} \quad 1\ \text{V} = 1\ \text{J/C}$$

21.3 Relating standard cell potential to standard electrode potentials in a voltaic cell (915):

$$E^0_{\text{cell}} = E^0_{\text{cathode (reduction)}} - E^0_{\text{anode (oxidation)}}$$

21.4 Defining the Faraday constant (924):

$$F = 9.65\times10^4 \frac{\text{J}}{\text{V·mol e}^-} \quad (3\text{ sf})$$

21.5 Relating the free energy change to electrical work and cell potential (924):

$$\Delta G = -w_{\text{max}} = -nFE_{\text{cell}}$$

21.6 Finding the standard free energy change from the standard cell potential (924):

$$\Delta G^0 = -nFE^0_{\text{cell}}$$

21.7 Finding the equilibrium constant from the standard cell potential (924):

$$E^0_{\text{cell}} = \frac{RT}{nF} \ln K$$

21.8 Substituting known values of R, F, and T into Equation 21.7 and converting to common logarithms (925):

$$E^0_{\text{cell}} = \frac{0.0592\ \text{V}}{n} \log K \quad \text{or} \quad \log K = \frac{nE^0_{\text{cell}}}{0.0592\ \text{V}} \qquad (\text{at } 298\ \text{K})$$

21.9 Calculating the nonstandard cell potential (Nernst equation) (926):

$$E_{\text{cell}} = E^0_{\text{cell}} - \frac{RT}{nF} \ln Q$$

21.10 Substituting known values of R, F, and T into the Nernst equation and converting to common logarithms (926):

$$E_{\text{cell}} = E^0_{\text{cell}} - \frac{0.0592\ \text{V}}{n} \log Q \qquad (\text{at } 298\ \text{K})$$

21.11 Relating current to charge and time (945):

$$\text{Current} = \text{charge/time} \quad \text{or} \quad 1\ \text{A} = 1\ \text{C/s}$$

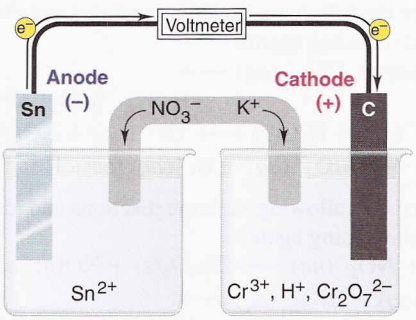
21.2 $Sn(s) \longrightarrow Sn^{2+}(aq) + 2e^-$ [anode; oxidation]

$6e^- + 14H^+(aq) + Cr_2O_7^{2-}(aq) \longrightarrow 2Cr^{3+}(aq) + 7H_2O(l)$ [cathode; reduction]

$3Sn(s) + Cr_2O_7^{2-}(aq) + 14H^+(aq) \longrightarrow 3Sn^{2+}(aq) + 2Cr^{3+}(aq) + 7H_2O(l)$ [overall]

Cell notation:
$Sn(s) \mid Sn^{2+}(aq) \parallel H^+(aq), Cr_2O_7^{2-}(aq), Cr^{3+}(aq) \mid$ graphite



21.3 $Br_2(aq) + 2e^- \longrightarrow 2Br^-(aq)$ $E^0_{bromine} = 1.07$ V [cathode]

$2V^{3+}(aq) + 2H_2O(l) \longrightarrow 2VO^{2+}(aq) + 4H^+(aq) + 2e^-$ $E^0_{vanadium} = ?$ [anode]

$E^0_{vanadium} = E^0_{bromine} - E^0_{cell} = 1.07\text{ V} - 1.39\text{ V} = -0.32\text{ V}$

21.4 $Fe^{2+}(aq) + 2e^- \longrightarrow Fe(s)$ $E^0 = -0.44$ V

$2[Fe^{2+}(aq) \longrightarrow Fe^{3+}(aq) + e^-]$ $E^0 = 0.77$ V

$3Fe^{2+}(aq) \longrightarrow 2Fe^{3+}(aq) + Fe(s)$

$E^0_{cell} = -0.44\text{ V} - 0.77\text{ V} = -1.21\text{ V}$

The reaction is nonspontaneous. The spontaneous reaction is

$2Fe^{3+}(aq) + Fe(s) \longrightarrow 3Fe^{2+}(aq)$ $E^0_{cell} = 1.21$ V

$Fe > Fe^{2+} > Fe^{3+}$

21.5 $Cd(s) + Cu^{2+}(aq) \longrightarrow Cd^{2+}(aq) + Cu(s)$

$\Delta G^0 = -RT \ln K = -8.314\text{ J/mol}\cdot K \times 298\text{ K} \times \ln K$

$= -143\text{ kJ};\ K = 1.2\times10^{25}$

$$E^0_{cell} = \frac{0.0592\text{ V}}{2} \log (1.2\times10^{25}) = 0.742\text{ V}$$

21.6 $Fe(s) \longrightarrow Fe^{2+}(aq) + 2e^-$ $E^0 = -0.44$ V

$Cu^{2+}(aq) + 2e^- \longrightarrow Cu(s)$ $E^0 = 0.34$ V

$Fe(s) + Cu^{2+}(aq) \longrightarrow Fe^{2+}(aq) + Cu(s)$ $E^0_{cell} = 0.78$ V

So $E_{cell} = 0.78\text{ V} + 0.25\text{ V} = 1.03\text{ V}$

$$1.03\text{ V} = 0.78\text{ V} - \frac{0.0592\text{ V}}{2} \log \frac{[Fe^{2+}]}{[Cu^{2+}]}$$

$$\frac{[Fe^{2+}]}{[Cu^{2+}]} = 3.6\times10^{-9}$$

$[Fe^{2+}] = 3.6\times10^{-9} \times 0.30\ M = 1.1\times10^{-9}\ M$

21.7 $Au^{3+}(aq;\ 2.5\times10^{-2}\ M)$ [B] $\longrightarrow$ $Au^{3+}(aq;\ 7.0\times10^{-4}\ M)$ [A]

$$E_{cell} = 0\text{ V} - \left(\frac{0.0592\text{ V}}{3} \times \log \frac{7.0\times10^{-4}}{2.5\times10^{-2}}\right) = 0.0306\text{ V}$$

A is negative, so it is the anode.

21.8 Oxidizing agents: K^+ and Al^{3+}.
Reducing agents: F^- and Br^-.
Al is above and to the right of K in the periodic table, so it has a higher IE:

$Al^{3+}(l) + 3e^- \longrightarrow Al(s)$ [cathode; reduction]

Br is below F in Group 7A(17), so it has a lower EN:

$2Br^-(l) \longrightarrow Br_2(g) + 2e^-$ [anode; oxidation]

$2Al^{3+}(l) + 6Br^-(l) \longrightarrow 2Al(s) + 3Br_2(g)$ [overall]

21.9 The reduction with the more positive electrode potential is $Au^{3+}(aq) + 3e^- \longrightarrow Au(s)$; $E^0 = 1.50$ V [cathode; reduction]

Because of overvoltage, O_2 will not form at the anode, so Br_2 will form:

$2Br^-(aq) \longrightarrow Br_2(l) + 2e^-$; $E^0 = 1.07$ V [cathode; oxidation]

21.10 $Cu^{2+}(aq) + 2e^- \longrightarrow Cu(s)$; therefore,
2 mol e^-/1 mol Cu = 2 mol e^-/63.55 g Cu

$$\text{Time (min)} = 1.50\text{ g Cu} \times \frac{2\text{ mol e}^-}{63.55\text{ g Cu}} \times \frac{9.65\times10^4\text{ C}}{1\text{ mol e}^-} \times \frac{1\text{ s}}{4.75\text{ C}} \times \frac{1\text{ min}}{60\text{ s}}$$

$= 16.0$ min

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

Note: Unless stated otherwise, all problems refer to systems at 298 K (25°C).

Redox Reactions and Electrochemical Cells

(Sample Problem 21.1)

Concept Review Questions

21.1 Define *oxidation* and *reduction* in terms of electron transfer and change in oxidation number.

21.2 Why must an electrochemical process involve a redox reaction?

21.3 Can one half-reaction in a redox process take place independently of the other? Explain.

21.4 Water is used to balance O atoms in the half-reaction method. Why can't O^{2-} ions be used instead?

21.5 During the redox balancing process, what step is taken to ensure that e^- loss equals e^- gain?

21.6 How are protons removed when balancing a redox reaction in basic solution?

21.7 Are spectator ions used to balance the half-reactions of a redox reaction? At what stage might spectator ions enter the balancing process?

21.8 Which type of electrochemical cell has $\Delta G_{sys} < 0$? Which type shows an increase in free energy?

21.9 Which statements are true? Correct any that are false.

(a) In a voltaic cell, the anode is negative relative to the cathode.

(b) Oxidation occurs at the anode of a voltaic or an electrolytic cell.

(c) Electrons flow into the cathode of an electrolytic cell.

(d) In a voltaic cell, the surroundings do work on the system.

(e) A metal that plates out of an electrolytic cell appears on the cathode.

(f) The cell electrolyte provides a solution of mobile electrons.

Skill-Building Exercises *(grouped in similar pairs)*

21.10 Consider the following balanced redox reaction:

$$16H^+(aq) + 2MnO_4^-(aq) + 10Cl^-(aq) \longrightarrow 2Mn^{2+}(aq) + 5Cl_2(g) + 8H_2O(l)$$

(a) Which species is being oxidized?

(b) Which species is being reduced?

(c) Which species is the oxidizing agent?

(d) Which species is the reducing agent?

(e) From which species to which does electron transfer occur?

(f) Write the balanced molecular equation, with K^+ and SO_4^{2-} as the spectator ions.

21.11 Consider the following balanced redox reaction:

$$2CrO_2^-(aq) + 2H_2O(l) + 6ClO^-(aq) \longrightarrow 2CrO_4^{2-}(aq) + 3Cl_2(g) + 4OH^-(aq)$$

(a) Which species is being oxidized?

(b) Which species is being reduced?

(c) Which species is the oxidizing agent?

(d) Which species is the reducing agent?

(e) From which species to which does electron transfer occur?

(f) Write the balanced molecular equation, with Na^+ as the spectator ion.

21.12 Balance the following skeleton reactions and identify the oxidizing and reducing agents:

(a) $ClO_3^-(aq) + I^-(aq) \longrightarrow I_2(s) + Cl^-(aq)$ [acidic]

(b) $MnO_4^-(aq) + SO_3^{2-}(aq) \longrightarrow MnO_2(s) + SO_4^{2-}(aq)$ [basic]

(c) $MnO_4^-(aq) + H_2O_2(aq) \longrightarrow Mn^{2+}(aq) + O_2(g)$ [acidic]

21.13 Balance the following skeleton reactions and identify the oxidizing and reducing agents:

(a) $O_2(g) + NO(g) \longrightarrow NO_3^-(aq)$ [acidic]

(b) $CrO_4^{2-}(aq) + Cu(s) \longrightarrow Cr(OH)_3(s) + Cu(OH)_2(s)$ [basic]

(c) $AsO_4^{3-}(aq) + NO_2^-(aq) \longrightarrow AsO_2^-(aq) + NO_3^-(aq)$ [basic]

21.14 Balance the following skeleton reactions and identify the oxidizing and reducing agents:

(a) $Cr_2O_7^{2-}(aq) + Zn(s) \longrightarrow Zn^{2+}(aq) + Cr^{3+}(aq)$ [acidic]

(b) $Fe(OH)_2(s) + MnO_4^-(aq) \longrightarrow MnO_2(s) + Fe(OH)_3(s)$ [basic]

(c) $Zn(s) + NO_3^-(aq) \longrightarrow Zn^{2+}(aq) + N_2(g)$ [acidic]

21.15 Balance the following skeleton reactions and identify the oxidizing and reducing agents:

(a) $BH_4^-(aq) + ClO_3^-(aq) \longrightarrow H_2BO_3^-(aq) + Cl^-(aq)$ [basic]

(b) $CrO_4^{2-}(aq) + N_2O(g) \longrightarrow Cr^{3+}(aq) + NO(g)$ [acidic]

(c) $Br_2(l) \longrightarrow BrO_3^-(aq) + Br^-(aq)$ [basic]

21.16 Balance the following skeleton reactions and identify the oxidizing and reducing agents:

(a) $Sb(s) + NO_3^-(aq) \longrightarrow Sb_4O_6(s) + NO(g)$ [acidic]

(b) $Mn^{2+}(aq) + BiO_3^-(aq) \longrightarrow MnO_4^-(aq) + Bi^{3+}(aq)$ [acidic]

(c) $Fe(OH)_2(s) + Pb(OH)_3^-(aq) \longrightarrow Fe(OH)_3(s) + Pb(s)$ [basic]

21.17 Balance the following skeleton reactions and identify the oxidizing and reducing agents:

(a) $NO_2(g) \longrightarrow NO_3^-(aq) + NO_2^-(aq)$ [basic]

(b) $Zn(s) + NO_3^-(aq) \longrightarrow Zn(OH)_4^{2-}(aq) + NH_3(g)$ [basic]

(c) $H_2S(g) + NO_3^-(aq) \longrightarrow S_8(s) + NO(g)$ [acidic]

21.18 Balance the following skeleton reactions and identify the oxidizing and reducing agents:

(a) $As_4O_6(s) + MnO_4^-(aq) \longrightarrow AsO_4^{3-}(aq) + Mn^{2+}(aq)$ [acidic]

(b) $P_4(s) \longrightarrow HPO_3^{2-}(aq) + PH_3(g)$ [acidic]

(c) $MnO_4^-(aq) + CN^-(aq) \longrightarrow MnO_2(s) + CNO^-(aq)$ [basic]

21.19 Balance the following skeleton reactions and identify the oxidizing and reducing agents:

(a) $SO_3^{2-}(aq) + Cl_2(g) \longrightarrow SO_4^{2-}(aq) + Cl^-(aq)$ [basic]

(b) $Fe(CN)_6^{3-}(aq) + Re(s) \longrightarrow Fe(CN)_6^{4-}(aq) + ReO_4^-(aq)$ [basic]

(c) $MnO_4^-(aq) + HCOOH(aq) \longrightarrow Mn^{2+}(aq) + CO_2(g)$ [acidic]

Problems in Context

21.20 In many residential water systems, the aqueous Fe^{3+} concentration is high enough to stain sinks and turn drinking water light brown. The iron content is analyzed by first reducing the Fe^{3+} to Fe^{2+} and then titrating with MnO_4^- in acidic solution. Balance the skeleton reaction of the titration step:

$$Fe^{2+}(aq) + MnO_4^-(aq) \longrightarrow Mn^{2+}(aq) + Fe^{3+}(aq)$$

21.21 *Aqua regia,* a mixture of concentrated HNO_3 and HCl, was developed by alchemists as a means to "dissolve" gold. The process is actually a redox reaction with the following simplified skeleton reaction:

$$Au(s) + NO_3^-(aq) + Cl^-(aq) \longrightarrow AuCl_4^-(aq) + NO_2(g)$$

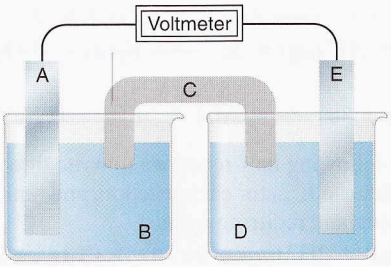
(a) Balance the reaction by the half-reaction method.
(b) What are the oxidizing and reducing agents?
(c) What is the function of HCl in aqua regia?

Voltaic Cells: Using Spontaneous Reactions to Generate Electrical Energy

(Sample Problem 21.2)

Concept Review Questions

21.22 Consider the following general voltaic cell:



Identify the (a) anode, (b) cathode, (c) salt bridge, (d) electrode at which e^- leave the cell, (e) electrode with a positive charge, and (f) electrode that gains mass as the cell operates (assuming that a metal plates out).

21.23 Why does a voltaic cell not operate unless the two compartments are connected through an external circuit?

21.24 What purpose does the salt bridge serve in a voltaic cell, and how does it accomplish this purpose?

21.25 What is the difference between an active and an inactive electrode? Why are inactive electrodes used? Name two substances commonly used for inactive electrodes.

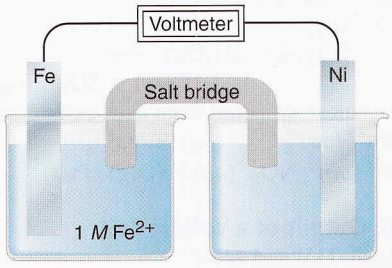
21.26 When a piece of metal A is placed in a solution containing ions of metal B, metal B plates out on the piece of A.
(a) Which metal is being oxidized?
(b) Which metal is being displaced?
(c) Which metal would you use as the anode in a voltaic cell incorporating these two metals?
(d) If bubbles of H_2 form when B is placed in acid, will they form if A is placed in acid? Explain.

Skill-Building Exercises *(grouped in similar pairs)*

21.27 A voltaic cell is constructed with an Sn/Sn^{2+} half-cell and a Zn/Zn^{2+} half-cell. The zinc electrode is negative.
(a) Write balanced half-reactions and the overall reaction.
(b) Diagram the cell, labeling electrodes with their charges and showing the directions of electron flow in the circuit and of cation and anion flow in the salt bridge.

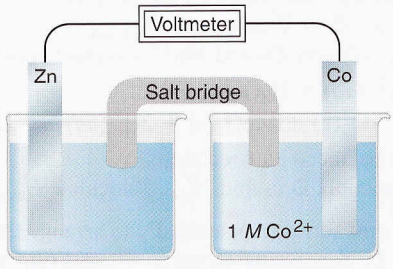
21.28 A voltaic cell is constructed with an Ag/Ag^+ half-cell and a Pb/Pb^{2+} half-cell. The silver electrode is positive.
(a) Write balanced half-reactions and the overall reaction.
(b) Diagram the cell, labeling electrodes with their charges and showing the directions of electron flow in the circuit and of cation and anion flow in the salt bridge.

21.29 Consider the following voltaic cell:



(a) In which direction do electrons flow in the external circuit?
(b) In which half-cell does oxidation occur?
(c) In which half-cell do electrons enter the cell?
(d) At which electrode are electrons consumed?
(e) Which electrode is negatively charged?
(f) Which electrode decreases in mass during cell operation?
(g) Suggest a solution for the cathode electrolyte.
(h) Suggest a pair of ions for the salt bridge.
(i) For which electrode could you use an inactive material?
(j) In which direction do anions within the salt bridge move to maintain charge neutrality?
(k) Write balanced half-reactions and an overall cell reaction.

21.30 Consider the following voltaic cell:



(a) In which direction do electrons flow in the external circuit?
(b) In which half-cell does reduction occur?
(c) In which half-cell do electrons leave the cell?
(d) At which electrode are electrons generated?
(e) Which electrode is positively charged?
(f) Which electrode increases in mass during cell operation?
(g) Suggest a solution for the anode electrolyte.
(h) Suggest a pair of ions for the salt bridge.
(i) For which electrode could you use an inactive material?
(j) In which direction do cations within the salt bridge move to maintain charge neutrality?
(k) Write balanced half-reactions and an overall cell reaction.

21.31 A voltaic cell is constructed with an Fe/Fe^{2+} half-cell and an Mn/Mn^{2+} half-cell. The iron electrode is positive.
(a) Write balanced half-reactions and the overall reaction.
(b) Diagram the cell, labeling electrodes with their charges and showing the directions of electron flow in the circuit and of cation and anion flow in the salt bridge.

21.32 A voltaic cell is constructed with a Cu/Cu^{2+} half-cell and an Ni/Ni^{2+} half-cell. The nickel electrode is negative.
(a) Write balanced half-reactions and the overall reaction.
(b) Diagram the cell, labeling electrodes with their charges and showing the directions of electron flow in the circuit and of cation and anion flow in the salt bridge.

21.33 Write the cell notation for the voltaic cell that incorporates each of the following redox reactions:
(a) $Al(s) + Cr^{3+}(aq) \longrightarrow Al^{3+}(aq) + Cr(s)$
(b) $Cu^{2+}(aq) + SO_2(g) + 2H_2O(l) \longrightarrow Cu(s) + SO_4^{2-}(aq) + 4H^+(aq)$

21.34 Write a balanced equation from each cell notation:
(a) $Mn(s) \mid Mn^{2+}(aq) \parallel Cd^{2+}(aq) \mid Cd(s)$
(b) $Fe(s) \mid Fe^{2+}(aq) \parallel NO_3^-(aq) \mid NO(g) \mid Pt(s)$

Cell Potential: Output of a Voltaic Cell

(Sample Problems 21.3 and 21.4)

Concept Review Questions

21.35 How is a standard reference electrode used to determine unknown $E^0_{\text{half-cell}}$ values?

21.36 What does a negative E^0_{cell} indicate about a redox reaction? What does it indicate about the reverse reaction?

21.37 The standard cell potential is a thermodynamic state function. How are E^0 values treated similarly to ΔH^0, ΔG^0, and S^0 values? How are they treated differently?

Skill-Building Exercises *(grouped in similar pairs)*

21.38 In basic solution, Se^{2-} and SO_3^{2-} ions react spontaneously:

$$2Se^{2-}(aq) + 2SO_3^{2-}(aq) + 3H_2O(l) \longrightarrow 2Se(s) + 6OH^-(aq) + S_2O_3^{2-}(aq) \qquad E^0_{\text{cell}} = 0.35\ \text{V}$$

(a) Write balanced half-reactions for the process.
(b) If E^0_{sulfite} is -0.57 V, calculate E^0_{selenium}.

21.39 In acidic solution, O_3 and Mn^{2+} ion react spontaneously:

$$O_3(g) + Mn^{2+}(aq) + H_2O(l) \longrightarrow O_2(g) + MnO_2(s) + 2H^+(aq) \qquad E^0_{\text{cell}} = 0.84\ \text{V}$$

(a) Write the balanced half-reactions.
(b) Using Appendix D to find E^0_{ozone}, calculate $E^0_{\text{manganese}}$.

21.40 Use the emf series (Appendix D) to arrange the species.
(a) In order of *decreasing* strength as *oxidizing* agents: Fe^{3+}, Br_2, Cu^{2+}
(b) In order of *increasing* strength as *oxidizing* agents: Ca^{2+}, $Cr_2O_7^{2-}$, Ag^+

21.41 Use the emf series (Appendix D) to arrange the species.
(a) In order of *decreasing* strength as *reducing* agents: SO_2, $PbSO_4$, MnO_2
(b) In order of *increasing* strength as *reducing* agents: Hg, Fe, Sn

21.42 Balance each skeleton reaction, calculate E^0_{cell}, and state whether the reaction is spontaneous:
(a) $Co(s) + H^+(aq) \longrightarrow Co^{2+}(aq) + H_2(g)$
(b) $Mn^{2+}(aq) + Br_2(l) \longrightarrow MnO_4^-(aq) + Br^-(aq)$ [acidic]
(c) $Hg_2^{2+}(aq) \longrightarrow Hg^{2+}(aq) + Hg(l)$

21.43 Balance each skeleton reaction, calculate E^0_{cell}, and state whether the reaction is spontaneous:
(a) $Cl_2(g) + Fe^{2+}(aq) \longrightarrow Cl^-(aq) + Fe^{3+}(aq)$
(b) $Mn^{2+}(aq) + Co^{3+}(aq) \longrightarrow MnO_2(s) + Co^{2+}(aq)$ [acidic]
(c) $AgCl(s) + NO(g) \longrightarrow Ag(s) + Cl^-(aq) + NO_3^-(aq)$ [acidic]

21.44 Balance each skeleton reaction, calculate E^0_{cell}, and state whether the reaction is spontaneous:
(a) $Ag(s) + Cu^{2+}(aq) \longrightarrow Ag^+(aq) + Cu(s)$
(b) $Cd(s) + Cr_2O_7^{2-}(aq) \longrightarrow Cd^{2+}(aq) + Cr^{3+}(aq)$
(c) $Ni^{2+}(aq) + Pb(s) \longrightarrow Ni(s) + Pb^{2+}(aq)$

21.45 Balance each skeleton reaction, calculate E^0_{cell}, and state whether the reaction is spontaneous:
(a) $Cu^+(aq) + PbO_2(s) + SO_4^{2-}(aq) \longrightarrow PbSO_4(s) + Cu^{2+}(aq)$ [acidic]
(b) $H_2O_2(aq) + Ni^{2+}(aq) \longrightarrow O_2(g) + Ni(s)$ [acidic]
(c) $MnO_2(s) + Ag^+(aq) \longrightarrow MnO_4^-(aq) + Ag(s)$ [basic]

21.46 Use the following half-reactions to write three spontaneous reactions, calculate E^0_{cell} for each reaction, and rank the strengths of the oxidizing and reducing agents:
(1) $Al^{3+}(aq) + 3e^- \longrightarrow Al(s) \qquad E^0 = -1.66\ \text{V}$
(2) $N_2O_4(g) + 2e^- \longrightarrow 2NO_2^-(aq) \qquad E^0 = 0.867\ \text{V}$
(3) $SO_4^{2-}(aq) + H_2O(l) + 2e^- \longrightarrow SO_3^{2-}(aq) + 2OH^-(aq) \qquad E^0 = 0.93\ \text{V}$

21.47 Use the following half-reactions to write three spontaneous reactions, calculate E^0_{cell} for each reaction, and rank the strengths of the oxidizing and reducing agents:
(1) $Au^+(aq) + e^- \longrightarrow Au(s) \qquad E^0 = 1.69\ \text{V}$
(2) $N_2O(g) + 2H^+(aq) + 2e^- \longrightarrow N_2(g) + H_2O(l) \qquad E^0 = 1.77\ \text{V}$
(3) $Cr^{3+}(aq) + 3e^- \longrightarrow Cr(s) \qquad E^0 = -0.74\ \text{V}$

21.48 Use the following half-reactions to write three spontaneous reactions, calculate E^0_{cell} for each reaction, and rank the strengths of the oxidizing and reducing agents:
(1) $2HClO(aq) + 2H^+(aq) + 2e^- \longrightarrow Cl_2(g) + 2H_2O(l) \qquad E^0 = 1.63\ \text{V}$
(2) $Pt^{2+}(aq) + 2e^- \longrightarrow Pt(s) \qquad E^0 = 1.20\ \text{V}$
(3) $PbSO_4(s) + 2e^- \longrightarrow Pb(s) + SO_4^{2-}(aq) \qquad E^0 = -0.31\ \text{V}$

21.49 Use the following half-reactions to write three spontaneous reactions, calculate E^0_{cell} for each reaction, and rank the strengths of the oxidizing and reducing agents:
(1) $I_2(s) + 2e^- \longrightarrow 2I^-(aq) \qquad E^0 = 0.53\ \text{V}$
(2) $S_2O_8^{2-}(aq) + 2e^- \longrightarrow 2SO_4^{2-}(aq) \qquad E^0 = 2.01\ \text{V}$
(3) $Cr_2O_7^{2-}(aq) + 14H^+(aq) + 6e^- \longrightarrow 2Cr^{3+}(aq) + 7H_2O(l) \qquad E^0 = 1.33\ \text{V}$

Problems in Context

21.50 When metal A is placed in a solution of a salt of metal B, the surface of metal A changes color. When metal B is placed in acid solution, gas bubbles form on the surface of the metal. When metal A is placed in a solution of a salt of metal C, no change is observed in the solution or on the metal A surface. Will metal C cause formation of H_2 when placed in acid solution? Rank metals A, B, and C in order of *decreasing* reducing strength.

21.51 When a clean iron nail is placed in an aqueous solution of copper(II) sulfate, the nail becomes coated with a brownish black material.
(a) What is the material coating the iron?
(b) What are the oxidizing and reducing agents?
(c) Can this reaction be made into a voltaic cell?
(d) Write the balanced equation for the reaction.
(e) Calculate E^0_{cell} for the process.

Free Energy and Electrical Work

(Sample Problems 21.5 to 21.7)

Concept Review Questions

21.52 (a) How do the relative magnitudes of Q and K relate to the signs of ΔG and E_{cell}? Explain.
(b) Can a cell do work when $Q/K > 1$ or $Q/K < 1$? Explain.

21.53 A voltaic cell consists of a metal A/A^+ electrode and a metal B/B^+ electrode, with the A/A^+ electrode negative. The initial $[A^+]/[B^+]$ is such that $E_{cell} > E^0_{cell}$.
(a) How do $[A^+]$ and $[B^+]$ change as the cell operates?
(b) How does E_{cell} change as the cell operates?
(c) What is $[A^+]/[B^+]$ when $E_{cell} = E^0_{cell}$? Explain.
(d) Is it possible for E_{cell} to be less than E^0_{cell}? Explain.

21.54 Explain whether E_{cell} of a voltaic cell will increase or decrease with each of the following changes:
(a) Decrease in cell temperature
(b) Increase in [active ion] in the anode compartment
(c) Increase in [active ion] in the cathode compartment
(d) Increase in pressure of a gaseous reactant in the cathode compartment

21.55 In a concentration cell, is the more concentrated electrolyte in the cathode or the anode compartment? Explain.

Skill-Building Exercises *(grouped in similar pairs)*

21.56 What is the value of the equilibrium constant for the reaction between each pair at 25°C?
(a) $Ni(s)$ and $Ag^+(aq)$ (b) $Fe(s)$ and $Cr^{3+}(aq)$

21.57 What is the value of the equilibrium constant for the reaction between each pair at 25°C?
(a) $Al(s)$ and $Cd^{2+}(aq)$ (b) $I_2(s)$ and $Br^-(aq)$

21.58 What is the value of the equilibrium constant for the reaction between each pair at 25°C?
(a) $Ag(s)$ and $Mn^{2+}(aq)$ (b) $Cl_2(g)$ and $Br^-(aq)$

21.59 What is the value of the equilibrium constant for the reaction between each pair at 25°C?
(a) $Cr(s)$ and $Cu^{2+}(aq)$ (b) $Sn(s)$ and $Pb^{2+}(aq)$

21.60 Calculate ΔG^0 for each of the reactions in Problem 21.56.

21.61 Calculate ΔG^0 for each of the reactions in Problem 21.57.

21.62 Calculate ΔG^0 for each of the reactions in Problem 21.58.

21.63 Calculate ΔG^0 for each of the reactions in Problem 21.59.

21.64 What are E^0_{cell} and ΔG^0 of a redox reaction at 25°C for which $n = 1$ and $K = 5.0\times10^3$?

21.65 What are E^0_{cell} and ΔG^0 of a redox reaction at 25°C for which $n = 1$ and $K = 5.0\times10^{-6}$?

21.66 What are E^0_{cell} and ΔG^0 of a redox reaction at 25°C for which $n = 2$ and $K = 75$?

21.67 What are E^0_{cell} and ΔG^0 of a redox reaction at 25°C for which $n = 2$ and $K = 0.075$?

21.68 A voltaic cell consists of a standard hydrogen electrode in one half-cell and a Cu/Cu^{2+} half-cell. Calculate $[Cu^{2+}]$ when E_{cell} is 0.25 V.

21.69 A voltaic cell consists of an Mn/Mn^{2+} half-cell and a Pb/Pb^{2+} half-cell. Calculate $[Pb^{2+}]$ when $[Mn^{2+}]$ is 1.3 M and E_{cell} is 0.42 V.

21.70 A voltaic cell with Ni/Ni^{2+} and Co/Co^{2+} half-cells has the following initial concentrations: $[Ni^{2+}] = 0.80\ M$; $[Co^{2+}] = 0.20\ M$.
(a) What is the initial E_{cell}?
(b) What is $[Ni^{2+}]$ when E_{cell} reaches 0.03 V?
(c) What are the equilibrium concentrations of the ions?

21.71 A voltaic cell with Mn/Mn^{2+} and Cd/Cd^{2+} half-cells has the following initial concentrations: $[Mn^{2+}] = 0.090\ M$; $[Cd^{2+}] = 0.060\ M$.
(a) What is the initial E_{cell}?
(b) What is E_{cell} when $[Cd^{2+}]$ reaches 0.050 M?
(c) What is $[Mn^{2+}]$ when E_{cell} reaches 0.055 V?
(d) What are the equilibrium concentrations of the ions?

21.72 A concentration cell consists of two H_2/H^+ half-cells. Half-cell A has H_2 at 0.90 atm bubbling into 0.10 M HCl. Half-cell B has H_2 at 0.50 atm bubbling into 2.0 M HCl. Which half-cell houses the anode? What is the voltage of the cell?

21.73 A concentration cell consists of two Sn/Sn^{2+} half-cells. The electrolyte in compartment A is 0.13 M $Sn(NO_3)_2$. The electrolyte in B is 0.87 M $Sn(NO_3)_2$. Which half-cell houses the cathode? What is the voltage of the cell?

Electrochemical Processes in Batteries

Concept Review Questions

21.74 What is the direction of electron flow with respect to the anode and the cathode in a battery? Explain.

21.75 In the everyday batteries used for flashlights, toys, etc., no salt bridge is evident. What is used in these cells to separate the anode and cathode compartments?

21.76 Both a D-sized and an AAA-sized alkaline battery have an output of 1.5 V. What property of the cell potential allows this to occur? What is different about these two batteries?

Problems in Context

21.77 Many common electrical devices require the use of more than one battery.
(a) How many alkaline batteries must be placed in series to light a flashlight with a 6.0-V bulb?
(b) What is the voltage requirement of a camera that uses six silver batteries?
(c) How many volts can a car battery deliver if two of its anode/cathode cells are shorted?

Corrosion: A Case of Environmental Electrochemistry

Concept Review Questions

21.78 During reconstruction of the Statue of Liberty, Teflon spacers were placed between the iron skeleton and the copper plates that cover the statue. What purpose do these spacers serve?

21.79 Why do steel bridge-supports rust at the waterline but not above or below it?

21.80 After the 1930s, chromium replaced nickel for corrosion resistance and appearance on car bumpers and trim. How does chromium protect steel from corrosion?

21.81 Which of the following metals are suitable for use as sacrificial anodes to protect against corrosion of underground iron pipes? If any are not suitable, explain why:
(a) Aluminum
(b) Magnesium
(c) Sodium
(d) Lead
(e) Nickel
(f) Zinc
(g) Chromium

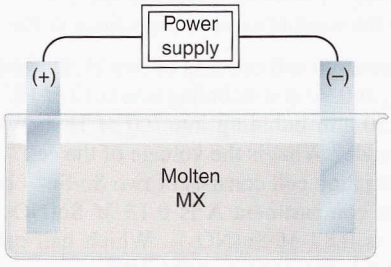
Electrolytic Cells: Using Electrical Energy to Drive Nonspontaneous Reactions

(Sample Problems 21.8 to 21.10)

Concept Review Questions

Note: Unless stated otherwise, assume that the electrolytic cells in the following problems operate at 100% efficiency.

21.82 Consider the following general electrolytic cell:



(a) At which electrode does oxidation occur?
(b) At which electrode does elemental M form?
(c) At which electrode are electrons being released by ions?
(d) At which electrode are electrons entering the cell?

21.83 A voltaic cell consists of Cr/Cr^{3+} and Cd/Cd^{2+} half-cells with all components in their standard states. After 10 minutes of operation, a thin coating of cadmium metal has plated out on the cathode. Describe what will happen if you attach the negative terminal of a dry cell (1.5 V) to the cell cathode and the positive terminal to the cell anode.

21.84 Why are $E_{\text{half-cell}}$ values for the oxidation and reduction of water different from $E^0_{\text{half-cell}}$ values for the same processes?

21.85 In an aqueous electrolytic cell, nitrate ions never react at the anode, but nitrite ions do. Explain.

21.86 How does overvoltage influence the products in the electrolysis of aqueous salts?

Skill-Building Exercises *(grouped in similar pairs)*

21.87 In the electrolysis of molten NaBr,
(a) What product forms at the anode?
(b) What product forms at the cathode?

21.88 In the electrolysis of molten BaI_2,
(a) What product forms at the negative electrode?
(b) What product forms at the positive electrode?

21.89 In the electrolysis of a molten mixture of KI and MgF_2, identify the product that forms at the anode and at the cathode.

21.90 In the electrolysis of a molten mixture of CsBr and $SrCl_2$, identify the product that forms at the negative electrode and at the positive electrode.

21.91 In the electrolysis of a molten mixture of NaCl and $CaBr_2$, identify the product that forms at the anode and at the cathode.

21.92 In the electrolysis of a molten mixture of RbF and $CaCl_2$, identify the product that forms at the negative electrode and at the positive electrode.

21.93 Identify those elements that can be prepared by electrolysis of their aqueous salts: copper, barium, aluminum, bromine.

21.94 Identify those elements that can be prepared by electrolysis of their aqueous salts: strontium, gold, tin, chlorine.

21.95 Identify those elements that can be prepared by electrolysis of their aqueous salts: lithium, iodine, zinc, silver.

21.96 Identify those elements that can be prepared by electrolysis of their aqueous salts: fluorine, manganese, iron, cadmium.

21.97 What product forms at each electrode in the aqueous electrolysis of the following salts: (a) LiF; (b) $SnSO_4$?

21.98 What product forms at each electrode in the aqueous electrolysis of the following salts: (a) $ZnBr_2$; (b) $Cu(HCO_3)_2$?

21.99 What product forms at each electrode in the aqueous electrolysis of the following salts: (a) $Cr(NO_3)_3$; (b) $MnCl_2$?

21.100 What product forms at each electrode in the aqueous electrolysis of the following salts: (a) FeI_2; (b) K_3PO_4?

21.101 Electrolysis of molten $MgCl_2$ is the final production step in the isolation of magnesium from seawater by the Dow process (Section 22.4). Assuming that 35.6 g of Mg metal forms,
(a) How many moles of electrons are required?
(b) How many coulombs are required?
(c) How many amps will produce this amount in 2.50 h?

21.102 Electrolysis of molten NaCl in a Downs cell is the major isolation step in the production of sodium metal (Section 22.4). Assuming that 215 g of Na metal forms,
(a) How many moles of electrons are required?
(b) How many coulombs are required?
(c) How many amps will produce this amount in 9.50 h?

21.103 How many grams of radium can form by passing 215 C through an electrolytic cell containing a molten radium salt?

21.104 How many grams of aluminum can form by passing 305 C through an electrolytic cell containing a molten aluminum salt?

21.105 How many seconds does it take to deposit 85.5 g of Zn on a steel gate when 23.0 A is passed through a $ZnSO_4$ solution?

21.106 How many seconds does it take to deposit 1.63 g of Ni on a decorative drawer handle when 13.7 A is passed through a $Ni(NO_3)_2$ solution?

Problems in Context

21.107 A professor adds Na_2SO_4 to water to facilitate its electrolysis in a lecture demonstration. (a) What is the purpose of the Na_2SO_4? (b) Why is the water electrolyzed instead of the salt?

21.108 Subterranean brines in parts of the United States are rich in iodides and bromides and serve as an industrial source of these elements. In one recovery method, the brines are evaporated to dryness and then melted and electrolyzed. Which halogen is more likely to form from this treatment? Why?

21.109 Zinc plating (galvanizing) is an important means of corrosion protection. Although the process is done customarily by dipping the object into molten zinc, the metal can also be electroplated from aqueous solutions. How many grams of zinc can be deposited on a steel tank from a $ZnSO_4$ solution when a 0.755-A current flows for 2.00 days?

Comprehensive Problems

21.110 The MnO_2 used in alkaline batteries can be produced by an electrochemical process of which one half-reaction is

$$Mn^{2+}(aq) + 2H_2O(l) \longrightarrow MnO_2(s) + 4H^+(aq) + 2e^-$$

If a current of 25.0 A is used, how many hours are needed to produce 1.00 kg of MnO_2? At which electrode is the MnO_2 formed?

21.111 Car manufacturers are developing engines that use H_2 as fuel. In Iceland, Sweden, and other parts of Scandinavia, where hydroelectric plants produce inexpensive electric power, the H_2 can be made industrially by the electrolysis of water.

(a) How many coulombs are needed to produce 2.5×10^6 L of H_2 gas at 10.0 atm and 25°C? (Assume the ideal gas law applies.)
(b) If the coulombs are supplied at 1.24 V, how many joules are produced?
(c) If the combustion of oil yields 4.0×10^4 kJ/kg, what mass of oil must be burned to yield the number of joules in part (b)?

21.112 The overall cell reaction occurring in an alkaline battery is

$$Zn(s) + MnO_2(s) + H_2O(l) \longrightarrow ZnO(s) + Mn(OH)_2(s)$$

(a) How many moles of electrons flow per mole of reaction?
(b) If 2.50 g of zinc is oxidized, how many grams of manganese dioxide and of water are consumed?
(c) What is the total mass of reactants consumed in part (b)?
(d) How many coulombs are produced in part (b)?
(e) In practice, voltaic cells of a given capacity (coulombs) are heavier than the calculation in part (c) indicates. Explain.

21.113 An inexpensive and accurate method of measuring the quantity of electricity passing through a circuit is to pass it through a solution of a metal ion and weigh the metal deposited. A silver electrode immersed in an Ag^+ solution weighs 1.7854 g before the current passes and weighs 1.8016 g after the current has passed. How many coulombs have passed?

21.114 Brass, an alloy of copper and zinc, can be produced by simultaneously electroplating the two metals from a solution containing their 2+ ions. If exactly 70.0% of the total current is used to plate copper, while 30.0% goes to plating zinc, what is the mass percent of copper in the brass?

21.115 Compare and contrast a voltaic cell and an electrolytic cell with respect to each of the following:
(a) Sign of the free energy change
(b) Nature of the half-reaction at the anode
(c) Nature of the half-reaction at the cathode
(d) Charge on the electrode labeled "anode"
(e) Electrode from which electrons leave the cell

21.116 A thin circular-disk earring 5.00 cm in diameter is plated with a coating of gold 0.20 mm thick from an Au^{3+} bath.
(a) How many days does it take to deposit the gold on one side of one earring if the current is 0.010 A (d of gold = 19.3 g/cm^3)?
(b) How many days does it take to deposit the gold on both sides of the pair of earrings?
(c) If the price of gold is \$320 per troy ounce (31.10 g), what is the total cost of the gold plating?

21.117 (a) How many minutes does it take to form 10.0 L of O_2 measured at 99.8 kPa and 28°C from water if a current of 1.3 A passes through the electrolytic cell? (b) What mass of H_2 forms?

21.118 Trains powered by electricity, including subways, use direct current. One conductor is the overhead wire (or "third rail" for subways), and the other is the rails upon which the wheels run. The rails are on supports in contact with the ground. To minimize corrosion, should the overhead wire or the rails be connected to the positive terminal? Explain.

21.119 A silver button battery used in a watch contains 16.0 g of zinc and can run until 80% of the zinc is consumed. (a) How many days can the battery run at a current of 4.8 milliamps? (b) When the battery dies, 95% of the Ag_2O has been consumed. How many grams of Ag was used to make the battery? (c) If Ag costs \$5.50 per troy ounce (31.10 g), what is the cost of the Ag consumed each day the watch runs?

21.120 Like any piece of apparatus, an electrolytic cell operates at less than 100% efficiency. A cell depositing Cu from a Cu^{2+} bath operates for 10 h with an average current of 5.8 A. If 53.4 g of copper is deposited, at what efficiency is the cell operating?

21.121 Commercial electrolysis is performed on both molten NaCl and aqueous NaCl solutions. Identify the anode product, cathode product, species reduced, and species oxidized for the (a) molten electrolysis and (b) aqueous electrolysis.

21.122 To examine the effect of ion removal on cell voltage, a chemist constructs two voltaic cells, each with a standard hydrogen electrode in one compartment. One cell also contains a Pb/Pb^{2+} half-cell; the other contains a Cu/Cu^{2+} half-cell.
(a) What is E^0 of each cell at 298 K?
(b) Which electrode in each cell is negative?
(c) When Na_2S solution is added to the Pb^{2+} electrolyte, solid PbS forms. What happens to the cell voltage?
(d) When sufficient Na_2S is added to the Cu^{2+} electrolyte, CuS forms and $[Cu^{2+}]$ drops to 1×10^{-16} M. Find the cell voltage.

21.123 Electrodes used in electrocardiography are disposable, and many incorporate silver. The metal is deposited in a thin layer on a small plastic "button," and then some is converted to AgCl:

$$Ag(s) + Cl^-(aq) \rightleftharpoons AgCl(s) + e^-$$

(a) If the surface area of the button is 2.0 cm^2 and the thickness of the silver layer is 7.0×10^{-6} m, calculate the volume (in cm^3) of Ag used in one electrode.
(b) The density of silver metal is 10.5 g/cm^3. How many grams of silver are used per electrode?
(c) If the silver is plated on the button from an Ag^+ solution with a current of 10.0 mA, how many minutes does the plating take?
(d) If bulk silver costs \$5.50 per troy ounce (31.10 g), what is the cost (in cents) of the silver in one disposable electrode?

21.124 Commercial aluminum production is done by the electrolysis of a bath containing Al_2O_3 dissolved in molten Na_3AlF_6. Why isn't it done by electrolysis of an aqueous $AlCl_3$ solution?

21.125 Comparing the standard electrode potentials (E^0) of the Group 1A(1) metals Li, Na, and K with the negative of their first ionization energies reveals a discrepancy:

Ionization process reversed: $M^+(g) + e^- \rightleftharpoons M(g)$ $(-IE)$
Electrode reaction: $M^+(aq) + e^- \rightleftharpoons M(s)$ (E^0)

Metal	−IE (kJ/mol)	E^0 (V)
Li	−520	−3.05
Na	−496	−2.71
K	−419	−2.93

Note that the electrode potentials do not decrease smoothly down the group, as the ionization energies do. You might expect that if it is more difficult to remove an electron from an atom to form a gaseous ion (larger IE), then it would be less difficult to add an electron to an aqueous ion to form an atom (smaller E^0), yet $Li^+(aq)$ is *more* difficult to reduce than $Na^+(aq)$. Applying Hess's law, use an approach similar to that for a Born-Haber cycle to break down the process occurring at the electrode into three steps and label the energy involved in each step. How can you account for the discrepancy?

21.126 To improve conductivity in the electroplating of automobile bumpers, a thin coating of copper separates the steel from a heavy coating of chromium.
(a) What mass of Cu is deposited on an automobile trim piece if plating continues for 1.25 h at a current of 5.0 A?

(b) If the area of the trim piece is 50.0 cm^2, what is the thickness of the Cu coating (d of Cu = 8.95 g/cm^3)?

21.127 In Appendix D, standard electrode potentials range from about +3 to −3 V. Thus, it might seem possible to use a half-cell from each end of this range to construct a cell with a voltage of approximately 6 V. However, most commercial aqueous voltaic cells have E^0 values of 1.5 to 2 V. Why are there no aqueous cells with significantly higher potentials?

21.128 Tin is used to coat "tin" cans used for food storage. If the tin is scratched and the iron of the can exposed, will the iron corrode more or less rapidly than if the tin were not present? Inside the can, the tin itself coated with a clear varnish. Explain.

21.129 Commercial electrolytic cells for producing aluminum operate at 5.0 V and 100,000 A.

(a) How long does it take to produce exactly 1 metric ton (1000 kg) of aluminum?

(b) How much electrical power (in kilowatt-hours, kW·h) is used [1 W = 1 J/s; 1 kW·h = 3.6×10^3 kJ]?

(c) If electricity costs 0.90¢ per kW·h and cell efficiency is 90.%, what is the cost of producing exactly 1 lb of aluminum?

21.130 Magnesium bars are connected electrically to underground iron pipes to serve as sacrificial anodes.

(a) Do electrons flow from the bar to the pipe or the reverse?

(b) A 12-kg Mg bar is attached to an iron pipe, and it takes 8.5 yr for the Mg to be consumed. What is the average current flowing between the Mg and the Fe during this period?

21.131 Bubbles of H_2 form when metal D is placed in hot H_2O. No reaction occurs when D is placed in a solution of a salt of metal E, but D is discolored and coated immediately when placed in a solution of a salt of metal F. What happens if E is placed in a solution of a salt of metal F? Rank metals D, E, and F in order of *increasing* reducing strength.

21.132 Calcium is obtained industrially by electrolysis of molten $CaCl_2$ and is used in aluminum alloys. How many coulombs are needed to produce 10.0 g of Ca metal? If a cell runs at 15 A, how many minutes will it take to produce 10.0 g of Ca(s)?

21.133 In addition to reacting with gold (see Problem 21.21), aqua regia is used to bring other precious metals into solution. Balance the skeleton equation for the reaction with Pt:

$$Pt(s) + NO_3^-(aq) + Cl^-(aq) \longrightarrow PtCl_6^{2-}(aq) + NO(g)$$

21.134 The following reactions are used in batteries:

I $2H_2(g) + O_2(g) \longrightarrow 2H_2O(l)$ $\quad E_{cell} = 1.23$ V

II $Pb(s) + PbO_2(s) + 2H_2SO_4(aq) \longrightarrow 2PbSO_4(s) + 2H_2O(l)$ $\quad E_{cell} = 2.04$ V

III $2Na(l) + FeCl_2(s) \longrightarrow 2NaCl(s) + Fe(s)$ $\quad E_{cell} = 2.35$ V

Reaction I is used in fuel cells, II in the automobile lead-acid battery, and III in an experimental high-temperature battery for powering electric vehicles. The aim is to obtain as much work as possible from a cell, while keeping its weight to a minimum.

(a) In each cell, find the moles of electrons transferred and ΔG.

(b) Calculate the ratio, in kJ/g, of w_{max} to mass of reactants for each of the cells. Which has the highest ratio, which the lowest, and why? (*Note:* For simplicity, ignore the masses of cell components that do not appear in the cell as reactants, including electrode materials, electrolytes, separators, cell casing, wiring, etc.)

21.135 A current is applied to two electrolytic cells in series. In the first, silver is deposited; in the second, a zinc electrode is consumed. How much Ag is plated out if 1.2 g of Zn dissolves?

21.136 You are investigating a particular chemical reaction. State all the types of data available in standard tables that enable you to calculate the equilibrium constant for the reaction at 298 K.

21.137 Maintenance personnel at an electric power plant must pay careful attention to corrosion of the turbine blades. Why does iron corrode faster in steam and hot water than in cold water?

21.138 A voltaic cell using Cu/Cu^{2+} and Sn/Sn^{2+} half-cells is set up at standard conditions, and each compartment has a volume of 245 mL. The cell delivers 0.15 A for 54.0 h. (a) How many grams of Cu(s) are deposited? (b) What is the $[Cu^{2+}]$ remaining?

21.139 The $E_{half\text{-}cell}$ for the reduction of water is very different from the $E^0_{half\text{-}cell}$ value. Calculate the $E_{half\text{-}cell}$ value when H_2 is in its standard state.

21.140 From the skeleton equations below, create a list of balanced half-reactions in which the strongest oxidizing agent is on top and the weakest is on the bottom:

$$U^{3+}(aq) + Cr^{3+}(aq) \longrightarrow Cr^{2+}(aq) + U^{4+}(aq)$$
$$Fe(s) + Sn^{2+}(aq) \longrightarrow Sn(s) + Fe^{2+}(aq)$$
$$Fe(s) + U^{4+}(aq) \longrightarrow \text{no reaction}$$
$$Cr^{3+}(aq) + Fe(s) \longrightarrow Cr^{2+}(aq) + Fe^{2+}(aq)$$
$$Cr^{2+}(aq) + Sn^{2+}(aq) \longrightarrow Sn(s) + Cr^{3+}(aq)$$

21.141 You are given the following three half-reactions:

(1) $Fe^{3+}(aq) + e^- \rightleftharpoons Fe^{2+}(aq)$

(2) $Fe^{2+}(aq) + 2e^- \rightleftharpoons Fe(s)$

(3) $Fe^{3+}(aq) + 3e^- \rightleftharpoons Fe(s)$

(a) Use $E^0_{half\text{-}cell}$ values for (1) and (2) to find $E^0_{half\text{-}cell}$ for (3).

(b) Calculate ΔG^0 for (1) and (2) from their $E^0_{half\text{-}cell}$ values.

(c) Calculate ΔG^0 for (3) from (1) and (2).

(d) Calculate $E^0_{half\text{-}cell}$ for (3) from its ΔG^0.

(e) What is the relationship between the $E^0_{half\text{-}cell}$ values for (1) and (2) and the $E^0_{half\text{-}cell}$ value for (3)?

21.142 Use the half-reaction method to balance the equation for the conversion of ethanol to acetic acid in acid solution:

$$CH_3CH_2OH + Cr_2O_7^{2-} \longrightarrow CH_3COOH + Cr^{3+}$$

21.143 When zinc is refined by electrolysis, the desired half-reaction at the cathode is

$$Zn^{2+}(aq) + 2e^- \longrightarrow Zn(s)$$

A competing reaction, which lowers the yield, is the formation of hydrogen gas:

$$2H^+(aq) + 2e^- \longrightarrow H_2(g)$$

If 91.50% of the current flowing results in zinc being deposited, while 8.50% produces hydrogen gas, how many liters of H_2, measured at STP, form per kilogram of zinc?

21.144 A chemist designs an ion-specific probe for measuring $[Ag^+]$ in an NaCl solution saturated with AgCl. One half-cell has an Ag-wire electrode immersed in the unknown AgCl-saturated NaCl solution. It is connected through a salt bridge to the other half-cell, which has a calomel reference electrode [a platinum wire immersed in a paste of mercury and calomel (Hg_2Cl_2)] in a saturated KCl solution. The measured E_{cell} is 0.060 V.

(a) Given the following standard half-reactions, calculate $[Ag^+]$.

Calomel: $Hg_2Cl_2(s) + 2e^- \longrightarrow 2Hg(l) + 2Cl^-(aq)$ $\quad E^0 = 0.24$ V

Silver: $Ag^+(aq) + e^- \longrightarrow Ag(s)$ $\quad E^0 = 0.80$ V

(*Hint:* Assume $[Cl^-]$ is so high that it is essentially constant.)

(b) A mining engineer wants an ore sample analyzed with the Ag^+-selective probe. After pretreating the ore sample, the chemist measures the cell voltage as 0.57 V. What is $[Ag^+]$?

21.145 Use Appendix D to calculate the K_{sp} of AgCl.

21.146 Black-and-white photographic film is coated with silver halides. Because silver is expensive, the manufacturer monitors the Ag^+ content of the waste stream, $[Ag^+]_{waste}$, from the plant with an Ag^+-selective electrode at 25°C. A stream of known Ag^+ concentration, $[Ag^+]_{standard}$, is passed over the electrode in turn with the waste stream and the data recorded by a computer.
(a) Write the equations relating the nonstandard cell potential to the standard cell potential and $[Ag^+]$ for each solution.
(b) Combine these into a single equation to find $[Ag^+]_{waste}$.
(c) Rewrite the equation from part (b) to find $[Ag^+]_{waste}$ in ng/L.
(d) If E_{waste} is 0.003 V higher than $E_{standard}$, and the standard solution contains 1000. ng/L, what is $[Ag^+]_{waste}$?
(e) Rewrite the equation in part (b) to find $[Ag^+]_{waste}$ for a system in which T changes and T_{waste} and $T_{standard}$ may be different.

21.147 Calculate the K_f of $Ag(NH_3)_2^+$ from

$$Ag^+(aq) + e^- \rightleftharpoons Ag(s) \qquad E^0 = 0.80\ V$$
$$Ag(NH_3)_2^+(aq) + e^- \rightleftharpoons Ag(s) + 2NH_3(aq) \qquad E^0 = 0.37\ V$$

21.148 Even though the toxicity of cadmium has become a concern, nickel-cadmium (nicad) batteries are still used commonly in many devices. The overall cell reaction is

$$Cd(s) + 2NiO(OH)(s) + 2H_2O(l) \longrightarrow 2Ni(OH)(s) + Cd(OH)_2(s)$$

A certain nicad battery weighs 13.3 g and has a capacity of 300. mA·h (that is, the cell can store charge equivalent to a current of 300. mA flowing for 1 h).
(a) What is the capacity of this cell in coulombs?
(b) What mass of reactants is needed to deliver 300. mA·h?
(c) What percentage of the cell mass consists of reactants?

21.149 The zinc-air battery is a less expensive alternative for silver batteries in hearing aids. The cell reaction is

$$2Zn(s) + O_2(g) \longrightarrow 2ZnO(s)$$

A new battery weighs 0.275 g. The zinc accounts for exactly $\frac{1}{10}$ of the mass, and the oxygen does not contribute to the mass because it is supplied by the air.
(a) How much electricity (in C) can the battery deliver?
(b) How much free energy (in J) is released if E_{cell} is 1.3 V?

21.150 Use Appendix D to create an activity series of Mn, Fe, Ag, Sn, Cr, Cu, Ba, Al, Na, Hg, Ni, Li, Au, Zn, and Pb. Rank these metals in order of decreasing reducing strength, and divide them into three groups: those that displace H_2 from water, those that displace H_2 from acid, and those that cannot displace H_2.

21.151 Both Ti and V are reactive enough to displace H_2 from water. The difference in their $E^0_{half\text{-}cell}$ values is 0.43 V. Given

$$V(s) + Cu^{2+}(aq) \longrightarrow V^{2+}(aq) + Cu(s) \qquad \Delta G^0 = -298\ kJ/mol$$

use Appendix D to calculate the $E^0_{half\text{-}cell}$ values for V and Ti.

21.152 For the reaction

$$S_4O_6^{2-}(aq) + 2I^-(aq) \longrightarrow I_2(s) + S_2O_3^{2-}(aq) \qquad \Delta G^0 = 87.8\ kJ/mol$$

(a) Identify the oxidizing and reducing agents. (b) Calculate E^0_{cell}. (c) For the reduction half-reaction, write a balanced equation, give the oxidation number of each element, and calculate $E^0_{half\text{-}cell}$.

21.153 Two concentration cells are prepared, both with 90.0 mL of 0.0100 M $Cu(NO_3)_2$ and a Cu bar in each half-cell.
(a) In the first concentration cell, 10.0 mL of 0.500 M NH_3 is added to one half-cell; the complex ion $Cu(NH_3)_4^{2+}$ forms, and E_{cell} is 0.129 V. Calculate K_f for the formation of the complex ion.
(b) Calculate E_{cell} when an additional 10.0 mL of 0.500 M NH_3 is added.
(c) In the second concentration cell, 10.0 mL of 0.500 M NaOH is added to one half-cell; the precipitate $Cu(OH)_2$ forms ($K_{sp} = 2.2\times10^{-20}$). Calculate E^0_{cell}.
(d) What would the molarity of NaOH have to be for the addition of 10.0 mL to result in an E^0_{cell} of 0.340 V?

21.154 Two voltaic cells are to be joined so that one will run the other as an electrolytic cell. In the first cell, one half-cell has Au foil in 1.00 M $Au(NO_3)_3$, and the other half-cell has a Cr bar in 1.00 M $Cr(NO_3)_3$. In the second cell, one half-cell has a Co bar in 1.00 M $Co(NO_3)_2$, and the other half-cell has a Zn bar in 1.00 M $Zn(NO_3)_2$. (a) Calculate E^0_{cell} for each cell. (b) Calculate the total potential if the two cells are connected as voltaic cells in series. (c) When the electrode wires are switched in one of the cells, which cell will run as the voltaic cell and which as the electrolytic cell? (d) Which metal ion is being reduced in each cell? (e) If 2.00 g of metal plates out in the voltaic cell, how much metal ion plates out in the electrolytic cell?

21.155 A voltaic cell has one half-cell with a Cu bar in a 1.00 M Cu^{2+} salt, and the other half-cell with a Cd bar in the same volume of a 1.00 M Cd^{2+} salt. (a) Find E^0_{cell}, ΔG^0, and K. (b) As the cell operates, $[Cd^{2+}]$ increases; find E_{cell} and ΔG when $[Cd^{2+}]$ is 1.95 M. (c) Find E_{cell}, ΔG, and $[Cu^{2+}]$ at equilibrium.

21.156 Gasoline is a mixture of hydrocarbons, but we can assume it is pure octane, $C_8H_{18}(l)$ ($\Delta H^0_f = -250.1$ kJ/mol). As an alternative to gasoline, research is underway to use H_2, produced by the electrolysis of water, in fuel cells to power cars.
(a) Calculate ΔH^0 when 1.00 gal of gasoline ($d = 0.7028$ g/mL) burns to produce carbon dioxide gas and water vapor.
(b) How many liters of H_2 at 25°C and 1.00 atm must burn to produce this quantity of energy?
(c) How long would it take to produce this amount of H_2 by electrolysis with a current of 1.00×10^3 A at 5.00 V?
(d) How much power in kilowatt·hours (kW·h) is required to generate this amount of H_2? (1 W = 1 J/s, 1 J = 1 C·V, and 1 kW·h = 3.6×10^6 J.)
(e) If the cell is 90.0% efficient and electricity costs 0.950¢ per kW·h, what is the cost of producing the amount of H_2 equivalent to 1.00 gal of gasoline?

21.157 Balance the following redox reactions:
(a) In acidic solution, xenon trioxide reacts with iodide ion to produce xenon gas, triiodide ion (I_3^-), and water.
(b) In basic solution, the hydrogen xenate ion ($HXeO_4^-$) disproportionates to xenon gas, perxenate ion (XeO_6^{4-}), water, and oxygen gas.
(c) In basic solution, bismuthate ion (BiO_3^-) reacts with manganese(II) ion to produce bismuth(III) and permanganate ions.
(d) In basic solution, oxygen difluoride reacts to produce fluoride ion, oxygen gas, and water.
(e) In acidic solution, manganese(IV) oxide reacts with sulfite ion to form manganese(II) ion, water, and dithionate ion ($S_2O_6^{2-}$).
(f) In one of the few reactions known for astatine, the oxidation of astinide ion by chlorine gas in acid solution produces astinate ion (AtO_3^-) and chloride ion.

21.158 If the E_{cell} of the following cell is 0.915 V, what is the pH in the anode compartment?

$$Pt(s) \mid H_2(1.00\ atm) \mid H^+(aq) \parallel Ag^+(0.100\ M) \mid Ag(s)$$

Elements within This view of Mt. St. Helens shows the remains of volcanic activity, the only source of elements from deep within Earth. Virtually all the elements and compounds we use exist in the crust, and the most important undergo vast cycles in which organisms play key roles. In this chapter, we apply concepts from earlier chapters to the practical side of chemistry—how we obtain and utilize the elements.

22.5 **Chemical Manufacturing: Two Case Studies**
Sulfuric Acid
The Chlor-Alkali Process

In this chapter we return to the periodic table, but from a new perspective. In Chapter 14, we considered the atomic, physical, and chemical behavior of the main-group elements. Here, we examine various elements from a practical viewpoint to learn how much of an element is present in nature, in what form it occurs, how organisms affect its distribution, and how we isolate it for our own use.

Remember that chemistry is, above all, a practical science, and its concepts were developed to address real-life problems: How do we isolate and recycle aluminum? How do we make iron stronger? How do we lower energy costs and increase yield in the production of sulfuric acid? How does fossil-fuel combustion affect the environmental cycling of carbon? Here, we apply concepts you learned from the chapters on kinetics, equilibrium, thermodynamics, and electrochemistry to explain chemical processes in nature and industry that influence our lives.

IN THIS CHAPTER . . . We first discuss the abundances and sources of elements on Earth, then consider how three essential elements—carbon, nitrogen, and phosphorus—cycle through the environment. After seeing where and in what forms elements are found, we focus on their isolation and utilization. We discuss general redox and metallurgical procedures for extracting an element from its ore and examine in detail the isolation and uses of certain key elements. The chapter ends with a close look at two of the most important processes in chemical manufacturing: the production of sulfuric acid and the isolation of chlorine.

Concepts & Skills to Review

before you study this chapter

- catalysts and reaction rate (Section 16.8)
- Le Châtelier's principle (Section 17.6)
- acid-base equilibria (Sections 18.3 and 18.9)
- solubility and complex-ion equilibria (Sections 19.3 and 19.4)
- temperature and reaction spontaneity (Section 20.3)
- free energy and equilibrium (Section 20.4)
- standard electrode potentials (Section 21.3)
- electrolysis of molten salts and aqueous solutions (Section 21.7)

22.1 HOW THE ELEMENTS OCCUR IN NATURE

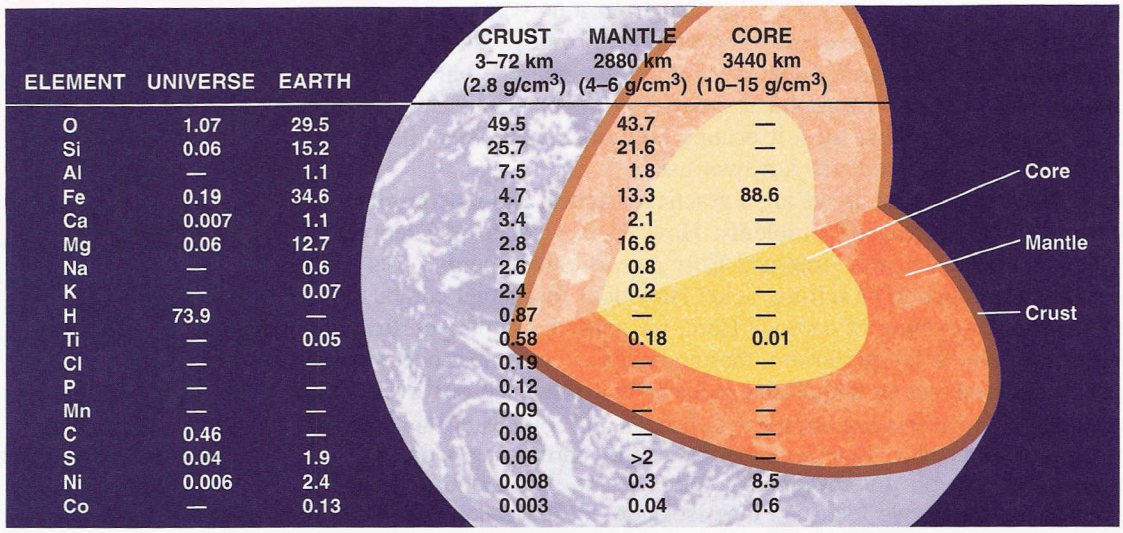
To begin our examination of how we use the elements, let's take inventory of our elemental stock—the distribution and relative amounts of the elements on Earth, especially that thin outer portion of the planet that we can reach.

Earth's Structure and the Abundance of the Elements

Any attempt to isolate an element must begin with a knowledge of its **abundance,** the amount of the element in a particular region of the natural world. The abundances of the elements on Earth and in its various regions are the result of the specific details of our planet's evolution.

Formation and Layering of Planet Earth About 4.5 billion years ago, vast clouds of cold gases and interstellar debris from exploded older stars gradually coalesced into the Sun and planets. At first, Earth was a cold, solid sphere of uniformly distributed elements and simple compounds. In the next billion years or so, heat from radioactive decay and virtually continuous meteor impacts raised the planet's temperature to around 10^4 K, sufficient to form an enormous molten mass. Any remaining gaseous elements, such as the cosmically abundant hydrogen and helium, were ejected into space.

As Earth cooled, chemical and physical processes resulted in its **differentiation,** the formation of regions of different composition and density. Differentiation gave Earth its layered internal structure, which consists of a dense (10–15 g/cm^3) **core,** composed of a molten outer core and a solid Moon-sized inner core. (Recent evidence has revealed remarkable properties of the inner core: it is nearly as hot as the surface of the Sun and spins within the molten outer core slightly faster than does Earth itself!) Around the core lies a thick homogeneous **mantle,** consisting of lower and upper portions, with an overall density of 4–6 g/cm^3. All the comings and goings of life take place on the thin heterogeneous **crust** (average density = 2.8 g/cm^3). Figure 22.1 on the next page shows these layers and compares the abundances of some key elements in the universe, the whole Earth (actually core plus mantle only, which account for more than 99%



ELEMENT	UNIVERSE	EARTH	CRUST 3–72 km (2.8 g/cm³)	MANTLE 2880 km (4–6 g/cm³)	CORE 3440 km (10–15 g/cm³)
O	1.07	29.5	49.5	43.7	—
Si	0.06	15.2	25.7	21.6	—

Ni	0.006	2.4	0.008	0.3	8.5
Co	—	0.13	0.003	0.04	0.6

Figure 22.1 Cosmic and terrestrial abundances of selected elements (mass percent). The mass percents of the elements are superimposed on a cutaway of Earth. The internal structure consists of a large core, thick mantle, and thin crust. The densities of these regions are indicated in the column heads. Blank abundance values mean either that reliable data are not available or that the value is less than 0.001% by mass. (Helium is not listed because it is not abundant on Earth, but it accounts for 24.0% by mass of the universe.)

of its mass), and Earth's three regions. Because the deepest terrestrial sampling can penetrate only a few kilometers into the crust, some of these data represent extrapolations from meteor samples and from seismic studies of earthquakes. Several points stand out:

1. Cosmic and whole-Earth abundances are very different, particularly for H.
2. The elements O, Si, Fe, and Mg are abundant both cosmically and on Earth. Together, they account for more than 90% of Earth's mass.
3. The core is particularly rich in the dense Group 8B metals: Co, Ni, and especially Fe, the most abundant element in the whole Earth.
4. Crustal abundances are very different from whole-Earth abundances. The crust makes up only 0.4% of Earth's mass, but has the largest share of nonmetals, metalloids, and light, active metals: Al, Ca, Na, and K. The mantle contains smaller proportions of these, and the core has none. Oxygen is the most abundant element in the crust and mantle but is absent from the core.

These compositional differences in Earth's major layers, or *phases,* arose from the effects of thermal energy. When Earth was molten, gravity and convection caused more dense materials to sink and less dense materials to rise. Most of the Fe sank to form the core, or *iron phase*. In the light outer phase, oxygen combined with Si, Al, Mg, and some Fe to form silicates, the material of rocks. This *silicate phase* later separated into the mantle and crust. The *sulfide phase,* intermediate in density and insoluble in the other two, consisted mostly of iron sulfide and mixed with parts of the silicate phase above and the iron phase below. *Outgassing,* the expulsion of trapped gases, produced a thin, primitive atmosphere, probably a mixture of water vapor (which gave rise to the oceans), carbon monoxide, and nitrogen (or ammonia).

The distribution of the remaining elements (discussed here using the new group numbers) was controlled by their chemical affinity for one of the three phases. In general terms, as Figure 22.2 shows, elements with low or high electronegativity—active metals (Groups 1 through 5, Cr, and Mn) and nonmetals (O, lighter members of Groups 13 to 15, and all of Group 17)—tended to congregate in the silicate phase as ionic compounds. Metals with intermediate electronegativities (many from Groups 6 to 10) dissolved in the iron core. Lower-melting transition metals and many metals and metalloids in Groups 11 to 16 became concentrated in the sulfide phase.

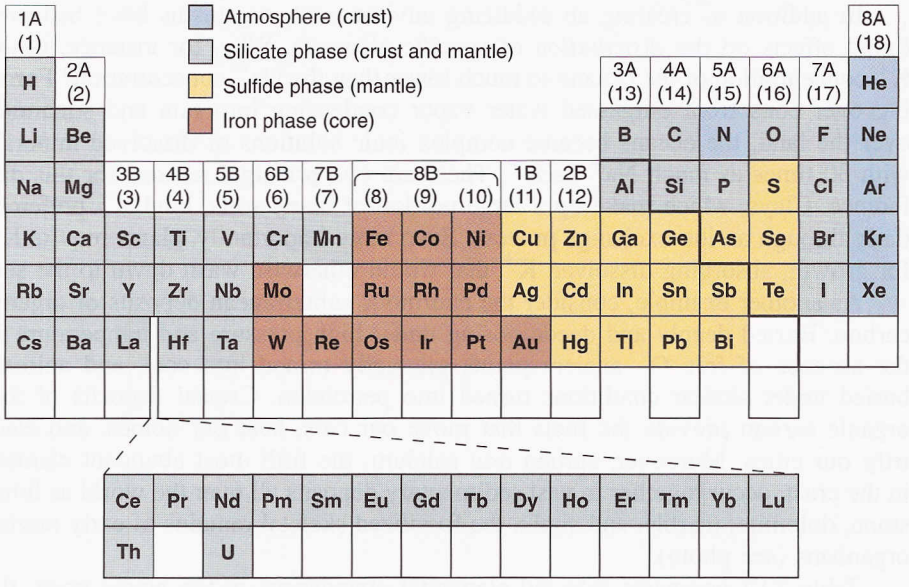

Figure 22.2 Geochemical differentiation of the elements. During Earth's formation, elements became concentrated primarily in the atmosphere or one of three phases: silicate, sulfide, or iron.

The Impact of Life on Crustal Abundances At present, the crust is the only accessible portion of our planet, so only crustal abundances have practical significance. The crust is divided into solid, liquid, and gaseous portions called the **lithosphere, hydrosphere,** and **atmosphere.** Over billions of years, weathering and volcanic upsurges have dramatically altered the composition of the crust. The **biosphere,** which consists of the living systems that have inhabited the planet, has been another *major influence on crustal element composition and distribution.*

When the earliest rocks were forming and the ocean basins filling with water, binary inorganic molecules in the atmosphere were reacting to form first simple, and then more complex, organic molecules. The energy for these (mostly) endothermic changes was supplied by lightning, solar radiation, geologic heating, and meteoric impact. In an amazingly short period of time, probably no more than 500 million years, the first organisms appeared. It took perhaps another billion years for these to evolve into simple algae that could derive metabolic energy from photosynthesis, converting CO_2 and H_2O into organic molecules and releasing O_2 as a by-product. The importance of this process to crustal chemistry cannot be overstated. Over the next 300 million years, the atmosphere gradually became richer in O_2, and *oxidation became the major source of free energy in the crust and biosphere.* Geologists mark this period by the appearance of Fe(III)-containing minerals in place of the Fe(II)-containing minerals that had predominated (Figure 22.3A). Paleontologists see in it an explosion of O_2-utilizing lifeforms, a few of which evolved into the organisms of today (Figure 22.3B).

Figure 22.3 Ancient effects of an O_2-rich atmosphere. A, With the appearance of photosynthetic organisms and the resulting oxidizing environment, much of the iron(II) in minerals was oxidized to iron(III). These ancient banded-iron formations (red beds) from Michigan contain hematite, Fe_2O_3. **B,** A fossil of *Hallucigenia sparsa,* one of the multicellular organisms found in the Burgess shale, British Columbia, Canada, whose appearance coincided with the increase in O_2. Many of these organisms have no known modern descendants, having disappeared in a mass extinction at the end of the Cambrian Period about 505 million years ago.

Dolomite Mountains, Italy

In addition to creating an oxidizing environment, organisms have had profound effects on the *distribution* of specific elements. Why, for instance, is the K^+ concentration of the oceans so much lower than the Na^+ concentration? Forming over eons from outgassed water vapor condensing into rain and streaming over the land, the oceans became complex ionic solutions of dissolved minerals with 30 times as much Na^+ as K^+. There are two principal reasons for this difference. Clays, which make up a large portion of many soils, bind K^+ preferentially through an ion-exchange process. Even more importantly, plants require K^+ for growth, absorbing dissolved K^+ that would otherwise wash down to the sea.

As another example, consider the enormous subterranean deposits of organic carbon. Buried deeply and decomposing under high pressure and temperature in the absence of free O_2, ancient plants gradually turned into coal, and animals buried under similar conditions turned into petroleum. Crustal deposits of this organic carbon provide the fuels that move our cars, heat our homes, and electrify our cities. Moreover, carbon *and* calcium, the fifth most abundant element in the crust, occur together in vast sedimentary deposits all over the world as limestone, dolomite, marble, and chalk, the fossilized skeletal remains of early marine organisms (see photo).

Table 22.1 compares selected elemental abundances in the whole crust, the three crustal regions, and the human body, a representative portion of the biosphere. Note the quantities of the four major elements of life—O, C, H, and N. Oxygen is either the first or second most abundant element in all cases. The biosphere contains large amounts of carbon in its biomolecules and large amounts of hydrogen as water. Nitrogen is abundant in the atmosphere as free N_2 and in organisms as part of their proteins. Phosphorus and sulfur occur in exceptionally high amounts in organisms, too.

One striking difference among the lithosphere, hydrosphere, and biosphere (human) is in the abundances of the transition metals vanadium through zinc.

Table 22.1 Abundance of Selected Elements in the Crust, Its Regions, and the Human Body as Representative of the Biosphere (Mass %)

		Crustal Regions			
Element	Crust	Lithosphere	Hydrosphere	Atmosphere	Human
O	49.5	45.5	85.8	23.0	65.0
C	0.08	0.018	—	0.01	18.0
H	0.87	0.15	10.7	0.02	10.0
N	0.03	0.002	—	75.5	3.0
P	0.12	0.11	—	—	1.0
Mg	1.9	2.76	0.13	—	0.50
K	2.4	1.84	0.04	—	0.34
Ca	3.4	4.66	0.05	—	2.4
S	0.06	0.034	—	—	0.26
Na	2.6	2.27	1.1	—	0.14
Cl	0.19	0.013	2.1	—	0.15
Fe	4.7	6.2	—	—	0.005
Zn	0.013	0.008	—	—	0.003
Cr	0.02	0.012	—	—	3×10^{-6}
Co	0.003	0.003	—	—	3×10^{-6}
Cu	0.007	0.007	—	—	4×10^{-4}
Mn	0.09	0.11	—	—	1×10^{-4}
Ni	0.008	0.010	—	—	3×10^{-6}
V	0.015	0.014	—	—	3×10^{-6}

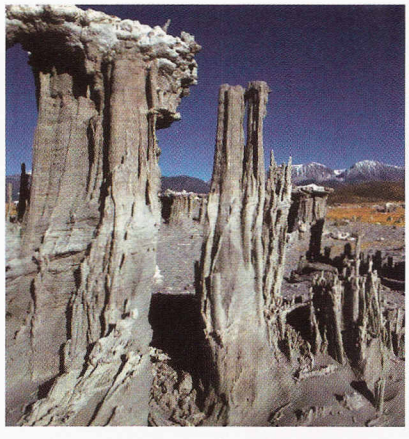
Their relatively insoluble oxides and sulfides make them much scarcer in water than on land. Yet organisms, which evolved in the seas, developed the ability to concentrate the trace amounts of these elements present in their aqueous environment. In every case, the biological concentration shows an increase of at least 100-fold, with Mn increasing about 1000-fold, and Cu, Zn, and Fe even more. Each of these elements performs an essential role in living systems (see Chemical Connections, pp. 1035–1036).

Sources of the Elements

Given an element's abundance in a region of the crust, we must next determine its **occurrence,** or **source,** the form(s) in which the element exists. Practical considerations often determine the commercial source. Oxygen, for example, is abundant in all three crustal regions, but the atmosphere is its primary industrial source because it occurs there as the free element. Nitrogen and the noble gases (except helium) are also obtained from the atmosphere. Several other elements occur uncombined, formed in large deposits by prehistoric biological action; examples are sulfur in caprock salt domes and nearly pure carbon in coal. The relatively unreactive elements gold and platinum also occur in an uncombined (*native*) state.

The overwhelming majority of elements, however, occur in **ores,** natural compounds or mixtures of compounds from which an element can be extracted by economically feasible means. The phrase "economically feasible" refers to an important point: *the financial costs of mining, isolating, and purifying an element must be considered when choosing a process to obtain it.*

Figure 22.4 shows the most useful sources of the elements. Alkali metal halides are ores for both of their component groups of elements. One example of how cost influences recovery concerns the feasibility of using silicates as ores. Even though many elements occur as silicates, most of these sources are very stable thermodynamically. Thus, the cost of the energy required to process them prohibits their use—aside from silicon, only lithium and beryllium are obtained from their silicates. The Group 2A(2) metals occur as carbonates in the marble and limestone of mountain ranges, although magnesium's great abundance in seawater makes that the preferred source, as we discuss later.



Deposit of borate (tufa), the ore of boron.

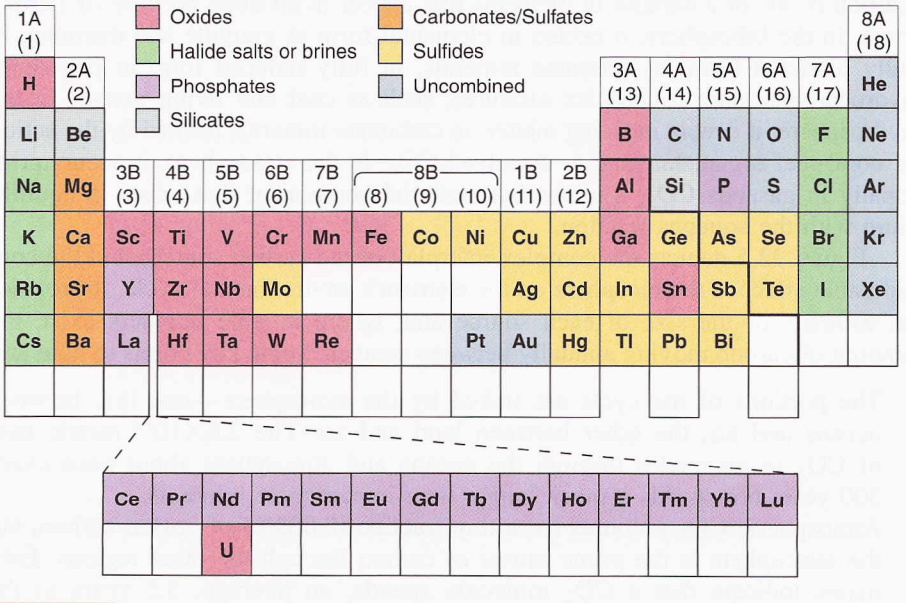


Figure 22.4 Sources of the elements. The major sources of most of the elements are shown. Although a few elements occur uncombined, most are obtained from their oxide or sulfide ores.

The ores of most industrially important metals are either *oxides,* which dominate the left half of the transition series, or *sulfides,* which dominate the right half of the transition series and a few of the main groups beyond. The reasons for the prominence of oxides and sulfides are complex and include processes of weathering, selective precipitation, and relative solubilities. Certain atomic properties are relevant as well. Elements toward the left side of the periodic table have lower ionization energies and electronegativities, so they tend to give up electrons or hold them loosely in bonds. The O^{2-} ion is small enough to approach a metal cation closely, which results in a high lattice energy for the oxide. In contrast, elements toward the right side have higher ionization energies and electronegativities. Thus, they tend to form bonds that are more covalent, which suits the larger, more polarizable S^{2-} ion.

SECTION SUMMARY

As the young Earth cooled, the elements became differentiated into a dense, metallic core, a silicate-rich mantle, and a low-density crust. High abundances of light metals, metalloids, and nonmetals are concentrated in the crust, which consists of the lithosphere (solid), hydrosphere (liquid), and atmosphere (gaseous). The biosphere (living systems) has affected crustal chemistry primarily by producing free O_2, and thus an oxidizing environment. Some elements occur in their native state, but most are combined in ores. The ores of most important metallic elements are oxides or sulfides.

22.2 THE CYCLING OF ELEMENTS THROUGH THE ENVIRONMENT

The distributions of many elements are in flux, changing at widely differing rates. The physical, chemical, and biological paths that the atoms of an element take on their journey through regions of the crust constitute the element's **environmental cycle.** In this section, we consider the cycles for three important elements—carbon, nitrogen, and phosphorus—and highlight the effects of humans on them.

The Carbon Cycle

Carbon is one of a handful of elements that appear in all three portions of Earth's crust. In the lithosphere, it occurs in elemental form as graphite and diamond, in fully oxidized form in carbonate minerals, in fully reduced form in petroleum hydrocarbons, and in complex mixtures, such as coal and living matter. In the hydrosphere, it occurs in living matter, in carbonate minerals formed by the action of coral-reef organisms, and in dissolved CO_2. In the atmosphere, it occurs principally in gaseous CO_2, a minor but essential component that exists in equilibrium with the aqueous fraction.

Figure 22.5 depicts the complex interplay of the carbon sources and the considerable effect of the biosphere on the element's environmental cycle. It provides an estimate of the size of each source and, where reliable numbers exist, the amount of carbon moving annually between sources. Some key points to note are:

- The portions of the cycle are linked by the atmosphere—one link between oceans and air, the other between land and air. The 2.6×10^{12} metric tons of CO_2 in air cycles through the oceans and atmosphere about once every 300 years but spends a much longer time in carbonate minerals.
- Atmospheric CO_2 accounts for a tiny fraction (0.003%) of crustal carbon, but the atmosphere is the prime mover of carbon through the other regions. Estimates indicate that a CO_2 molecule spends, on average, 3.5 years in the atmosphere.

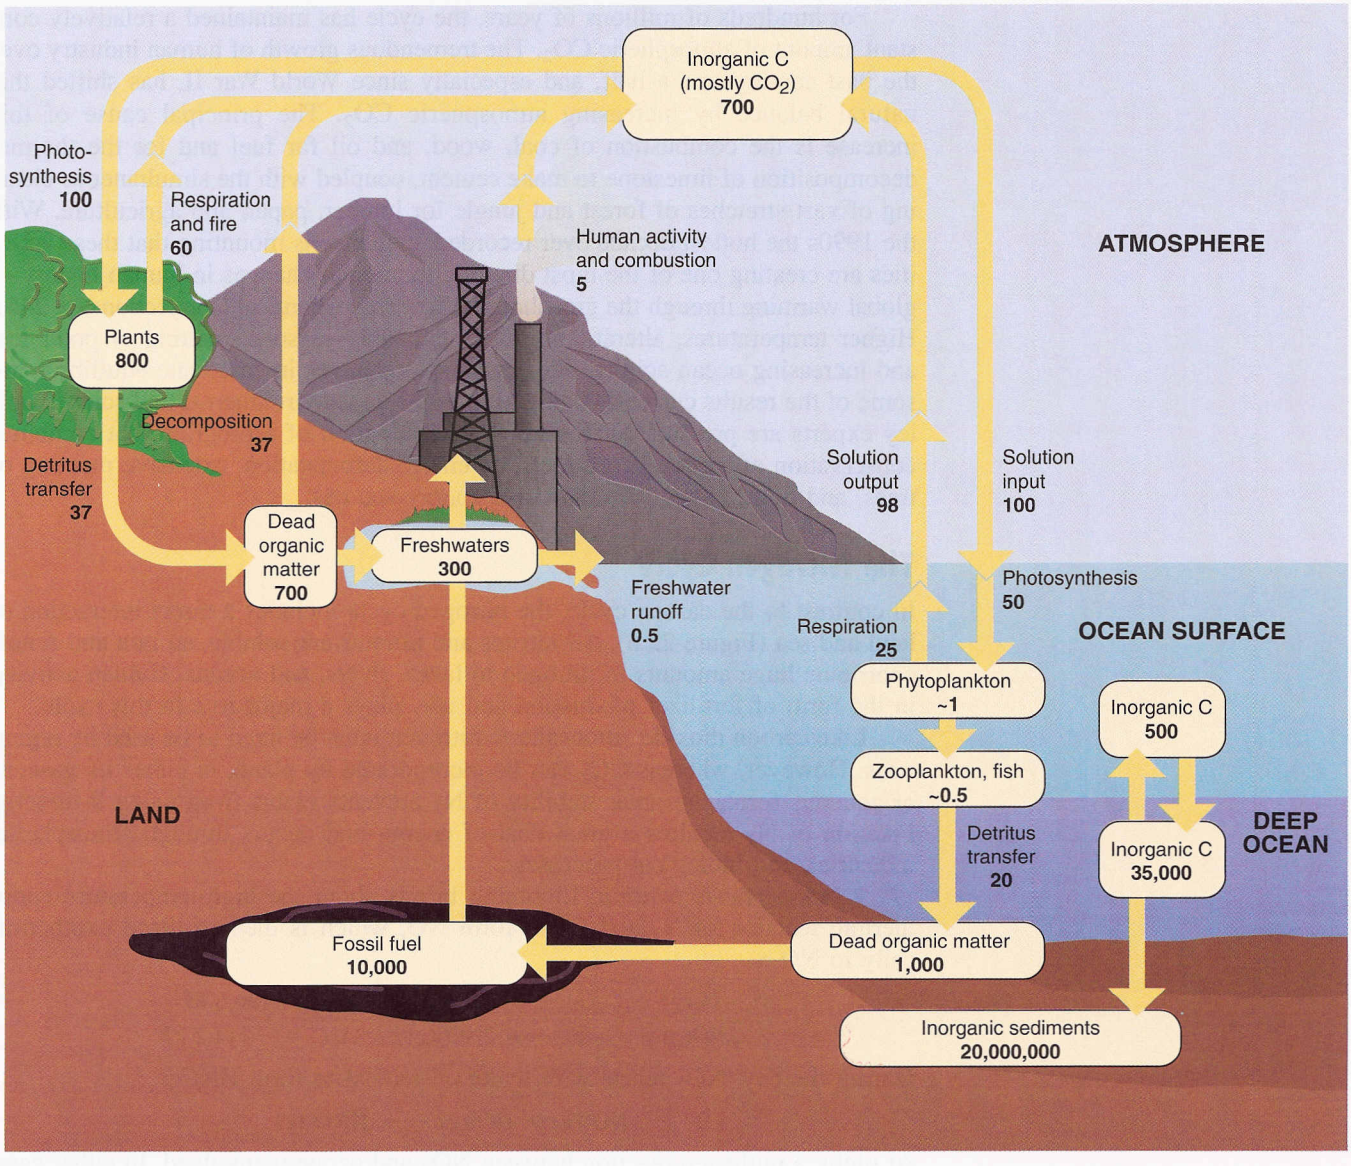

Figure 22.5 The carbon cycle. The major sources and changes in carbon distribution are shown. Note that the atmosphere is the major conduit of carbon between land and sea and that CO_2 becomes fixed through the action of organisms. Numbers in boxes refer to the size of the source; numbers along arrows refer to the annual movement of the element from source to source. Values are in 10^9 metric tons of C (1 metric ton = 1000 kg = 1.1 tons).

- The land and oceans are also in contact with the largest sources of carbon, which are effectively immobilized as carbonates, coal, and oil in the rocky sediment beneath the soil.
- The biological processes of *photosynthesis, respiration,* and *decay* are major factors in the carbon cycle. **Fixation** is the process of converting a gaseous substance into a condensed, more usable form. Via photosynthesis, marine plankton and terrestrial plants use sunlight to fix atmospheric CO_2 into carbohydrates. Plants release CO_2 by respiration at night and, much more slowly, when they decay. Animals eat the plants and release CO_2 by respiration and in their decay.
- Natural fires and volcanoes also release CO_2 into the air.

For hundreds of millions of years, the cycle has maintained a relatively constant amount of atmospheric CO_2. The tremendous growth of human industry over the past century and a half, and especially since World War II, has shifted this natural balance by increasing atmospheric CO_2. The principal cause of this increase is the combustion of coal, wood, and oil for fuel and for the thermal decomposition of limestone to make cement, coupled with the simultaneous clearing of vast stretches of forest and jungle for lumber, paper, and agriculture. With the 1990s the hottest decade ever recorded, evidence is mounting that these activities are creating one of the most dire environmental changes in human history—global warming through the greenhouse effect (see Chemical Connections, p. 246). Higher temperatures, alterations in dry and rainy seasons, melting of polar ice, and increasing ocean acidity, with associated changes in carbonate equilibria, are some of the results currently being assessed. Most environmental and science policy experts are pressing for the immediate adoption of a program that combines conservation of carbon-based fuels, an end to deforestation, extensive planting of trees, and development of alternative energy sources.

The Nitrogen Cycle

In contrast to the carbon cycle, the nitrogen cycle includes a direct interaction of land and sea (Figure 22.6). All nitrites and nitrates are soluble, so rain and runoff contribute huge amounts of nitrogen to lakes, rivers, and oceans. Human activity, in the form of fertilizer production and use, plays a major role in this cycle.

Like carbon dioxide, atmospheric nitrogen must be fixed to be used by organisms. However, whereas CO_2 can be incorporated by plants in either its gaseous or aqueous form, the great stability of N_2 prevents plants from using it directly. Fixation of N_2 requires a great deal of energy and occurs through atmospheric, industrial, and biological processes:

1. *Atmospheric fixation.* Lightning brings about the high-temperature endothermic reaction of N_2 and O_2 to form NO, which is then oxidized exothermically to NO_2:

$$N_2(g) + O_2(g) \longrightarrow 2NO(g) \qquad \Delta H^0 = 180.6 \text{ kJ}$$
$$2NO(g) + O_2(g) \longrightarrow 2NO_2(g) \qquad \Delta H^0 = -114.2 \text{ kJ}$$

During the day, NO_2 reacts with hydroxyl radical to form HNO_3:

$$NO_2(g) + HO\cdot(g) \longrightarrow HNO_3(g)$$

At night, a multistep reaction between NO_2 and ozone is involved. In either case, rain dissociates the nitric acid, and $NO_3^-(aq)$ enters both sea and land to be utilized by plants.

2. *Industrial fixation.* Most human-caused fixation occurs industrially during ammonia synthesis via the Haber process (see Chemical Connections, pp. 755–756). The process takes place on an enormous scale: on a mole basis, NH_3 ranks first among compounds in amount produced. Some of this NH_3 is converted to HNO_3 in the Ostwald process (Chapter 14, p. 588), but most is used as fertilizer, either directly or in the form of urea and ammonium salts (sulfate, phosphate, and nitrate), which enter the biosphere as they are taken up by plants (item 3 below). In recent decades, high-temperature combustion in electric power plants and in car, truck, and plane engines has become an important contributor to total fixed nitrogen, mainly because of the enormous rise in vehicle traffic. High engine operating temperatures mimic lightning to form NO from the air taken in to burn the hydrocarbon fuel. The NO in exhaust gases reacts to form nitric acid in the atmosphere, which adds to the nitrate load that reaches the ground.

The overuse of fertilizers and automobiles presents an increasingly serious water pollution problem in many areas. Leaching of the land by rain causes nitrate from fertilizer use and vehicle operation to enter natural waters (lakes, rivers, and

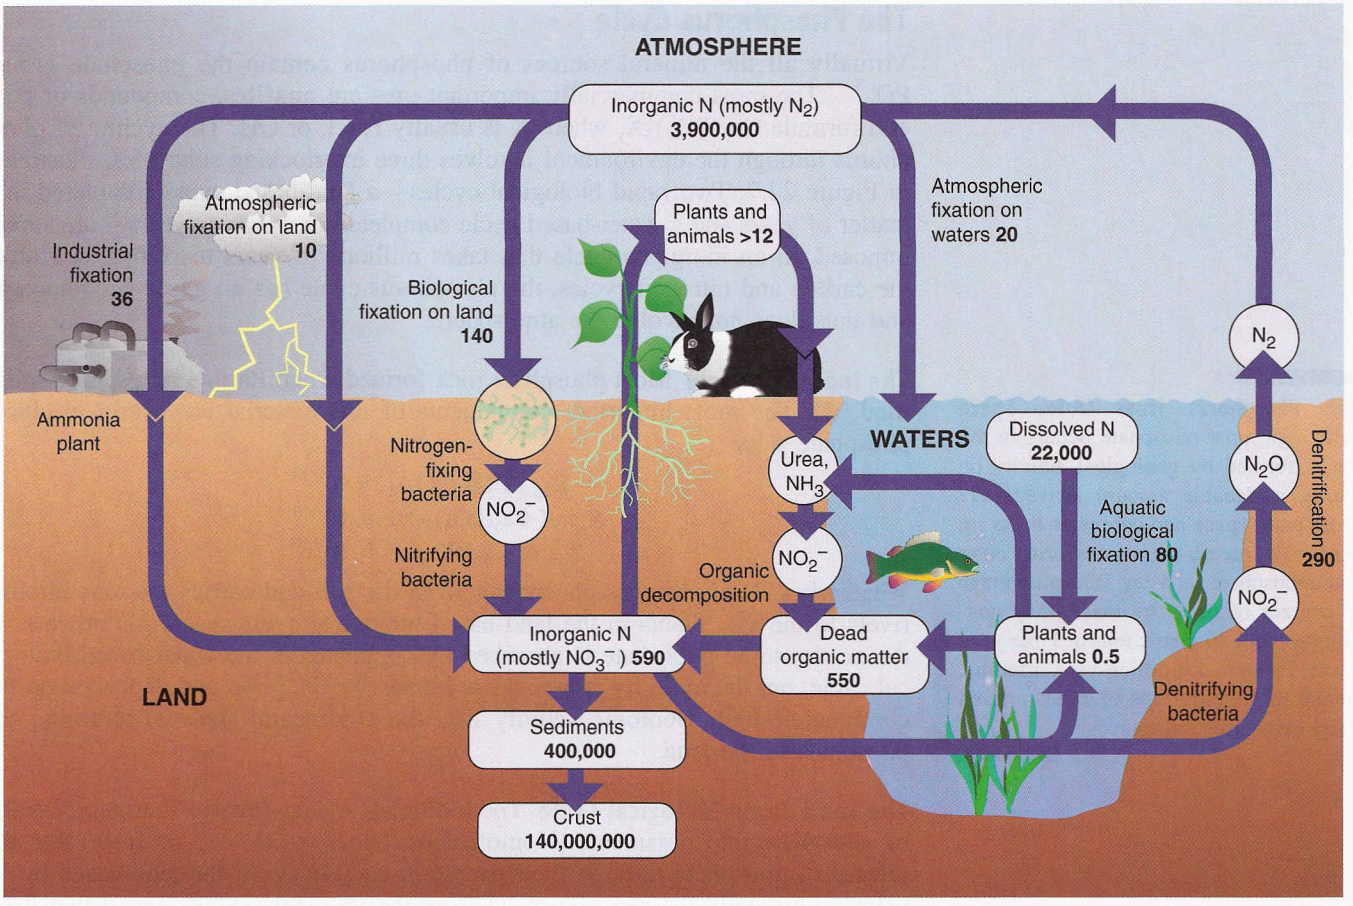

Figure 22.6 The nitrogen cycle. The major source of nitrogen, N_2, is fixed atmospherically, industrially, and biologically. Various types of bacteria are indispensable throughout the cycle. Numbers in boxes are in 10^9 metric tons of N and refer to the size of the source; numbers along arrows are in 10^6 metric tons of N and refer to the annual movement of the element between sources.

coastal estuaries) and cause *eutrophication,* the depletion of O_2 and the death of aquatic animal life from excessive algal and plant growth and decay. Excess nitrate also spoils nearby drinkable water.

3. *Biological fixation.* The biological fixation of atmospheric N_2 occurs in blue-green algae and in nitrogen-fixing bacteria that live on the roots of leguminous plants (such as peas, alfalfa, and clover). On a planetary scale, these microbial processes dwarf the previous two, fixing more than seven times as much nitrogen as the atmosphere and six times as much as industry. Root bacteria fix N_2 by reducing it to NH_3 and NH_4^+ through the action of enzymes that contain the transition metal molybdenum at their active site. Enzymes in other soil bacteria catalyze the multistep oxidation of NH_4^+ to NO_2^- and finally NO_3^-, which the plants reduce again to make their proteins. When the plants die, still other soil bacteria oxidize the proteins to NO_3^-.

Animals eat the plants, use the plant proteins to make their own proteins, and excrete nitrogenous wastes, such as urea $[(H_2N)_2C{=}O]$. The nitrogen in the proteins is released when the animals die and decay, and is converted by soil bacteria to NO_2^- and NO_3^- again. This central pool of inorganic nitrate has three main fates: some enters marine and terrestrial plants, some enters the enormous sediment store of mineral nitrates, and some is reduced by denitrifying bacteria to NO_2^- and then to N_2O and N_2, which re-enter the atmosphere to complete the cycle.

The Phosphorus Cycle

Virtually all the mineral sources of phosphorus contain the phosphate group, PO_4^{3-}. The most commercially important ores are **apatites,** compounds of general formula $Ca_5(PO_4)_3X$, where X is usually F, Cl, or OH. The cycling of phosphorus through the environment involves three interlocking subcycles, illustrated in Figure 22.7. Two rapid biological cycles—a land-based cycle completed in a matter of years and a water-based cycle completed in weeks to years—are superimposed on an inorganic cycle that takes millions of years to complete. Unlike the carbon and nitrogen cycles, the phosphorus cycle has no gaseous component and thus does *not* involve the atmosphere.

Phosphorus from Outer Space Although most phosphate occurs in the rocks formed by geological activity on Earth, a sizeable amount arrived here from outer space and continues to do so. About 100 metric tons of meteorites enter our atmosphere each day. With an average P content of 0.1% by mass, they contribute about 36 metric tons of P per year. Over Earth's 4.6-billion-year lifetime, about 10^{11} metric tons of P has arrived from extraterrestrial sources!

The Inorganic Cycle Most phosphate rock formed when Earth's lithosphere solidified. The most important components of this material are nearly insoluble phosphate salts:

$$K_{sp} \text{ of } Ca_3(PO_4)_2 \approx 10^{-29}$$
$$K_{sp} \text{ of } Ca_5(PO_4)_3OH \approx 10^{-51}$$
$$K_{sp} \text{ of } Ca_5(PO_4)_3F \approx 10^{-60}$$

Weathering slowly leaches phosphates from the soil and carries the ions through rivers to the sea. Plants in the land-based biological cycle speed this process. In the ocean, some phosphate is absorbed by organisms in the water-based biological cycle, but the majority is precipitated again by Ca^{2+} ion and deposited on the continental shelf. Geologic activity lifts the continental shelves, returning the phosphate to the land.

The Land-Based Biological Cycle The biological cycles involve the incorporation of phosphate into organisms (biomolecules, bones, teeth, and so forth) and the release of phosphate through their excretion and decay. In the land-based cycle, plants continually remove phosphate from the inorganic cycle. Recall that there are three phosphate oxoanions, and they exist in equilibrium in the aqueous environment:

$$H_2PO_4^- \rightleftharpoons HPO_4^{2-} + H^+ \rightleftharpoons PO_4^{3-} + H^+$$

In topsoil, phosphates occur as insoluble compounds of Ca^{2+}, Fe^{3+}, and Al^{3+}. Because plants can absorb only the water-soluble dihydrogen phosphate, they have evolved the ability to secrete acids near their roots to convert the insoluble salts gradually into the soluble ion:

$$Ca_3(PO_4)_2(s;\ \text{soil}) + 4H^+(aq;\ \text{secreted by plants}) \longrightarrow 3Ca^{2+}(aq) + 2H_2PO_4^-(aq;\ \text{absorbed by plants})$$

Animals that eat the plants excrete soluble phosphate, which is used in turn by newly growing plants. As the plants and animals excrete, die, and decay, some phosphate is washed into rivers and from there to the ocean. Most of the 2 million metric tons of phosphate that washes from land to sea each year comes from biological decay. Thus, the biosphere greatly increases the movement of phosphate from lithosphere to hydrosphere.

The Water-Based Biological Cycle Various phosphate oxoanions continually enter the aquatic environment. Studies that incorporate trace amounts of radioactive phosphorus into $H_2PO_4^-$ and monitor its uptake show that, within 1 minute, 50% of the ion is taken up by photosynthetic algae, which use it to synthesize

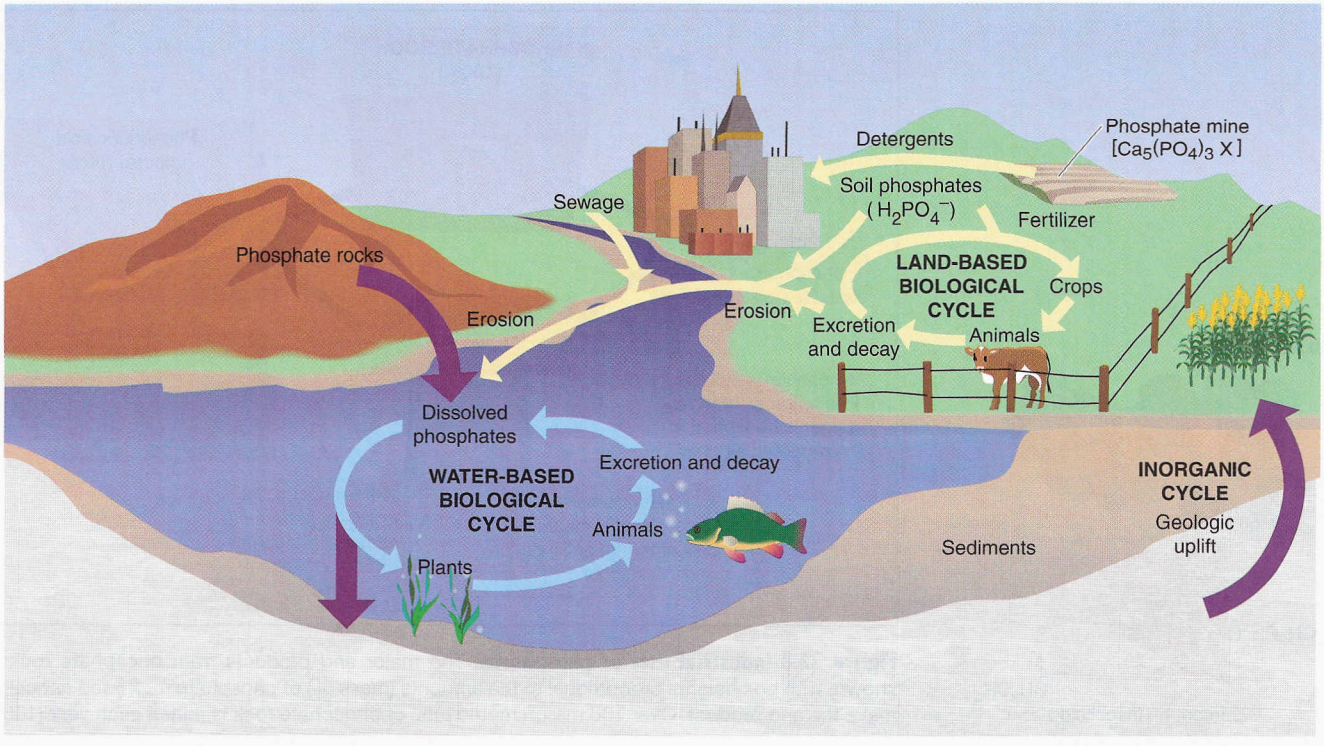

Figure 22.7 The phosphorus cycle. The inorganic subcycle *(purple arrows)*, water-based biological subcycle *(blue arrows)*, and land-based biological subcycle *(yellow arrows)* interact through erosion and through the growth and decay of organisms. The phosphorus cycle has no gaseous component.

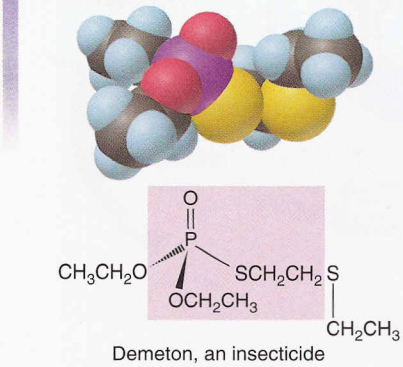
their biomolecules (this synthesis is denoted by the top curved arrow in the upcoming equation). The overall process might be represented by the following equation:

$$106CO_2(g) + 16NO_3^-(aq) + H_2PO_4^-(aq) + 122H_2O(l) + 17H^+(aq) \underset{\text{decay}}{\overset{\text{synthesis}}{\rightleftharpoons}} C_{106}H_{263}O_{110}N_{16}P(aq;\ \text{in algal cell fluid}) + 138O_2(g)$$

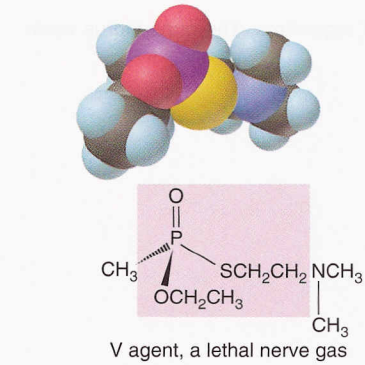
(The complex formula on the right represents the total composition of algal biomolecules, not some particular compound.)

As on land, animals eat the plants and are eaten by other animals, and they all excrete phosphate, die, and decay (denoted by the bottom curved arrow in the preceding equation). Some of the released phosphate is used by other aquatic organisms, and some returns to the land when fish-eating animals (mostly humans and birds) excrete phosphate, die, and decay. In addition, some aquatic phosphate precipitates with Ca^{2+}, sinks to the seabed, and returns to the long-term mineral deposits of the inorganic cycle.

Human Effects on Phosphorus Movement From prehistoric through preindustrial times, these interlocking phosphorus cycles were balanced. Modern human activity, however, alters the movement of phosphorus considerably. Our influence on the inorganic cycle is minimal, despite our annual removal of more than



Demeton, an insecticide



V agent, a lethal nerve gas

Phosphorus Nerve Poisons Because phosphorus is essential for all organisms, its compounds have many biological actions. In addition to their widespread use as fertilizers, phosphorus compounds are also used as pesticides *and* as military nerve gases. In fact, these two types of substances often have similar structures (see above) and modes of action. Both types affect the target organism by inactivating an enzyme involved in muscle contraction. They bind an amino acid critical to the enzyme's function, allowing the muscle to contract but not relax; the effect on the organism—insect or human—is often fatal. Chemists have synthesized a nerve-gas antidote whose shape mimics the binding site of the enzyme. The drug binds the poison, removing it from the enzyme, and is excreted.

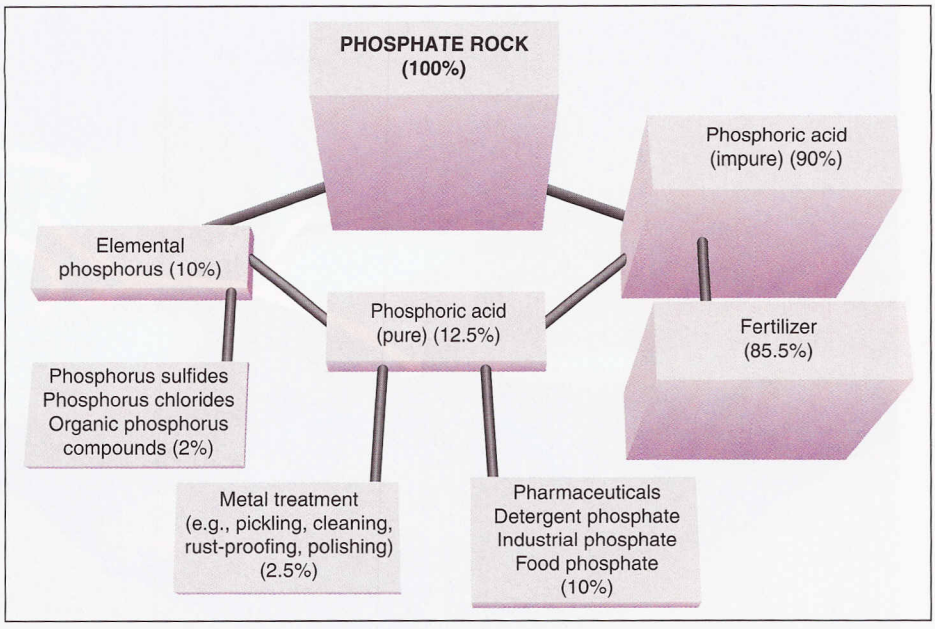


Figure 22.8 Industrial uses of phosphorus. The major end products from phosphate rock are shown, with box heights proportional to the amounts (mass %) of phosphate rock used annually to make the end product. Over 100 million metric tons of phosphate rock is mined each year (100%).

100 million metric tons of phosphate rock for a variety of uses (Figure 22.8). The end products of this removal, however, have unbalanced the two biological cycles.

The imbalance arises from our overuse of *soluble phosphate fertilizers,* such as $Ca(H_2PO_4)_2$ and $NH_4H_2PO_4$, the end products of about 85% of phosphate rock mined. Some fertilizer finds its way into rivers, lakes, and oceans to enter the water-based cycle. Much larger pollution sources, however, are the crops grown with the fertilizer and the detergents made from phosphate rock. The great majority of this phosphate arrives eventually in cities as crops, as animals that were fed crops, and as consumer products, such as the tripolyphosphates in detergents. Human garbage, excrement, wash water with detergents, and industrial wastewater containing phosphate return through sewers to the aquatic system. This human contribution equals the natural contribution—another 2 million metric tons of phosphate per year. The increased concentration in rivers and lakes causes eutrophication, which robs the water of O_2 so that it cannot support life. Such "dead" rivers and lakes are no longer usable for fishing, drinking, or recreation.

As early as 1912, a chemical solution to this problem was tried in Switzerland, where the enormous Lake Zurich had been choked with algae and become devoid of fish because of the release of human sewage. Treatment with $FeCl_3$ precipitated enough phosphate to return the lake gradually to its natural state. Soluble aluminum compounds have the same effect:

$$FeCl_3(aq) + PO_4^{3-}(aq) \longrightarrow FePO_4(s) + 3Cl^-(aq)$$

$$KAl(SO_4)_2 \cdot 12H_2O(aq) + PO_4^{3-}(aq) \longrightarrow AlPO_4(s) + K^+(aq) + 2SO_4^{2-}(aq) + 12H_2O(l)$$

After several lakes in the United States became polluted in this way, phosphates in detergents were drastically reduced, and stringent requirements for sewage treatment, including tertiary treatments to remove phosphate (see Chemical Connections, pp. 529–530), were put into effect. Lake Erie, which was severely polluted by the late 1960s and early 1970s, was the target of a program to reduce phosphates and is today relatively clean and restocked with fish.

SECTION SUMMARY

The environmental distribution of many elements changes cyclically with time and is affected in major ways by organisms. Carbon occurs in all three regions of Earth's crust, with atmospheric CO_2 linking the other two regions. Photosynthesis and decay of organisms alter the amount of carbon in the land and oceans. Human activity has increased atmospheric CO_2. Nitrogen is fixed by lightning, by industry, and primarily by microorganisms. When plants decay, bacteria decompose organic nitrogen and eventually return N_2 to the atmosphere. Through extensive use of fertilizers, humans have added excess nitrogen to freshwaters. The phosphorus cycle has no gaseous component. Inorganic phosphates leach slowly into land and water, where biological cycles interact. When plants and animals decay, they release phosphate to natural waters, where it is then absorbed by other plants and animals. Through overuse of phosphate fertilizers and detergents, humans double the amount of phosphorus entering aqueous systems.

22.3 METALLURGY: EXTRACTING A METAL FROM ITS ORE

Metallurgy is the branch of materials science concerned with the extraction and utilization of metals. In this section, we discuss the general procedures for isolating metals and, occasionally, the nonmetals that are found in their ores. The extraction process applies one or more of these three types of metallurgy: *pyrometallurgy* uses heat to obtain the metal, *electrometallurgy* employs an electrochemical step, and *hydrometallurgy* relies on the metal's aqueous solution chemistry.

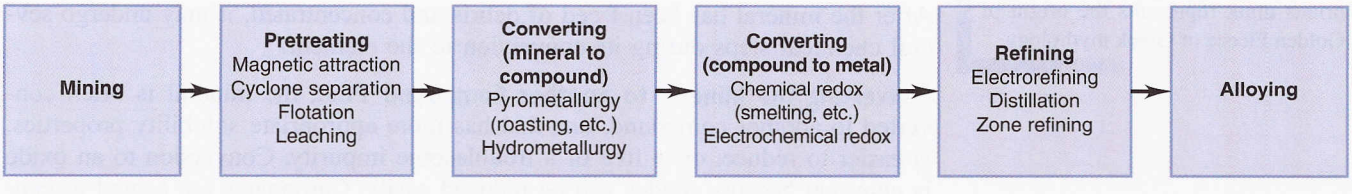
The extraction of an element begins with *mining the ore*. Most ores consist of mineral and gangue. The **mineral** contains the element; it is defined as a naturally occurring, homogeneous, crystalline inorganic solid, with a well-defined composition. The **gangue** is the portion of the ore with no commercial value, such as sand, rock, and clay attached to the mineral. Table 22.2 lists the common mineral sources of some metals.

Humans have been removing metals from Earth's crust for thousands of years, so most of the known concentrated sources are long gone. In many cases, ores containing very low mass percents of a metal are all that remain, and these require elaborate—and ingenious—extraction methods. Nevertheless, the general procedure for extracting most metals (and many nonmetals) involves a few basic steps, described in the upcoming subsections and previewed in Figure 22.9.

Table 22.2 Common Mineral Sources of Some Elements

Element	Mineral, Formula
Al	Gibbsite (in bauxite), $Al(OH)_3$
Ba	Barite, $BaSO_4$
Be	Beryl, $Be_3Al_2Si_6O_{18}$
Ca	Limestone, $CaCO_3$
Fe	Hematite, Fe_2O_3
Hg	Cinnabar, HgS
Na	Halite, NaCl
Pb	Galena, PbS
Sn	Cassiterite, SnO_2
Zn	Sphalerite, ZnS

Figure 22.9 Steps in metallurgy.



Pretreating the Ore

Following a crushing, grinding, or pulverizing step, which can be very expensive, pretreatment usually takes advantage of some physical or chemical difference to separate mineral from gangue. For magnetic minerals, such as magnetite (Fe_3O_4), a magnet can remove the mineral and leave the gangue behind. Where large density differences exist, a *cyclone separator* is used; it blows high-pressure air through the pulverized mixture to separate the particles. The lighter silicate-rich

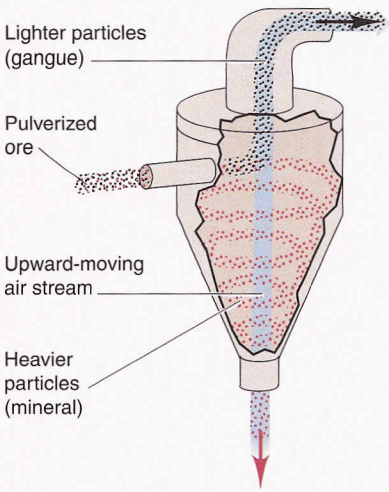


Figure 22.10 The cyclone separator. The pulverized ore enters at an angle, with the more dense particles (mineral) hitting the walls and spiraling downward, while the less dense particles (silicate-rich gangue) are carried upward in a stream of air.

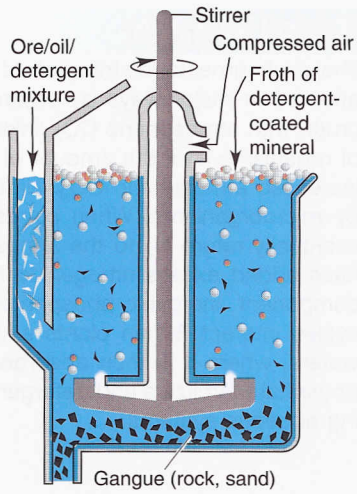

Figure 22.11 The flotation process. The pulverized ore is treated with an oil-detergent mixture, then stirred and aerated to create a froth that separates the detergent-coated mineral from the gangue. The mineral-rich froth is collected for further processing.

Panning and Fleecing for Gold The picture of the prospector, alone but for his faithful mule, hunched over the bank of a mountain stream patiently panning for gold, is mostly a relic of old movies. However, the process is valid. It is based on the very large density difference between gold (d = 19.3 g/cm^3) and sand ($d \approx$ 2.5 g/cm^3). In ancient times, river sands were washed over a sheep's fleece to trap the gold grains, a practice historians think represents the origin of the Golden Fleece of Greek mythology.

gangue is blown away, while the denser mineral-rich particles hit the walls of the separator and fall through the open bottom (Figure 22.10).

In **flotation,** an oil-detergent mixture is stirred with the pulverized ore in water to form a slurry (Figure 22.11). Flotation takes advantage of the different abilities of the surfaces of mineral and of gangue to become wet in contact with water and detergent. Rapid mixing moves air bubbles through the mixture and produces an oily, mineral-rich froth that floats, while the silicate particles sink. Skimming, followed by solvent removal of the oil-detergent mixture, isolates the concentrated mineral fraction. Flotation is a key step in copper recovery.

Leaching is a hydrometallurgical process that selectively extracts the metal, usually by forming a complex ion. The modern extraction of gold is a good example of this technique, because nuggets of the precious metal are found only in museums nowadays. The crushed ore, which often contains as little as 25 ppm of gold, is contained in a plastic-lined pool, treated with a cyanide ion solution, and aerated. In the presence of CN^-, the O_2 in air oxidizes gold metal to gold(I) ion, Au^+, which forms the soluble complex ion, $Au(CN)_2^-$:

$$4Au(s) + O_2(g) + 8CN^-(aq) + 2H_2O(l) \longrightarrow 4Au(CN)_2^-(aq) + 4OH^-(aq)$$

(The method has become controversial in some areas because cyanide lost from the contained area enters streams and lakes, where it poisons fish and birds.)

Converting Mineral to Element

After the mineral has been freed of debris and concentrated, it may undergo several chemical steps during its conversion to the element.

Converting the Mineral to Another Compound First, the mineral is often converted to another compound, one that has more appropriate solubility properties, is easier to reduce, or is free of a troublesome impurity. Conversion to an oxide is common because oxides can be reduced easily. Carbonates are heated to convert them to the oxide:

$$CaCO_3(s) \xrightarrow{\Delta} CaO(s) + CO_2(g)$$

Metal sulfides, such as ZnS, can be converted to oxides by **roasting** in air:

$$2ZnS(s) + 3O_2(g) \xrightarrow{\Delta} 2ZnO(s) + 2SO_2(g)$$

In most countries, hydrometallurgical methods are now used to avoid the atmospheric release of SO_2 during roasting. One way of processing copper, for example, is by bubbling air through an acidic slurry of insoluble Cu_2S, which completes both the pretreatment and conversion steps:

$$2Cu_2S(s) + 5O_2(g) + 4H^+(aq) \longrightarrow 4Cu^{2+}(aq) + 2SO_4^{2-}(aq) + 2H_2O(l)$$

Converting the Compound to the Element Through Chemical Redox The next step converts the new mineral form (usually an oxide) to the free element by either chemical or electrochemical methods. In chemical redox, a reducing agent reacts directly with the compound. The most common reducing agents are carbon, hydrogen, and an active metal.

1. *Reduction with carbon.* Carbon, in the form of coke (a porous residue from incomplete combustion of coal) or charcoal, is a very common reducing agent. Heating an oxide with a reducing agent such as coke to obtain the metal is called **smelting.** Many metal oxides, such as zinc oxide and tin(IV) oxide, are smelted with carbon to free the metal, which may need to be condensed and solidified:

$$ZnO(s) + C(s) \longrightarrow Zn(g) + CO(g)$$
$$SnO_2(s) + 2C(s) \longrightarrow Sn(l) + 2CO(g)$$

Several nonmetals that occur with positive oxidation states in minerals can be reduced with carbon as well. Phosphorus, for example, is produced from calcium phosphate:

$$2Ca_3(PO_4)_2(s) + 10C(s) + 6SiO_2(s) \longrightarrow 6CaSiO_3(s) + 10CO(g) + P_4(s)$$

(Metallic calcium is a much stronger reducing agent than carbon, so it is not formed.)

Low cost and ready availability explain why carbon is such a common reducing agent, and thermodynamic principles explain why it is such an effective one in many cases. Consider the standard free energy change (ΔG^0) for the reduction of tin(IV) oxide:

$$SnO_2(s) + 2C(s) \longrightarrow Sn(s) + 2CO(g) \qquad \Delta G^0 = 245 \text{ kJ at } 25°C \text{ (298 K)}$$

The magnitude and sign of ΔG^0 indicate a highly *non*spontaneous reaction for standard conditions at 25°C. However, because solid C becomes gaseous CO, the standard molar entropy change is very positive ($\Delta S^0 \approx 380$ J/K). Therefore, *the $-T\Delta S^0$ term of ΔG^0 becomes more negative with higher temperature* (Section 20.3). As the temperature increases, ΔG^0 decreases, and at a high enough temperature, the reaction becomes spontaneous ($\Delta G^0 < 0$). At 1000°C (1273 K), for example, $\Delta G^0 = -62.8$ kJ. The actual process is carried out at a temperature of around 1250°C (1523 K), so ΔG^0 is even more negative.

As you know, overall reactions often mask several intermediate steps. For instance, the reduction of tin(IV) oxide may begin with formation of tin(II) oxide:

$$SnO_2(s) + C(s) \longrightarrow \cancel{SnO(s)} + CO(g)$$
$$\cancel{SnO(s)} + C(s) \longrightarrow Sn(l) + CO(g)$$

[Molten tin (mp = 232 K) is obtained at this temperature.] The second step may even be composed of others, in which CO, not C, is the actual reducing agent:

$$SnO(s) + \cancel{CO(g)} \longrightarrow Sn(l) + \cancel{CO_2(g)}$$
$$\cancel{CO_2(g)} + C(s) \rightleftharpoons 2CO(g)$$

Other pyrometallurgical processes are similarly complex. Shortly, you'll see that the overall reaction for the smelting of iron is

$$2Fe_2O_3(s) + 3C(s) \longrightarrow 4Fe(l) + 3CO_2(g)$$

However, the actual process is a multistep one with CO as the reducing agent. The advantage of CO over C is the far greater contact the gaseous reducing agent can make with the other reactant, which speeds the process.

2. *Reduction with hydrogen.* For oxides of some metals, especially some members of Groups 6B(6) and 7B(7), reduction with carbon forms metal carbides. These carbides are difficult to convert further, so other reducing agents are used. Hydrogen gas is used for less active metals, such as tungsten:

$$WO_3(s) + 3H_2(g) \longrightarrow W(s) + 3H_2O(g)$$

One step in the purification of the metalloid germanium uses hydrogen:

$$GeO_2(s) + 2H_2(g) \longrightarrow Ge(s) + 2H_2O(g)$$

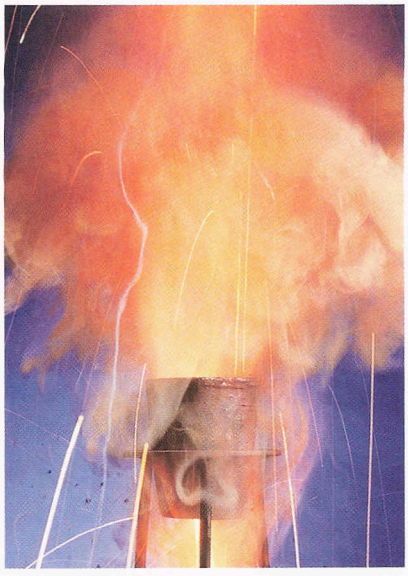

Figure 22.12 The thermite reaction. This highly exothermic redox reaction uses powdered aluminum to reduce metal oxides.

Animation: Thermite Reaction
Online Learning Center

3. *Reduction with an active metal.* When a metal might form an undesirable hydride, its oxide is reduced by a more active metal. In the *thermite reaction,* aluminum powder reduces the metal oxide in a spectacular exothermic reaction to give the molten metal (Figure 22.12). The reaction for chromium is

$$Cr_2O_3(s) + 2Al(s) \longrightarrow 2Cr(l) + Al_2O_3(s) \qquad \Delta H^0 << 0$$

Reduction by a more active metal is also used in situations that do not involve an oxide. In the extraction of gold, after the pretreatment by leaching, the gold(I) complex ion is reduced with zinc to form the metal and a zinc complex ion:

$$2Au(CN)_2^-(aq) + Zn(s) \longrightarrow 2Au(s) + Zn(CN)_4^{2-}(aq)$$

In some cases, an active metal, such as calcium, is used to recover an even more active metal, such as rubidium, from its molten salt:

$$Ca(l) + 2RbCl(l) \longrightarrow CaCl_2(l) + 2Rb(g)$$

A similar process is used to recover sodium, as detailed in the next section.

4. *Oxidation with an active nonmetal.* Just as chemical *reduction* of a mineral is used to obtain the metal, chemical *oxidation* of a mineral is sometimes used to obtain a nonmetal. A stronger oxidizing agent is used to remove electrons from the nonmetal anion to give the free nonmetal, as in the industrial production of iodine from concentrated brines by oxidation with chlorine gas:

$$2I^-(aq) + Cl_2(g) \longrightarrow 2Cl^-(aq) + I_2(s)$$

Converting the Compound to the Element Through Electrochemical Redox In these processes, the mineral components are converted to the elements in an electrolytic cell (Section 21.7). Sometimes, the *pure* mineral, in the form of the molten halide or oxide, is used to prevent unwanted side reactions. The cation is reduced to the metal at the cathode, and the anion is oxidized to the nonmetal at the anode:

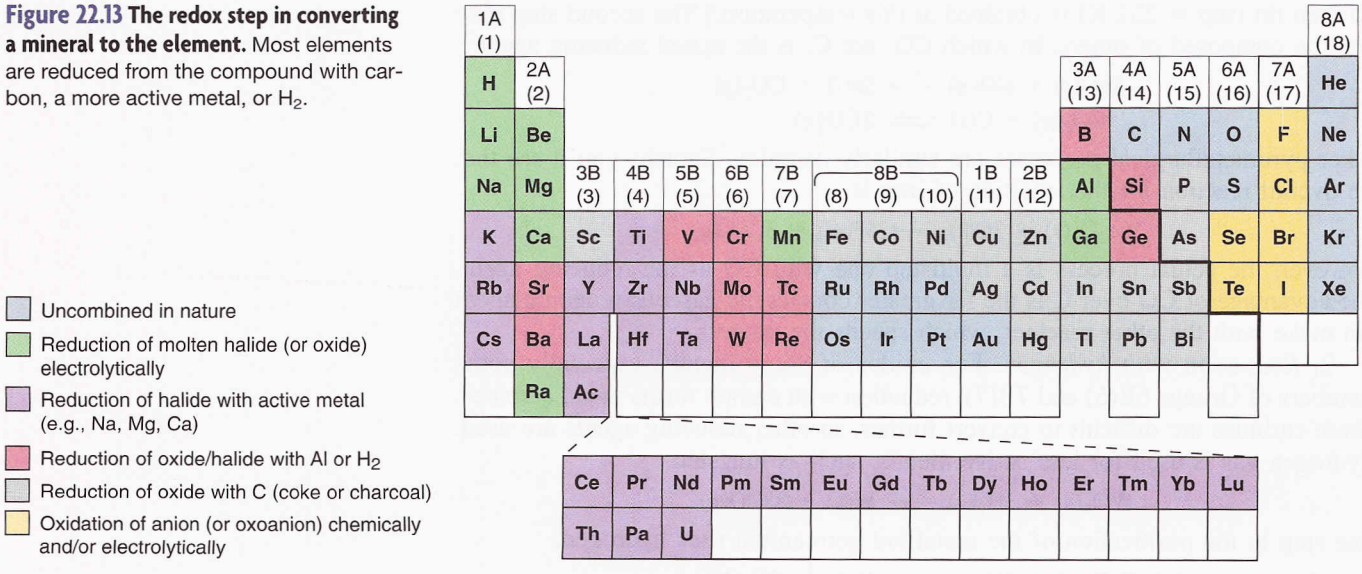
$$BeCl_2(l) \longrightarrow Be(s) + Cl_2(g)$$

High-purity hydrogen gas is prepared by electrochemical reduction:

$$2H_2O(l) \longrightarrow 2H_2(g) + O_2(g)$$

Specially designed cells separate the products to prevent recombination. Cost is a major factor in the use of electrolysis, and an inexpensive source of electricity is essential for large-scale methods. The current and voltage requirements depend on the electrochemical potential and any overvoltage effects. Figure 22.13 shows the most common step for obtaining each free element from its mineral.

Figure 22.13 The redox step in converting a mineral to the element. Most elements are reduced from the compound with carbon, a more active metal, or H_2.



Refining and Alloying the Element

At this point in the isolation process, the element typically contains impurities from previous steps, so it must be refined. Then, once purified, metallic elements are often alloyed to improve their properties.

Refining (Purifying) the Element Refining is a purification procedure, often carried out by one of three common methods. An electrolytic cell is employed in **electrorefining,** in which the impure metal acts as the anode and a sample of the pure metal acts as the cathode. As the reaction proceeds, the anode slowly disintegrates, and the metal ions are reduced to deposit on the cathode. In some cases, the impurities, which fall beneath the disintegrating anode, are the source of several valuable and less abundant elements. (We examine the electrorefining of copper shortly.)

Metals with relatively low boiling points, such as zinc and mercury, are refined by *distillation.*

In the process of **zone refining** (see the Gallery, p. 521), impurities are removed from a bar of the element by concentrating them in a thin molten zone, while the purified element recrystallizes. Metalloids used in electronic semiconductors, such as silicon and germanium, must be zone refined to greater than 99.999999% purity.

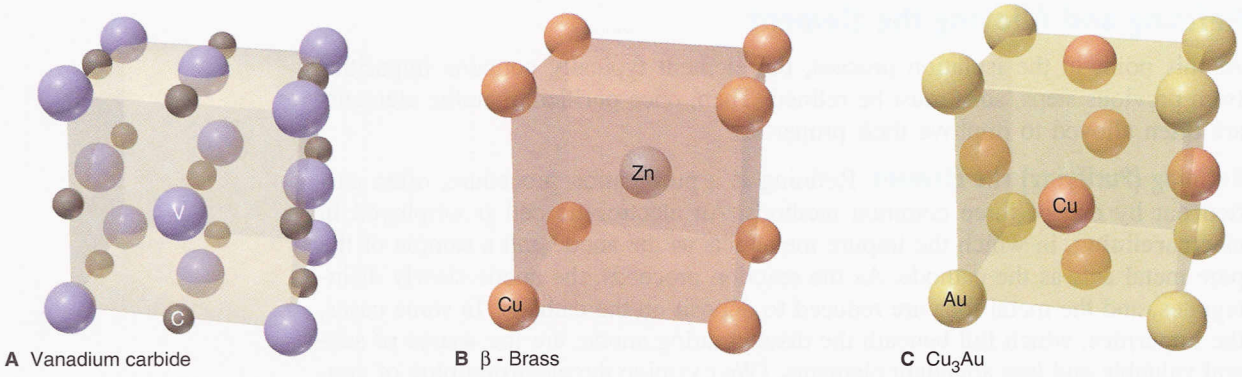
Alloying the Purified Element An **alloy** is a metal-like mixture consisting of solid phases of two or more pure elements, a solid solution, or, in some cases, distinct intermediate phases (these alloys are sometimes referred to as *intermetallic compounds*). The separate phases are often so finely divided that they can only be distinguished microscopically. Alloying a metal with other metals (and, in some cases, nonmetals) is done to alter the metal's melting point and to enhance properties such as luster, conductivity, malleability, ductility, and strength.

Iron, probably the most important metal, is used only when it is alloyed. In pure form, it is soft and corrodes easily. However, when alloyed with carbon and other metals, such as Mo for hardness and Cr and Ni for corrosion resistance, it forms the various steels. Copper stiffens when zinc is added to make brass. Mercury solidifies when alloyed with sodium, and vanadium becomes extremely tough with some carbon added. Table 22.3 shows the composition and uses of some common alloys.

The simplest alloys, called *binary alloys,* contain only two elements. In some cases, *the added element enters interstices,* spaces between the parent metal atoms

Table 22.3 Some Familiar Alloys and Their Composition

Name	Composition (Mass %)	Uses
Stainless steel	73–79 Fe, 14–18 Cr, 7–9 Ni	Cutlery, instruments
Nickel steel	96–98 Fe, 2–4 Ni	Cables, gears
High-speed steels	80–94 Fe, 14–20 W (or 6–12 Mo)	Cutting tools
Permalloy	78 Ni, 22 Fe	Ocean cables
Bronzes	70–95 Cu, 1–25 Zn, 1–18 Sn	Statues, castings
Brasses	50–80 Cu, 20–50 Zn	Plating, ornamental objects
Sterling silver	92.5 Ag, 7.5 Cu	Jewelry, tableware
14-Carat gold	58 Au, 4–28 Ag, 14–28 Cu	Jewelry
18-Carat white gold	75 Au, 12.5 Ag, 12.5 Cu	Jewelry
Typical tin solder	67 Pb, 33 Sn	Electrical connections
Dental amalgam	69 Ag, 18 Sn, 12 Cu, 1 Zn (dissolved in Hg)	Dental fillings



A Vanadium carbide **B** β - Brass **C** Cu_3Au

Figure 22.14 Three binary alloys.

in the crystal structure (Section 12.6). In vanadium carbide, for instance, carbon atoms occupy holes of a face-centered cubic vanadium unit cell (Figure 22.14A). In other cases, the *added element substitutes for parent atoms* in the unit cell. In many types of brass, for example, relatively few zinc atoms substitute randomly for copper atoms in the face-centered cubic copper unit cell (see Figure 13.4A). On the other hand, β-brass is an intermediate phase that crystallizes as the Zn:Cu ratio approaches 1:1 in a structure with a Zn atom surrounded by eight Cu atoms (Figure 22.14B). In one alloy of copper and gold, Cu atoms occupy the faces of a face-centered cube, and Au atoms lie at the corners (Figure 22.14C).

Atomic properties, including size, electron configuration, and number of valence electrons, determine which metals form stable alloys. Quantitative predictions indicate that transition metals having few *d* electrons often form stable alloys with transition metals having many *d* electrons. Thus, metals from the left half of the *d* block (Groups 3 to 5) often form alloys with metals from the right half (Groups 9 to 11). For example, electron-poor Zr, Nb, and Ta form strong alloys with electron-rich Ir, Pt, or Au; an example is the very stable $ZrPt_3$.

SECTION SUMMARY

Metallurgy involves mining an ore, separating it from debris, pretreating it to concentrate the mineral source, converting the mineral to another compound that is easier to process further, reducing this compound to the metal, purifying the metal, and in many cases, alloying it to obtain a more useful material.

22.4 TAPPING THE CRUST: ISOLATION AND USES OF THE ELEMENTS

Once an element's abundance and sources are known and the metallurgical methods chosen, the isolation process begins. Obviously, the process depends on the physical and chemical properties of the source: we isolate an element that occurs uncombined in the air differently from one dissolved in the sea or one found in a rocky ore. In this section, we detail methods for recovering some important elements; pay special attention to the application of ideas from earlier chapters to these key industrial processes.

Producing the Alkali Metals: Sodium and Potassium

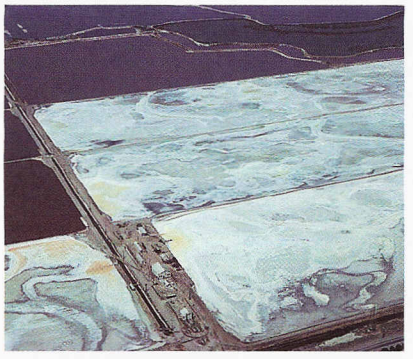
The alkali metals are among the most reactive elements and thus are always found as ions in nature, either in solid minerals or in aqueous solution. In the laboratory, the free elements must be protected from contact with air (for example, by being stored under mineral oil) to prevent their immediate oxidation and to minimize the possibility of fires. The two most important alkali metals are sodium

and potassium. Their abundant, water-soluble compounds are used throughout industry and research, and the Na^+ and K^+ ions are essential to organisms.

Industrial Production of Sodium and Potassium The sodium ore is *halite* (largely NaCl), which is obtained either by evaporation of concentrated salt solutions (brines) or by mining vast salt deposits formed from the evaporation of prehistoric seas. The Cheshire salt field in Britain, for example, is 60 km by 24 km by 400 m thick and contains more than 90% NaCl. Other large deposits occur in New Mexico, Michigan, New York, and Kansas.

The brine is evaporated to dryness, and the solid is crushed and fused (melted) for use in an electrolytic apparatus called the **Downs cell** (Figure 22.15). To reduce heating costs, the NaCl (mp = 801°C) is mixed with $1\frac{1}{2}$ parts $CaCl_2$ to form a mixture that melts at only 580°C. Reduction of the metal ions to Na and Ca takes place at a cylindrical steel cathode, with the molten metals floating on the denser molten salt mixture. As they rise through a short collecting pipe, the liquid Na is siphoned off, while a higher melting Na/Ca alloy solidifies and falls back into the molten electrolyte. Chloride ions are oxidized to Cl_2 gas at a large anode within an inverted cone-shaped chamber. The cell design separates the metals from the Cl_2 to prevent their explosive recombination. The Cl_2 gas is collected, purified, and sold as a valuable by-product.

Sylvite (mostly KCl) is the major ore of potassium. The metal is too soluble in molten KCl to be prepared by a method similar to that for sodium. Instead, chemical reduction of K^+ ions by liquid Na is used. The method is based on atomic properties and the nature of equilibrium systems. Recall that an Na atom is smaller than a K atom, so it holds its outer electron more tightly, as the first ionization energies indicate: IE_1 of Na = 496 kJ/mol; IE_1 of K = 419 kJ/mol. Thus, if the isolation method for K were based solely on this atomic property, Na would not be very effective at reducing K^+, and the reaction would not move very far toward products. An ingenious approach, which applies Le Châtelier's



A Plentiful Oceanic Supply of NaCl Will we ever run out of sodium chloride? Not likely. The rock-salt (halite) equivalent of NaCl in the world's oceans has been estimated at 1.9×10^7 km^3, about 150% of the volume of North America above sea level. Or, looking at this amount another way: a row of 1-km^3 cubes of NaCl would stretch from Earth to the Moon 47 times! The photo shows evaporative salt beds near San Francisco Bay.

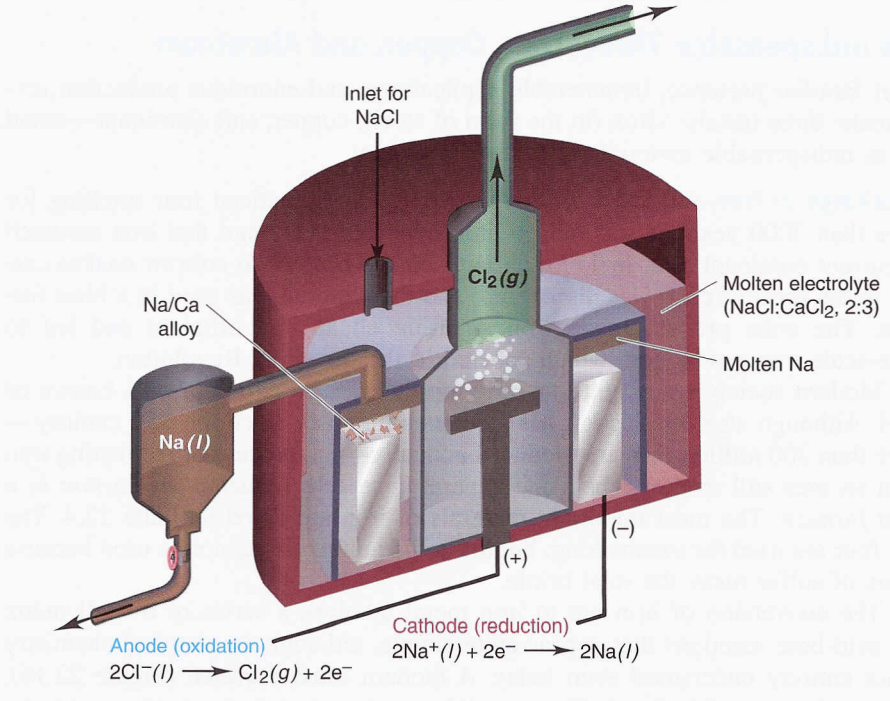


Figure 22.15 The Downs cell for production of sodium. The mixture of solid NaCl and $CaCl_2$ forms the molten electrolyte. Sodium and calcium are formed at the cathode and float, but an Na/Ca alloy solidifies and falls back into the bath. Chlorine gas forms at the anode.

principle, overcomes this drawback. The reduction is carried out at 850°C, which is above the boiling point of K, so the equilibrium mixture contains *gaseous* K:

$$Na(l) + K^+(l) \rightleftharpoons Na^+(l) + K(g)$$

As the K gas is removed, the system shifts to produce more K. The gas is then condensed and purified by fractional distillation. The same general method (with Ca as the reducing agent) is used to produce rubidium and cesium.

Uses of Sodium and Potassium The compounds of Na and K (and indeed, of all the alkali metals) have many more uses than the elements themselves [see the Group 1A(1) Family Portrait, p. 561]. Nevertheless, there are some interesting uses of the metals that take advantage of their strong reducing power. Large amounts of Na were used as an alloy with lead to make gasoline antiknock additives, such as tetraethyllead:

$$4C_2H_5Cl(g) + 4Na(s) + Pb(s) \longrightarrow (C_2H_5)_4Pb(l) + 4NaCl(s)$$

The toxic effects of environmental lead have made this use virtually nonexistent in the United States. Moreover, although leaded gasoline is still used in parts of Europe, recent legislation promises to eliminate this product early in this decade.

If certain types of nuclear reactors, called *breeder reactors* (Chapter 24), become a practical way to generate energy in the United States, Na production would increase enormously. Its low melting point, viscosity, and absorption of neutrons, combined with its high thermal conductivity and heat capacity, make it perfect for cooling the reactor and exchanging heat to the steam generator.

The major use of potassium at present is in an alloy with sodium for use as a heat exchanger in chemical and nuclear reactors. Another application relies on production of its superoxide, which it forms by direct contact with O_2:

$$K(s) + O_2(g) \longrightarrow KO_2(s)$$

This material is employed as an emergency source of O_2 in breathing masks for miners, divers, submarine crews, and firefighters (see photo):

$$4KO_2(s) + 4CO_2(g) + 2H_2O(g) \longrightarrow 4KHCO_3(s) + 3O_2(g)$$

Firefighter with KO_2 breathing mask.

The Indispensable Three: Iron, Copper, and Aluminum

Their familiar presence, innumerable applications, and enormous production levels make three metals—iron (in the form of steel), copper, and aluminum—stand out as indispensable materials of industrial society.

Metallurgy of Iron and Steel Although people have practiced iron smelting for more than 3000 years, it was only a little over 225 years ago that iron assumed its current dominant role. In 1773, an inexpensive process to convert coal to carbon in the form of coke was discovered, and the material was used in a blast furnace. The coke process made iron smelting cheap and efficient and led to large-scale iron production, which ushered in the Industrial Revolution.

Modern society rests, quite literally, on the various alloys of iron known as **steel.** Although steel production has grown enormously since the 18th century—more than 700 million tons are produced annually—the process of recovering iron from its ores still employs the same general approach: *reduction by carbon in a blast furnace.* The most important minerals of iron are listed in Table 22.4. The first four are used for steelmaking, but the sulfide minerals cannot be used because traces of sulfur make the steel brittle.

Table 22.4 Important Minerals of Iron

Mineral Type	Mineral, Formula
Oxide	Hematite, Fe_2O_3
	Magnetite, Fe_3O_4
	Ilmenite, $FeTiO_3$
Carbonate	Siderite, $FeCO_3$
Sulfide	Pyrite, FeS_2
	Pyrrhotite, FeS

The conversion of iron ore to iron metal involves a series of overall redox and acid-base reactions that appear quite simple, although the detailed chemistry is not entirely understood even today. A modern **blast furnace** (Figure 22.16), such as those used in South Korea and Japan, is a tower about 14 m wide by 40 m high, made of a brick that can withstand intense heat. The *charge,* which consists of an iron ore (usually hematite) containing the mineral, coke, and lime-

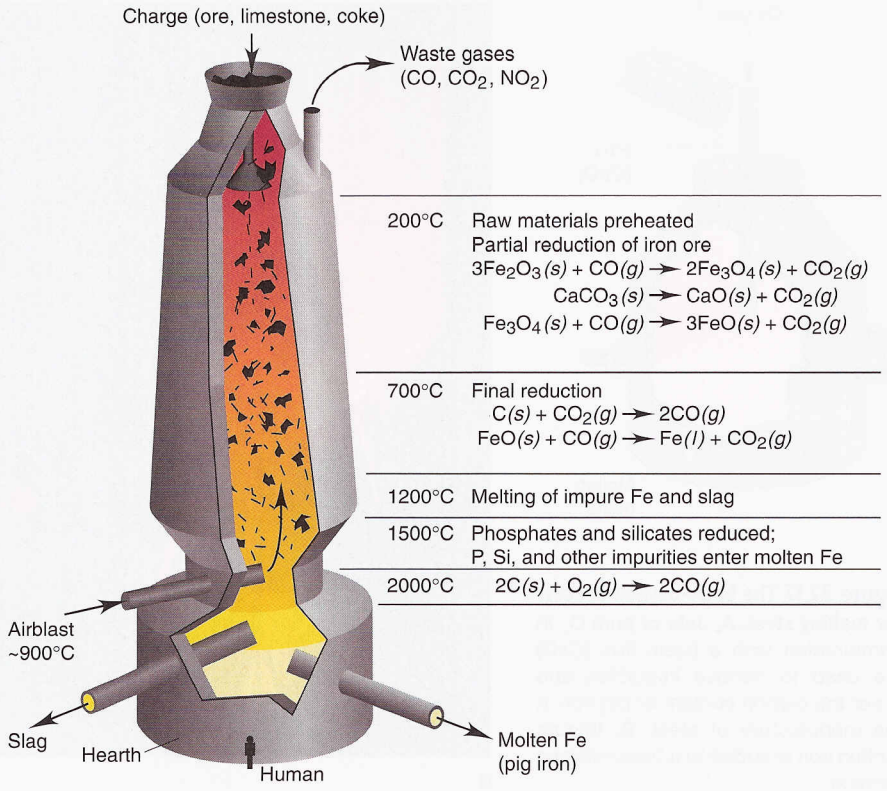

Figure 22.16 The major reactions in a blast furnace. Iron is produced from iron ore, coke, and limestone in a complex process that depends on the temperature at different heights in the furnace. (A human is shown for scale.)

Animation: Iron Smelting
Online Learning Center

stone, is fed through the top. More coke is burned in air at the bottom. The charge falls and meets a *blast* of rapidly rising hot air created by the burning coke:

$$2C(s) + O_2(g) \longrightarrow 2CO(g) + \textbf{\textit{heat}}$$

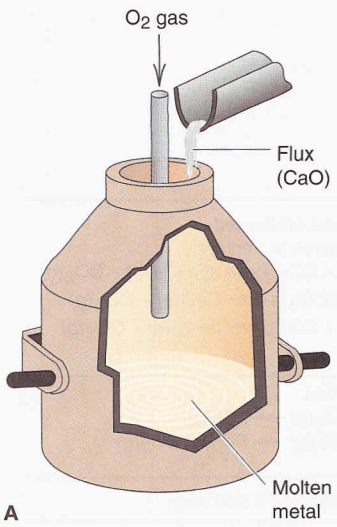
At the bottom of the furnace, the temperature exceeds 2000°C, while at the top, it reaches only 200°C. As a result, different stages of the overall reaction process occur at different heights as the charge descends:

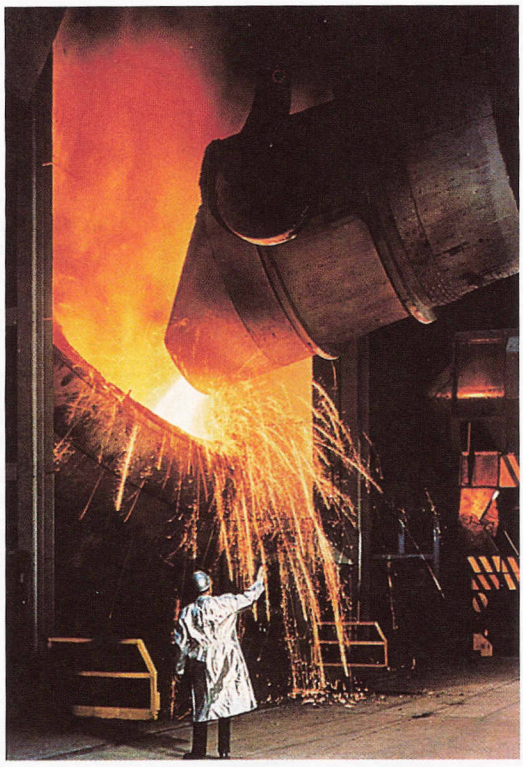
1. In the upper part of the furnace (200°C to 700°C), the charge is preheated, and a *partial reduction* step occurs. The hematite is reduced to magnetite and then to iron(II) oxide (FeO) by CO, the actual reducing agent for the iron oxides. Carbon dioxide is formed as well. Because the blast of hot air passes through the entire furnace in only 10 s, the various gas-solid reactions do *not* reach equilibrium, and many intermediate products form. Limestone also decomposes to form CO_2 and the basic oxide CaO, which is important later in the process.
2. Lower down, at 700°C to 1200°C, a *final reduction* step occurs, as some of the coke reduces CO_2 to form more CO, which reduces the FeO to Fe.
3. At still higher temperatures, between 1200°C and 1500°C, the iron melts and drips to the bottom of the furnace. Acidic silica particles from the gangue react with basic calcium oxide in a Lewis acid-base reaction to form a molten waste product called **slag:**

   $$CaO(s) + SiO_2(s) \longrightarrow CaSiO_3(l)$$

   The siliceous slag drips down and floats on the denser iron (much as Earth's silicate-rich mantle and crust float on its molten iron core).
4. Some unwanted reactions occur at this hottest stage, between 1500°C and 2000°C. Any remaining phosphates and silicates are reduced to P and Si, and some Mn and traces of S dissolve into the molten iron along with carbon. The resulting impure product is called *pig iron* and contains about 3% to 4% C. A small amount of pig iron is used to make *cast iron,* but most is purified and alloyed to make various kinds of steel.

Was It Slag That Made the Great Ship Go Down? Direct observation of the sunken luxury liner *Titanic* shows that six small slits caused by collision with an iceberg, rather than an enormous gash, sank the ship. The slits appear between sections of steel plates in the lower hull and suggest weakness in the rivets that connected the plates. Metallurgical analysis of the rivets shows three times as much slag content as modern rivets. Too much of this silicate-rich material makes the wrought iron used in the rivets brittle and easier to break under stress. Moreover, rather than being evenly distributed, the slag particles within the iron, viewed microscopically, appear to be clumped, which causes weak spots. Could low-grade rivets with too much slag have caused this tragedy? Follow-up analysis of more rivets and a historical search of rivet standards in the early 1900s may finally solve the mystery of what brought down the unsinkable *Titanic* and caused the deaths of 1500 passengers.

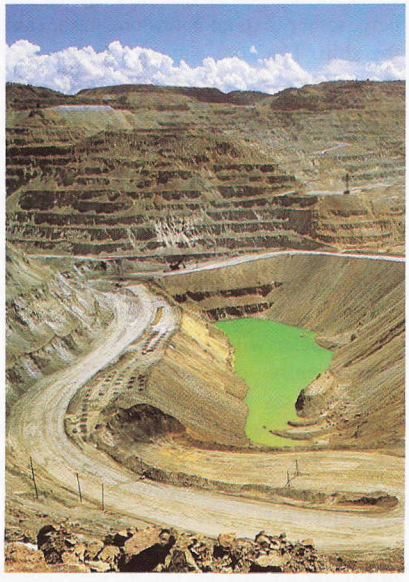




B

Figure 22.17 The basic-oxygen process for making steel. A, Jets of pure O_2 in combination with a basic flux (CaO) are used to remove impurities and lower the carbon content of pig iron in the manufacture of steel. **B,** Impure molten iron is added to a basic-oxygen furnace.

Pig iron is converted to steel in a separate furnace by means of the **basic-oxygen process,** as shown in Figure 22.17. High-pressure O_2 is blown over and through the molten iron, so that impurities (C, Si, P, Mn, S) are oxidized rapidly. The highly negative standard heats of formation of their oxides (such as ΔH_f^0 of $CO_2 = -394$ kJ/mol and ΔH_f^0 of $SiO_2 = -911$ kJ/mol) raise the temperature, which speeds the reaction. A lime (CaO) flux is added, which converts the oxides to a molten slag [primarily $CaSiO_3$ and $Ca_3(PO_4)_2$] that is decanted from the molten steel. The product is **carbon steel,** which contains 1% to 1.5% C and other impurities. It is alloyed with metals that prevent corrosion and increase its strength or flexibility.



Mining chalcopyrite.

Isolation and Electrorefining of Copper After many centuries of being mined to make bronze and brass articles, copper ores have become less plentiful and less rich in copper, so the metal is more expensive to extract. Despite this, more than 2.5 billion pounds of copper is produced in the United States annually. The most common copper ore is chalcopyrite, $CuFeS_2$, a mixed sulfide of FeS and CuS (see photo). Most remaining deposits contain less than 0.5% Cu by mass. To "win" this small amount of copper from the ore requires several metallurgical steps, including a final refining to achieve the 99.99% purity needed for electrical wiring, copper's most important application.

The low copper content in chalcopyrite must be enriched by removing the iron. The first step in copper extraction is pretreatment by flotation (see Figure 22.11, p. 974), which concentrates the ore to around 15% Cu by mass. The next step in many processing plants is a controlled roasting step, which oxidizes the FeS but not the CuS:

$$2FeCuS_2(s) + 3O_2(g) \longrightarrow 2CuS(s) + 2FeO(s) + 2SO_2(g)$$

To remove the FeO and convert the CuS to a more convenient form, the mixture is heated to 1100°C with sand and more of the concentrated ore. Several reactions occur in this step. The FeO reacts with sand to form a molten slag:

$$FeO(s) + SiO_2(s) \longrightarrow FeSiO_3(l)$$

The CuS is thermodynamically unstable at the elevated temperature and decomposes to yield Cu_2S, which is drawn off as a liquid.

In the final smelting step, the Cu_2S is roasted in air, which converts some of it to Cu_2O:

$$2Cu_2S(s) + 3O_2(g) \longrightarrow 2Cu_2O(s) + 2SO_2(g)$$

The two copper(I) compounds then react, with sulfide ion acting as the reducing agent:

$$Cu_2S(s) + 2Cu_2O(s) \longrightarrow 6Cu(l) + SO_2(g)$$

The copper obtained at this stage is usable for plumbing, but it must be purified further for electrical applications by removing unwanted impurities (Fe and Ni) as well as valuable ones (Ag, Au, and Pt). Purification is accomplished by *electrorefining,* which involves the oxidation of Cu and the formation of Cu^{2+} ions in solution, followed by their reduction and the plating out of Cu metal (Figure 22.18). The impure copper obtained from smelting is cast into plates to be used as anodes, and cathodes are made from already purified copper. The electrodes are immersed in acidified $CuSO_4$ solution, and a controlled voltage is applied that accomplishes two tasks simultaneously:

1. Copper and the more active impurities (Fe, Ni) are oxidized to their cations, while the less active ones (Ag, Au, Pt) are not. As the anode slabs react, these unoxidized metals fall off as a valuable "anode mud" and are purified separately. Sale of the precious metals in the anode mud nearly offsets the cost of electricity to operate the cell, making Cu wire inexpensive.
2. Because Cu is much less active than the Fe and Ni impurities, Cu^{2+} ions are reduced at the cathode, but Fe^{2+} and Ni^{2+} ions remain in solution:

$$Cu^{2+}(aq) + 2e^- \longrightarrow Cu(s) \qquad E^0 = 0.34\ V$$
$$Ni^{2+}(aq) + 2e^- \longrightarrow Ni(s) \qquad E^0 = -0.25\ V$$
$$Fe^{2+}(aq) + 2e^- \longrightarrow Fe(s) \qquad E^0 = -0.44\ V$$

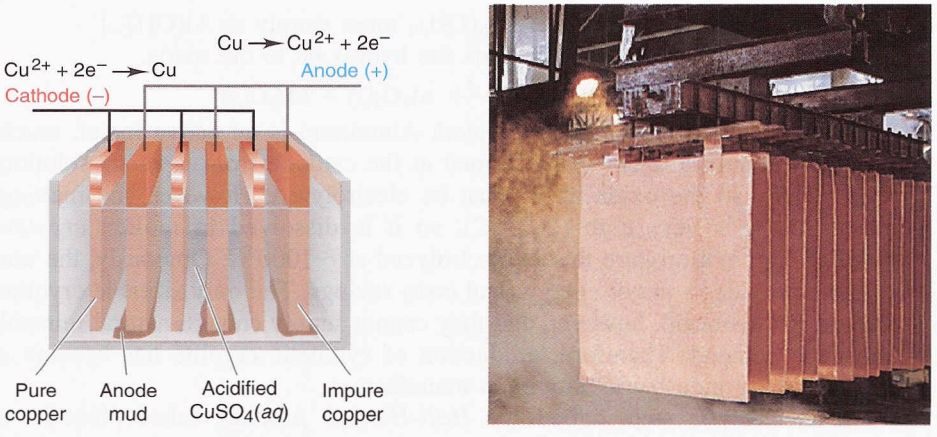


Figure 22.18 The electrorefining of copper. A, Copper is refined electrolytically, using impure slabs of copper as anodes and sheets of pure copper as cathodes. The Cu^{2+} ions released from the anode are reduced to Cu metal and plate out at the cathode. The "anode mud" contains valuable metal by-products. **B,** A small section of an industrial facility for electrorefining copper.

Isolation, Uses, and Recycling of Aluminum Aluminum is the most abundant metal in Earth's crust by mass and the third most abundant element (after O and Si). It is found in numerous aluminosilicate minerals (Gallery, pp. 580–581), such as feldspars, micas, and clays, and in the rare gems garnet, beryl, spinel, and turquoise. Corundum, pure aluminum oxide (Al_2O_3), is extremely hard; mixed with traces of transition metals, it exists as ruby and sapphire. Impure Al_2O_3 is used in sandpaper and other abrasives.

Mining bauxite.

Through eons of weathering, certain clays became *bauxite,* the major ore of aluminum. This mixed oxide-hydroxide occurs in enormous surface deposits in Mediterranean and tropical regions (see photo), but with world aluminum production approaching 100 million tons annually, it may someday be scarce. In addition to hydrated Al_2O_3 (about 75%), industrial-grade bauxite also contains Fe_2O_3, SiO_2, and TiO_2, which are removed during the extraction.

The overall two-step process combines hydro- and electrometallurgical techniques. In the first step, Al_2O_3 is separated from bauxite; in the second, it is converted to the metal.

1. *Isolating Al_2O_3 from bauxite.* After mining, bauxite is pretreated by extended boiling in 30% NaOH in the *Bayer process,* which involves acid-base, solubility, and complex-ion equilibria. The acidic SiO_2 and the amphoteric Al_2O_3 dissolve in the base, but the basic Fe_2O_3 and TiO_2 do not:

$$SiO_2(s) + 2NaOH(aq) + 2H_2O(l) \longrightarrow Na_2Si(OH)_6(aq)$$
$$Al_2O_3(s) + 2NaOH(aq) + 3H_2O(l) \longrightarrow 2NaAl(OH)_4(aq)$$
$$Fe_2O_3(s) + NaOH(aq) \longrightarrow \text{no reaction}$$
$$TiO_2(s) + NaOH(aq) \longrightarrow \text{no reaction}$$

Further heating slowly precipitates the $Na_2Si(OH)_6$ as an aluminosilicate, which is filtered out with the insoluble Fe_2O_3 and TiO_2 ("red mud").

Animation: Aluminum Production
Online Learning Center

Acidifying the filtrate precipitates Al^{3+} as $Al(OH)_3$. Recall from our discussion of complex-ion equilibria that the aluminate ion, $Al(OH)_4^-(aq)$, is actually the complex ion $Al(H_2O)_2(OH)_4^-$, in which four of the six water molecules surrounding Al^{3+} have each lost a proton (see Figure 19.16, p. 849). Weakly acidic CO_2 is added to produce a small amount of H^+ ion, which reacts with this complex ion. Cooling supersaturates the solution, and the solid that forms is filtered out:

$$CO_2(g) + H_2O \rightleftharpoons H^+(aq) + HCO_3^-(aq)$$
$$Al(H_2O)_2(OH)_4^-(aq) + H^+(aq) \longrightarrow Al(H_2O)_3(OH)_3(s)$$

[Recall that we usually write $Al(H_2O)_3(OH)_3$ more simply as $Al(OH)_3$.]

Drying at high temperature converts the hydroxide to the oxide:

$$2Al(H_2O)_3(OH)_3(s) \xrightarrow{\Delta} Al_2O_3(s) + 9H_2O(g)$$

2. *Converting Al_2O_3 to the free metal.* Aluminum is an active metal, much too strong a reducing agent to be formed at the cathode from aqueous solution (Section 21.7), so the oxide itself must be electrolyzed. However, the melting point of Al_2O_3 is very high (2030°C), so it is dissolved in molten *cryolite* (Na_3AlF_6) to give a mixture that is electrolyzed at ~1000°C. Obviously, the use of cryolite provides a major energy (and cost) savings. The only sizeable cryolite mines are in Greenland, however, and they cannot supply enough natural mineral to meet the demand. Therefore, production of synthetic cryolite has become a major subsidiary industry in aluminum manufacture.

The electrolytic step, called the *Hall-Heroult process,* takes place in a graphite-lined furnace, with the lining itself acting as the cathode. Anodes of graphite dip into the molten Al_2O_3-Na_3AlF_6 mixture (Figure 22.19). The cell typically operates at a moderate voltage of 4.5 V, but with an enormous current flow of 1.0×10^5 to 2.5×10^5 A.

The process is complex and its details are still not entirely known. Therefore, the specific reactions shown below are chosen from among several other possibilities. Molten cryolite contains several ions (including AlF_6^{3-}, AlF_4^-, and F^-), which react with Al_2O_3 to form fluoro-oxy ions (including $AlOF_3^{2-}$, $Al_2OF_6^{2-}$, and $Al_2O_2F_4^{2-}$) that dissolve in the mixture. For example,

$$2Al_2O_3(s) + 2AlF_6^{3-}(l) \longrightarrow 3Al_2O_2F_4^{2-}(l)$$

Al forms at the cathode (reduction), shown here with AlF_6^{3-} as reactant:

$$AlF_6^{3-}(l) + 3e^- \longrightarrow Al(l) + 6F^-(l) \qquad \text{[cathode; reduction]}$$

The graphite anodes are oxidized and form carbon dioxide gas. Using one of the fluoro-oxy species as an example, the anode reaction is

$$Al_2O_2F_4^{2-}(l) + 8F^-(l) + C(\text{graphite}) \longrightarrow 2AlF_6^{3-}(l) + CO_2(g) + 4e^-$$

[anode; oxidation]

Thus, the anodes are consumed in this half-reaction and must be replaced frequently.

Combining the three previous equations and making sure that e^- gained at the cathode equal e^- lost at the anode gives the overall reaction:

$$2Al_2O_3(\text{in } Na_3AlF_6) + 3C(\text{graphite}) \longrightarrow 4Al(l) + 3CO_2(g) \qquad \text{[overall (cell) reaction]}$$

The Hall-Heroult process uses an enormous quantity of energy: aluminum production accounts for more than 5% of total U.S. electrical usage.

Aluminum is a superb decorative, functional, and structural metal. It is lightweight, attractive, easy to work, and forms strong alloys. Although Al is very active, it does not corrode readily because of an adherent oxide layer that forms rapidly in air and prevents more O_2 from penetrating. Nevertheless, when it is in

Energy Received and Returned Aluminum manufacture in the United States uses more electricity in 1 day than a city of 100,000 uses in 1 year! The reason for the high energy needs of Al manufacture is the electron configuration of Al ([Ne] $3s^23p^1$). Each Al^{3+} ion needs $3e^-$ to form an Al atom, and the atomic mass of Al is so low (~27 g/mol) that 1 mol of e^- produces only 9 g of Al. Compare this with the mass of Mg or Ca (two other lightweight structural metals) that 1 mol of e^- produces:

$$\tfrac{1}{3}Al^{3+} + e^- = \tfrac{1}{3}Al(s), \sim 9\text{ g}$$

$$\tfrac{1}{2}Mg^{2+} + e^- = \tfrac{1}{2}Mg(s), \sim 12\text{ g}$$

$$\tfrac{1}{2}Ca^{2+} + e^- = \tfrac{1}{2}Ca(s), \sim 20\text{ g}$$

An Al battery can turn this disadvantage around. Once produced, Al represents a concentrated form of electrical energy that can deliver 1 mol of e^- (96,500 C) for every 9 g of Al consumed in the battery. Thus, its electrical output per gram of metal is high. In fact, aluminum-air batteries are now being produced.

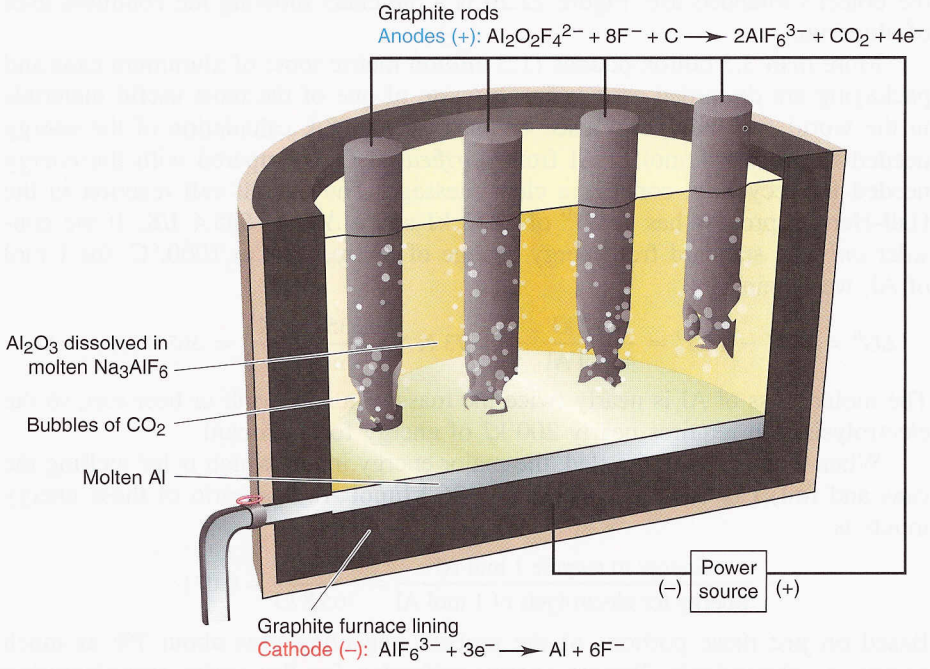

Figure 22.19 The electrolytic cell in the manufacture of aluminum. Purified Al_2O_3 is mixed with cryolite (Na_3AlF_6) and melted. Reduction at the graphite furnace lining (cathode) gives molten Al. Oxidation at the graphite rods (anodes) slowly converts them to CO_2, so they must be replaced periodically.

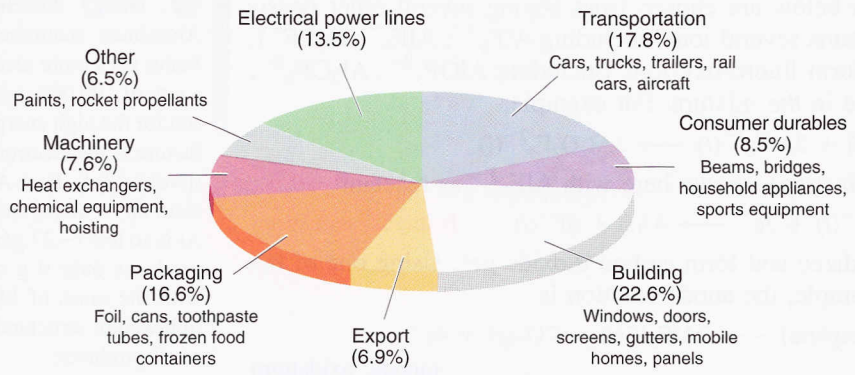

Figure 22.20 **The many familiar and essential uses of aluminum.**

contact with less active metals such as Fe, Cu, and Pb, aluminum becomes the anode and deteriorates rapidly (Section 21.6). To prevent this, aluminum objects are often *anodized*, that is, made to act as the anode in an electrolysis that coats them with an oxide layer. The object is immersed in a 20% H_2SO_4 bath and connected to a graphite cathode:

$$6H^+(aq) + 6e^- \longrightarrow 3H_2(g) \qquad \text{[cathode; reduction]}$$
$$2Al(s) + 3H_2O(l) \longrightarrow Al_2O_3(s) + 6H^+(aq) + 6e^- \qquad \text{[anode; oxidation]}$$
$$2Al(s) + 3H_2O(l) \longrightarrow Al_2O_3(s) + 3H_2(g) \qquad \text{[overall (cell) reaction]}$$

The Al_2O_3 layer deposited is typically from 10 μ to 100 μ thick, depending on the object's intended use. Figure 22.20 is a pie chart showing the countless uses of aluminum.

More than 3.5 billion pounds (1.5 million metric tons) of aluminum cans and packaging are discarded each year—a waste of one of the most useful materials in the world *and* the energy used to make it. A quick calculation of the energy needed to prepare 1 mol of Al from *purified* Al_2O_3, compared with the energy needed for recycling, conveys a clear message. The overall cell reaction in the Hall-Heroult process has a ΔH^0 of 2272 kJ and a ΔS^0 of 635.4 J/K. If we consider *only* the standard free energy change of the reaction at 1000.°C, for 1 mol of Al, we obtain

$$\Delta G^0 = \Delta H^0 - T\Delta S^0 = \frac{2272\text{ kJ}}{4\text{ mol Al}} - \left(1273\text{ K} \times \frac{0.6354\text{ kJ/K}}{4\text{ mol Al}}\right) = 365.8\text{ kJ/mol Al}$$

The molar mass of Al is nearly twice the mass of a soft-drink or beer can, so the electrolysis step requires nearly 200 kJ of energy for each can!

When aluminum is recycled, the major energy input (which is for melting the cans and foil) has been calculated as ~26 kJ/mol Al. The ratio of these energy inputs is

$$\frac{\text{Energy to recycle 1 mol Al}}{\text{Energy for electrolysis of 1 mol Al}} = \frac{26\text{ kJ}}{365.8\text{ kJ}} = 0.071$$

Based on just these portions of the process, recycling uses about 7% as much energy as electrolysis. Recent energy estimates for the entire manufacturing process (including mining, pretreating, maintaining operating conditions, electrolyzing, and so forth) are about 6000 kJ/mol Al, which means recycling requires less than 1% as much energy as manufacturing! The economic advantages, not to mention the environmental ones, are obvious, and recycling of aluminum has become common in the United States (see photo).

Crushed aluminum cans ready for recycling.

Mining the Sea: Magnesium and Bromine

In the not too distant future, as terrestrial sources of certain elements become scarce or too costly to mine, the oceans will become an important source. Despite the abundant distribution of magnesium on land, it is already being obtained from the sea, and its ocean-based production is a good example of the approach we might one day use for other elements. Bromine, too, is recovered from the sea as well as from inland brines.

Isolation and Uses of Magnesium The *Dow process* for the isolation of magnesium from the sea involves steps that are similar to the procedures used for rocky ores (Figure 22.21):

1. *Mining.* Intake of seawater and straining the debris are the "mining" steps. No pretreatment is needed.
2. *Converting to mineral.* The dissolved Mg^{2+} ion is converted to the mineral $Mg(OH)_2$ with $Ca(OH)_2$, which is generated on-site (at the plant). Seashells ($CaCO_3$) are crushed, decomposed with heat to CaO, and mixed with water to make slaked lime [$Ca(OH)_2$]. This is pumped into the seawater intake tank to precipitate the dissolved Mg^{2+} as the hydroxide ($K_{sp} \approx 10^{-9}$):
$$Ca(OH)_2(aq) + Mg^{2+}(aq) \longrightarrow Mg(OH)_2(s) + Ca^{2+}(aq)$$
3. *Converting to compound.* The solid $Mg(OH)_2$ is filtered and mixed with excess HCl, which is also made on-site, to form aqueous $MgCl_2$:
$$Mg(OH)_2(s) + 2HCl(aq) \longrightarrow MgCl_2(aq) + 2H_2O(l)$$
The water is evaporated in stages to give solid, hydrated $MgCl_2 \cdot nH_2O$.
4. *Electrochemical redox.* Heating above 700°C drives off the water of hydration and melts the $MgCl_2$. Electrolysis gives chlorine gas and the molten metal, which floats on the denser molten salt:
$$MgCl_2(l) \longrightarrow Mg(l) + Cl_2(g)$$
The Cl_2 that forms is recycled to make the HCl used in step 3.

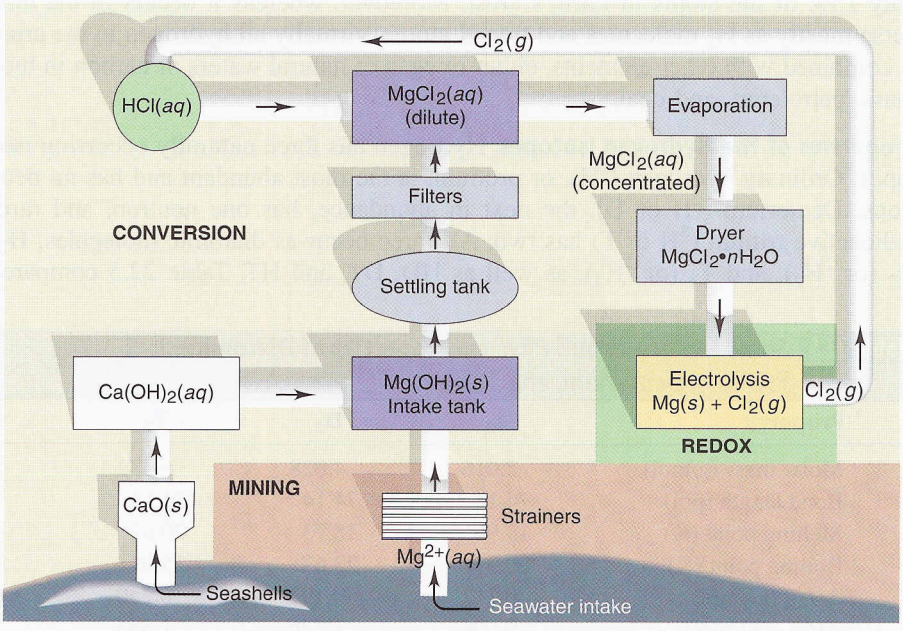

Figure 22.21 The production of elemental Mg from seawater. The Dow process involves obtaining Mg^{2+} ion from seawater; the Mg^{2+} is converted to $Mg(OH)_2$ and then to aqueous $MgCl_2$, which is evaporated to dryness and then electrolytically reduced to Mg metal and Cl_2 gas.

Jet engine assembly.

Magnesium is the lightest structural metal available (about one-half the density of Al and one-fifth that of steel). Although Mg is quite reactive, it forms an extremely adherent, high-melting oxide layer (MgO); thus, it finds many uses in metal alloys and can be machined into any form. Magnesium alloys occur in everything from aircraft bodies to camera bodies, and from luggage to auto engine blocks. The pure metal is a strong reducing agent, which makes it useful for sacrificial anodes (Section 21.6) and in the metallurgical extraction of other metals, such as Be, Ti, Zr, Hf, and U. For example, titanium, an essential component of jet engines (see photo), is made from its major ore, ilmenite, in two steps:

$$(1)\quad 2FeTiO_3(s) + 7Cl_2(g) + 6C(s) \longrightarrow 2TiCl_4(l) + 2FeCl_3(s) + 6CO(g)$$

$$(2)\quad TiCl_4(l) + 2Mg(l) \longrightarrow Ti(s) + 2MgCl_2(l)$$

Isolation and Uses of Bromine The largest source of bromine is the oceans, where it occurs as Br^- at a concentration of 0.065 g/L (65 ppm). However, the cost of concentrating such a dilute solution shifts the choice of source, when available, to much more concentrated salt lakes and natural brines. Arkansas brines, the most important source in the United States, contain about 4.5 g Br^-/L (4500 ppm). At standard-state conditions, the Br^- is readily oxidized to Br_2 with aqueous Cl_2:

$$2Br^-(aq) + Cl_2(aq) \longrightarrow Br_2(l) + 2Cl^-(aq) \qquad \Delta G^0 = -61.5 \text{ kJ}$$

The Br_2 is removed by passing steam through the mixture and then cooling and drying the liquid bromine. Iodide is present in these brines also, and it is oxidized to I_2 by aqueous Cl_2 in a similar way.

World production of Br_2 is about 1% that of Cl_2. Its major use is in the preparation of organic chemicals, such as ethylene dibromide, which was added to leaded gasoline to prevent lead oxides from forming and depositing on engine parts. Newer products requiring bromine include the flame retardants in rugs and textiles. Bromine is also needed in the synthesis of inorganic chemicals, especially silver bromide for photographic emulsions.

The Many Sources and Uses of Hydrogen

Although hydrogen accounts for 90% of the atoms in the universe, it makes up only 15% of the atoms in Earth's crust. Moreover, whereas it occurs in the universe mostly as H_2 molecules and free H atoms, virtually all hydrogen in the crust is combined with other elements, either oxygen in natural waters or carbon in biomass, petroleum, and coal.

Properties of the Hydrogen Isotopes Hydrogen has three naturally occurring isotopes. Ordinary hydrogen (^1H), or protium, is the most abundant and has no neutrons. Deuterium (^2H or D), the next in abundance, has one neutron, and rare, radioactive tritium (^3H or T) has two. All three occur as diatomic molecules, H_2, D_2 (or $^2H_2$), and T_2 (or $^3H_2$), as well as HD, DT, and HT. Table 22.5 compares

Table 22.5 Some Molecular and Physical Properties of Diatomic Protium, Deuterium, and Tritium

Property	H_2	D_2	T_2
Molar mass (g/mol)	2.016	4.028	6.032
Bond length (pm)	74.14	74.14	74.14
Melting point (K)	13.96	18.73	20.62
Boiling point (K)	20.39	23.67	25.04
ΔH^0_{fus} (kJ/mol)	0.117	0.197	0.250
ΔH^0_{vap} (kJ/mol)	0.904	1.226	1.393
Bond energy (kJ/mol at 298 K)	432	443	447

some molecular and physical properties of H_2, D_2, and T_2. As you can see, the heavier the isotope is, the higher the molar mass of the molecule, and the higher its melting point, boiling point, and heats of phase change; it also effuses at a lower rate (Section 5.6).

Because hydrogen is so light, the relative difference in mass of its isotopes is enormous compared to that of isotopes of other common elements. (For example, the mass of ^{13}C is only 8% greater than that of ^{12}C.) Note, especially, that the mass difference leads to different bond energies, which affect reactivity. Because the mass of D is twice the mass of H, H atoms bonded to a given atom vibrate at a higher frequency than do D atoms, so their bonds are higher in energy. As a result, the *bond to H is weaker and thus quicker to break.* Therefore, any reaction that includes breaking a bond to hydrogen in the rate-determining step occurs *faster with H than with D.* This phenomenon is called a *kinetic isotope effect;* we'll see an example shortly. No other element displays a kinetic isotope effect nearly as large.

Industrial Production of Hydrogen Hydrogen gas (H_2) is produced on an industrial scale worldwide: 250,000 metric tons (3×10^{12} L at STP; equivalent to $\sim1\times10^{11}$ mol) are produced annually in the United States alone. All production methods are energy intensive, so the choice is determined by energy costs. In Scandinavia, where hydroelectric power is plentiful, electrolysis is the chosen method; on the other hand, where natural gas from oil refineries is plentiful, as in the United States and Great Britain, thermal methods are used to produce hydrogen.

The most common thermal methods use water and a simple hydrocarbon in two steps. Modern U.S. plants use methane, which has the highest H:C ratio of any hydrocarbon. In the first step, the reactants are heated to around 1000°C over a nickel-based catalyst in the endothermic *steam-reforming process:*

$$CH_4(g) + H_2O(g) \longrightarrow CO(g) + 3H_2(g) \qquad \Delta H = 206 \text{ kJ}$$

Heat is supplied by burning methane at the refinery. To generate more H_2, the product mixture (called *water gas*) is heated with steam at 400°C over an iron or cobalt oxide catalyst in the exothermic *water-gas shift reaction,* and the CO reacts:

$$H_2O(g) + CO(g) \rightleftharpoons CO_2(g) + H_2(g) \qquad \Delta H = -41 \text{ kJ}$$

The reaction mixture is recycled several times, which decreases the CO to around 0.2% by volume. Passing the mixture through liquid water removes the more soluble CO_2 (solubility = 0.034 mol/L) from the H_2 (solubility < 0.001 mol/L). Calcium oxide can also be used to remove CO_2 by formation of $CaCO_3$. By removing CO_2, these steps shift the equilibrium position to the right and produce H_2 that is about 98% pure. To attain greater purity (~99.9%), the gas mixture is passed through a *synthetic zeolite* (see the Gallery, p. 581) selected to filter out nearly all molecules larger than H_2.

In regions where inexpensive electricity is available, very pure H_2 is prepared through electrolysis of water with Pt (or Ni) electrodes:

$$2H_2O(l) + 2e^- \longrightarrow H_2(g) + 2OH^-(aq) \qquad E = -0.42 \text{ V} \quad \text{[cathode; reduction]}$$

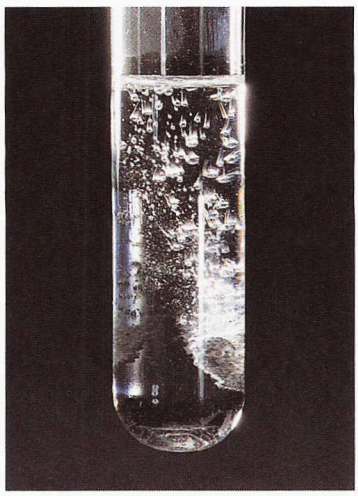
$$H_2O(l) \longrightarrow \tfrac{1}{2}O_2(g) + 2H^+(aq) + 2e^- \qquad E = 0.82 \text{ V} \quad \text{[anode; oxidation]}$$

$$H_2O(l) \longrightarrow H_2(g) + \tfrac{1}{2}O_2(g) \qquad E_{cell} = -0.42 \text{ V} - 0.82 \text{ V} = -1.24 \text{ V}$$

Overvoltage makes the cell potential about −2 V (Section 21.7). Therefore, under typical operating conditions, it takes about 400 kJ of energy to produce 1 mol of H_2:

$$\Delta G = -nFE = (-2 \text{ mol } e^-)\left(\frac{96.5 \text{ kJ}}{\text{V·mol } e^-}\right)(-2 \text{ V}) = 4\times10^2 \text{ kJ/mol } H_2$$

High-purity O_2 is a valuable by-product of this process that offsets some of the costs of isolating H_2.



Calcium reacts with water to form H_2.

Laboratory Production of Hydrogen You may already have produced small amounts of H_2 in the lab by one of several methods. A characteristic reaction of the very active metals in Groups 1A(1) and 2A(2) is the reduction of water to H_2 and OH^- (see photo):

$$Ca(s) + 2H_2O(l) \longrightarrow Ca^{2+}(aq) + 2OH^-(aq) + H_2(g)$$

Alternatively, the strongly reducing hydride ion can be used:

$$NaH(s) + H_2O(l) \longrightarrow Na^+(aq) + OH^-(aq) + H_2(g)$$

Less active metals reduce H^+ in acids:

$$Zn(s) + 2H^+(aq) \longrightarrow Zn^{2+}(aq) + H_2(g)$$

In view of hydrogen's great potential as a fuel, chemists are seeking ways to decompose water by lowering the overall activation energy of the process. More than 10,000 thermodynamically *and* kinetically favorable *water-splitting* schemes have been devised.

However, at 298 K, ΔG^0 for the decomposition of 1 mol of $H_2O(g)$ is 229 kJ, so all water-splitting schemes require energy. Given the increase in the number of moles of gas, ΔS^0 is positive; therefore, this is an endothermic process ($\Delta H^0 > 0$) and, at standard-state conditions, requires heat to occur spontaneously. One promising source of this heat is focused sunlight.

Industrial Uses of Hydrogen Typically, a plant produces H_2 to make some other end product. In fact, more than 95% of H_2 produced industrially is consumed on-site in ammonia or petrochemical facilities. In a plant that synthesizes NH_3 from N_2 and H_2, the reactant gases are formed through a series of reactions that involve methane, including the steam-reforming and water-gas shift reactions discussed previously. For this reason, the cost of NH_3 is closely correlated with that of CH_4.

Here is a typical example of how the reaction series in an ammonia plant works. The steam-reforming reaction is performed with excess CH_4, which depletes the reaction mixture of H_2O:

$$CH_4(g;\ \text{excess}) + H_2O(g) \longrightarrow CO(g) + 3H_2(g)$$

In the next step, an excess of the product mixture (CH_4, CO, and H_2) is burned in an amount of air ($N_2 + O_2$) that is insufficient to effect complete combustion, but is just enough to consume the O_2, heat the mixture to 1100°C, and form additional H_2O:

$$4CH_4(g;\ \text{excess}) + 7O_2(g) \longrightarrow 2CO_2(g) + 2CO(g) + 8H_2O(g)$$
$$2H_2(g;\ \text{excess}) + O_2(g) \longrightarrow 2H_2O(g)$$
$$2CO(g;\ \text{excess}) + O_2(g) \longrightarrow 2CO_2(g)$$

Any remaining CH_4 reacts by the steam-reforming reaction, the remaining CO reacts by the water-gas shift reaction ($H_2O + CO \rightleftharpoons CO_2 + H_2$) to form more H_2, and then the CO_2 is removed with CaO. The amounts are carefully adjusted to produce a final mixture that contains a 1:3 ratio of N_2 (from the added air) to H_2 (with traces of CH_4, Ar, and CO). This mixture is used directly in the synthesis of ammonia, described in Chapter 17 (see the Chemical Connections essay, pp. 755–756).

A second major use of H_2 is in *hydrogenation* of the C=C bonds in liquid oils to form the C—C bonds in solid fats and margarine. The process uses H_2 in contact with transition metal catalysts, such as powdered nickel (see Figure 16.24, p. 708). Solid fats are also used in commercial baked goods. Look at the list of ingredients on most packages of bread, cake, and cookies, and you'll see the "partially hydrogenated vegetable oils" made by this process.

Hydrogen is also essential in the manufacture of numerous "bulk" chemicals, those that are produced in large amounts because they have many further uses. One application that has been gaining great attention is the production

of methanol. In this process, carbon monoxide reacts with hydrogen over a copper–zinc oxide catalyst:

$$CO(g) + 2H_2(g) \xrightarrow{\text{Cu-ZnO catalyst}} CH_3OH(l)$$

Many automotive engineers expect methanol to be used as a gasoline additive.

Of course, as less expensive sources of hydrogen become available, it will be used directly in fuel cells (Section 21.5).

Production and Uses of Deuterium Deuterium and its compounds are produced from D_2O (heavy water), which is present as a minor component (0.016 mol % D_2O) in normal water and is isolated on the multiton scale by *electrolytic enrichment*. This process is based on the kinetic isotope effect for hydrogen noted earlier, specifically on the *higher rate of bond breaking for O—H bonds compared to O—D bonds*, and thus on the higher rate of electrolysis of H_2O compared with D_2O.

For example, with Pt electrodes, H_2O is electrolyzed about 14 times faster than D_2O. As some of the liquid decomposes to the elemental gases, the remainder becomes enriched in D_2O. Thus, by the time the volume of water has been reduced to 1/20,000 of its original volume, the remaining water is around 99% D_2O. By combining samples and repeating the electrolysis, more than 99.9% D_2O is obtained.

Deuterium gas is produced by electrolysis of D_2O or by any of the chemical reactions that produce hydrogen gas from water, such as

$$2Na(s) + 2D_2O(l) \longrightarrow 2Na^+(aq) + 2OD^-(aq) + D_2(g)$$

Compounds containing deuterium (or tritium) are produced from reactions that give rise to the corresponding hydrogen-containing compound; for example,

$$SiCl_4(l) + 2D_2O(l) \longrightarrow SiO_2(s) + 4DCl(g)$$

Compounds with acidic protons undergo hydrogen/deuterium exchange:

$$CH_3COOH(l) + D_2O(l;\ \text{excess}) \longrightarrow CH_3COOD(l) + DHO(l;\ \text{small amount})$$

Notice that only the acidic H atom, the one in the COOH group, is exchanged, not any of those attached to carbon. We discuss the natural and synthetic formation of tritium in Chapter 24.

SECTION SUMMARY

Production highlights of key elements are as follows:

- Na is isolated by electrolysis of molten NaCl in the Downs process; Cl_2 is a by-product.
- K is produced by reduction with Na in a thermal process.
- Fe is produced through a multistep high-temperature process in a blast furnace. The crude pig iron is converted to carbon steel in the basic-oxygen process and then alloyed with other metals to make different steels.
- Cu is produced by concentration of the ore through flotation, reduction to the metal by smelting, and purification by electrorefining. The metal has extensive electrical and plumbing uses.
- Al is extracted from bauxite by pretreating the ore with concentrated base, followed by electrolysis of the Al_2O_3 in molten cryolite. Al alloys are widely used in homes and industry. The total energy required to extract Al from its ore is over 100 times that needed for recycling it.
- The Mg^{2+} in seawater is converted to $Mg(OH)_2$ and then to $MgCl_2$, which is electrolyzed to obtain the metal; Mg forms strong, lightweight alloys.
- Br_2 is obtained from brines by oxidizing Br^- with Cl_2.
- H_2 is produced by electrolysis of water or in the formation of gaseous fuels from hydrocarbons. It is used in NH_3 production and in hydrogenation of vegetable oils. The isotopes of hydrogen differ significantly in atomic mass and thus in the rate at which their bonds to other atoms break. This difference is used to obtain D_2O from water.

22.5 CHEMICAL MANUFACTURING: TWO CASE STUDIES

From laboratory-scale endeavors of the first half of the 19th century, today's chemical industries have grown to multinational corporations producing materials that define modern life: polymers, electronics, pharmaceuticals, consumer goods, and fuels. In this final section, we examine the interplay of theory and practice in two of the most important processes in the inorganic chemical industry: (1) the contact process for the production of sulfuric acid, and (2) the chlor-alkali process for the production of chlorine.

Sulfuric Acid, the Most Important Chemical

The manufacture of sulfuric acid began more than 400 years ago, when the acid was known as *oil of vitriol* and was distilled from "green vitriol" ($FeSO_4 \cdot 7H_2O$). Considering its countless uses, it is not surprising that today sulfuric acid is produced throughout the world on a gigantic scale—more than 150 million tons a year. The green vitriol method and the many production methods used since have all been superseded by the modern **contact process,** which is based on the *catalyzed oxidation of* SO_2. Here are the key steps.

1. *Obtaining sulfur.* In most countries today, the production of sulfuric acid starts with the production of elemental sulfur, often by the *Claus process,* in which the H_2S in "sour" natural gas is chemically separated and then oxidized:

$$2H_2S(g) + 2O_2(g) \xrightarrow{\text{low temperature}} \tfrac{1}{8}S_8(g) + SO_2(g) + 2H_2O(g)$$

$$2H_2S(g) + SO_2(g) \xrightarrow{Fe_2O_3 \text{ catalyst}} \tfrac{3}{8}S_8(g) + 2H_2O(g)$$

Where natural gas is not abundant but natural underground deposits of the element are, sulfur is obtained by the *Frasch process,* a nonchemical method that taps these deposits. A hole is drilled to the deposit, and superheated water (about 160°C) is pumped down two outer concentric pipes to melt the sulfur (Figure 22.22A). Then, a combination of the hydrostatic pressure in the outermost pipe and the pressure of compressed air sent through a narrow inner pipe forces the sulfur to the surface (Figure 22.22B and C). The costs of drilling, pumping, and supplying water (5×10^6 gallons per day) are balanced somewhat by the fact that the product is very pure (~99.7% S).

2. *From sulfur to sulfur dioxide.* Once obtained, the sulfur is burned in air to form SO_2:

$$\tfrac{1}{8}S_8(s) + O_2(g) \longrightarrow SO_2(g) \qquad \Delta H^0 = -297 \text{ kJ}$$

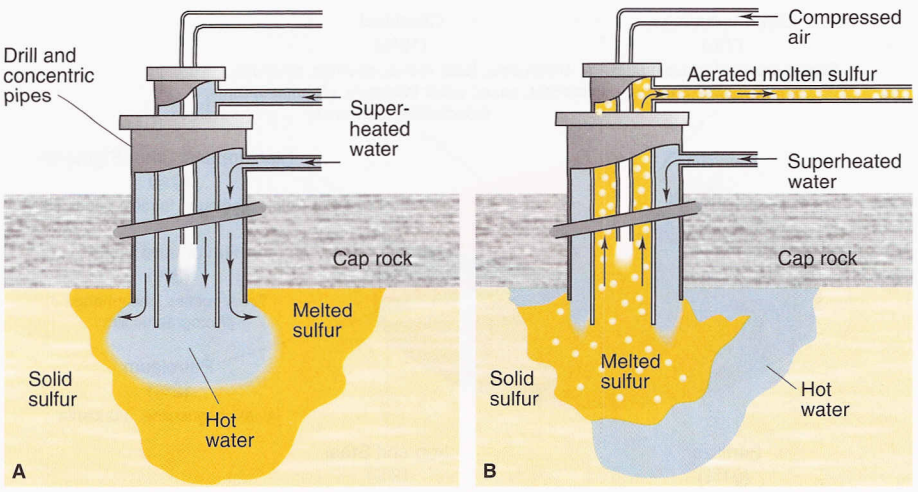
Some SO_2 is also obtained from the roasting of metal sulfide ores. About 90% of processed sulfur is used in making sulfur dioxide for production of the all-important sulfuric acid. Indeed, this end product from sulfur is central to so many chemical industries that a nation's level of sulfur production is a reliable indicator of its overall industrial capacity: the United States, Russia, Japan, and Germany are the top four sulfur producers.

3. *From sulfur dioxide to trioxide.* The contact process oxidizes SO_2 with O_2 to SO_3:

$$SO_2(g) + \tfrac{1}{2}O_2(g) \rightleftharpoons SO_3(g) \qquad \Delta H^0 = -99 \text{ kJ}$$

The reaction is *exothermic* and very *slow* at room temperature. From Le Châtelier's principle (Section 17.6), we know that the yield of SO_3 can be increased by (1) changing the temperature, (2) increasing the pressure (more moles of gas are on the left than on the right), or (3) adjusting the concentrations (adding excess O_2 and removing SO_3).

First, let's examine the temperature effect. Adding heat (raising the temperature) increases the frequency of SO_2-O_2 collisions and thus increases the *rate* of SO_3 formation. However, because the formation of SO_3 is exothermic, removing heat (lowering the temperature) shifts the equilibrium position to the right and



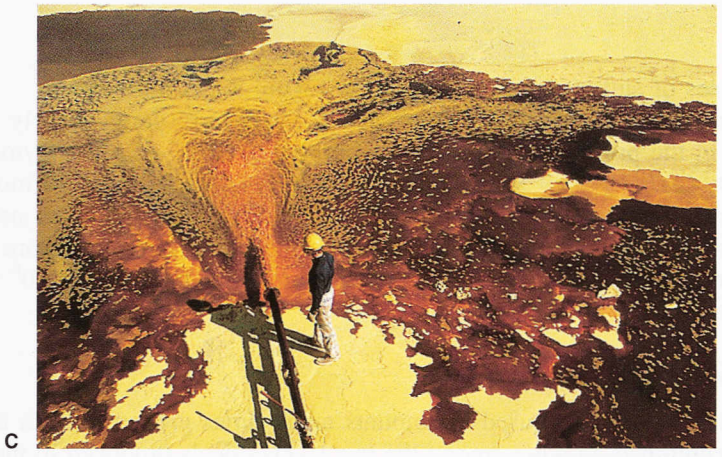


Figure 22.22 The Frasch process for mining elemental sulfur. This nonchemical process uses superheated water and compressed air to melt underground sulfur and bring it to the surface. **A,** Superheated water is forced down a drilled hole into the subterranean sulfur deposit, and the sulfur melts. **B,** Compressed air is sent down an inner pipe in the drilling apparatus to force up the molten sulfur. **C,** Sulfur obtained from the Frasch process.

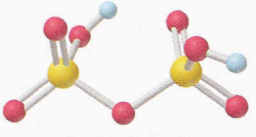
thus increases the *yield* of SO_3. This is a classic situation that calls for use of a catalyst. By lowering the activation energy, *a catalyst allows equilibrium to be reached more quickly and at a lower temperature;* thus, rate *and* yield are optimized (Section 16.8). The catalyst in the contact process is V_2O_5 on inert silica, which is active between 400°C and 600°C.

The pressure effect is small and economically not worth exploiting. The concentration effects are controlled by providing an excess of O_2 in the form of a 5:1 mixture of air:SO_2, or about 1:1 O_2:SO_2, about twice as much O_2 as is called for by the reaction stoichiometry. The mixture is passed over catalyst beds in four stages, and the SO_3 is removed at several points to favor more SO_3 formation. The overall yield of SO_3 is 99.5%.

4. *From sulfur trioxide to acid.* Sulfur trioxide is the anhydride of sulfuric acid, so a hydration step is next. However, SO_3 cannot be added to water because, at the operating temperature, it would first meet water vapor, which catalyzes its polymerization to $(SO_3)_x$, and results in a smoke of solid particles that makes poor contact with water and yields little acid. To prevent this, previously formed H_2SO_4 absorbs the SO_3 and forms pyrosulfuric acid (or disulfuric acid, $H_2S_2O_7$; see margin), which is then hydrolyzed with sufficient water:



disulfuric acid

$$SO_3(g) + H_2O(l) \longrightarrow H_2SO_4(l)\text{–[low yield]}$$
$$SO_3(g) + H_2SO_4(l) \longrightarrow H_2S_2O_7(l)$$
$$H_2S_2O_7(l) + H_2O(l) \longrightarrow 2H_2SO_4(l)$$

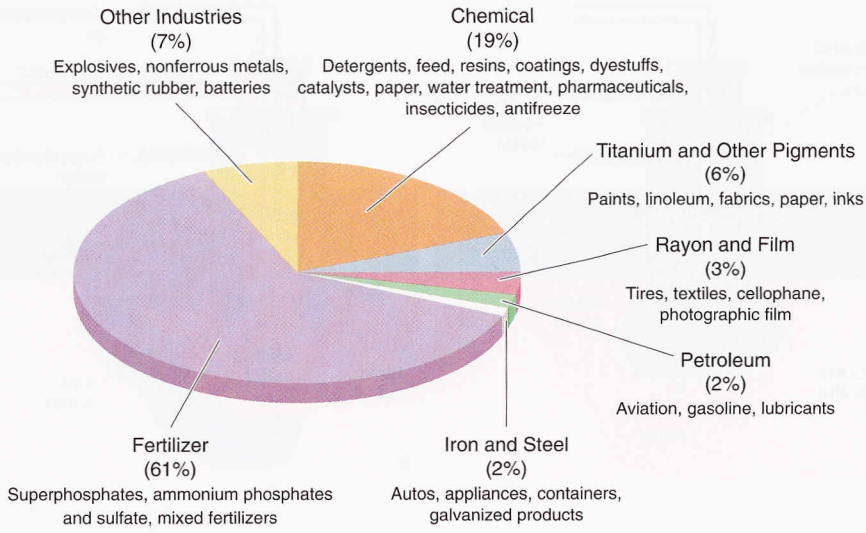


Figure 22.23 The many indispensable applications of sulfuric acid.

The uses of sulfuric acid are legion, as Figure 22.23 indicates.

Sulfuric acid is remarkably inexpensive (about \$150/ton), largely because each step in the process is exothermic—burning S ($\Delta H^0 = -297$ kJ/mol), oxidizing SO_2 ($\Delta H^0 = -99$ kJ/mol), hydrating SO_3 ($\Delta H^0 = -132$ kJ/mol)—and the heat is a valuable by-product. Three-quarters of the heat is sold as steam, and the rest of it is used to pump gases through the plant. A typical plant making 825 tons of H_2SO_4 per day produces enough steam to generate 7×10^6 watts of electric power.

The Chlor-Alkali Process

Chlorine is produced and used in amounts many times greater than all the other halogens combined, ranking among the top 10 chemicals produced in the United States. Its production methods depend on *the oxidation of Cl^- ion from NaCl.*

Earlier, we discussed the Downs process for isolating sodium, which yields Cl_2 gas as the other product (Section 22.4). The **chlor-alkali process,** which forms the basis of one of the largest inorganic chemical industries, electrolyzes concentrated aqueous NaCl to produce Cl_2 and several other important chemicals. As you learned in Section 21.7, the electrolysis of aqueous NaCl does not yield both of the component elements. Because of the effects of overvoltage, Cl^- ions rather than H_2O molecules are oxidized at the anode. However, Na^+ ions are not reduced at the cathode because the half-cell potential (−2.71 V) is much more negative than that for reduction of H_2O (−0.42 V), even with the normal overvoltage (around −0.6 V). Therefore, the half-reactions for electrolysis of aqueous NaCl are

$$2Cl^-(aq) \longrightarrow Cl_2(g) + 2e^- \qquad E^0 = 1.36\text{ V} \quad \text{[anode; oxidation]}$$

$$2H_2O(l) + 2e^- \longrightarrow 2OH^-(aq) + H_2(g) \qquad E \approx -1.0\text{ V} \quad \text{[cathode; reduction]}$$

$$2Cl^-(aq) + 2H_2O(l) \longrightarrow 2OH^-(aq) + H_2(g) + Cl_2(g) \qquad E_{cell} = -1.0\text{ V} - 1.36\text{ V} = -2.4\text{ V}$$

To obtain commercially meaningful amounts of Cl_2, however, a voltage almost twice this value and a current in excess of 3×10^4 A are used.

When we include the spectator ion Na^+, the total ionic equation shows another important product made by the process:

$$2Na^+(aq) + 2Cl^-(aq) + 2H_2O(l) \longrightarrow 2Na^+(aq) + 2OH^-(aq) + H_2(g) + Cl_2(g)$$

As Figure 22.24 shows, the sodium salts in the cathode compartment exist as an aqueous mixture of NaCl and NaOH; the NaCl is removed by fractional crystallization. Thus, in this version of the chlor-alkali process, which uses an *asbestos*

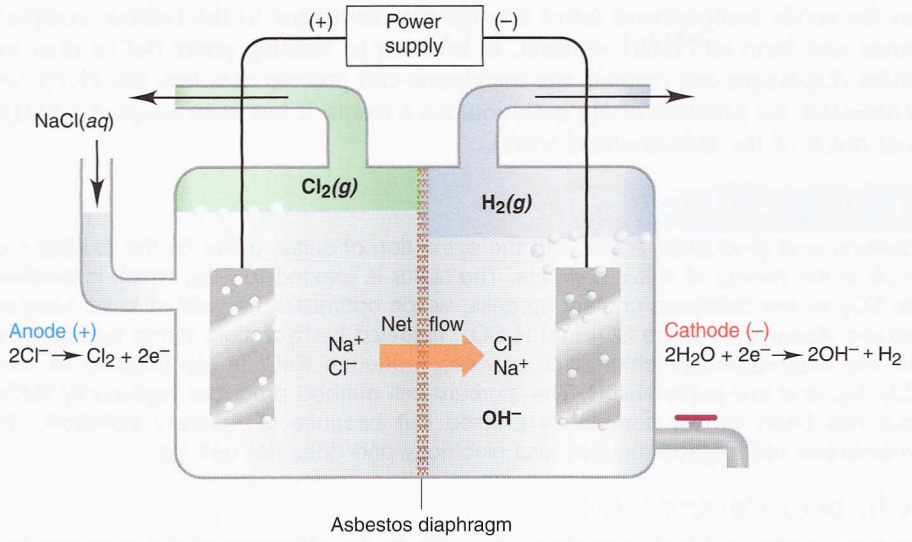

Figure 22.24 A diaphragm cell for the chlor-alkali process. This process uses concentrated aqueous NaCl to make NaOH, Cl_2, and H_2 in an electrolytic cell. The difference in liquid level between compartments keeps a net movement of solution into the cathode compartment, which prevents reaction between OH^- and Cl_2. The cathode electrolyte is concentrated and fractionally crystallized to give industrial-grade NaOH.

diaphragm to separate the anode and cathode compartments, electrolysis of NaCl brines yields Cl_2, H_2, and industrial-grade NaOH, an important base. Like other reactive products, H_2 and Cl_2 are kept apart to prevent explosive recombination. Note the higher liquid level in the anode compartment. This slight hydrostatic pressure difference minimizes backflow of NaOH, which prevents the disproportionation (self–oxidation-reduction) reactions of Cl_2 that occur in the presence of OH^- (Section 14.9), such as

$$Cl_2(g) + 2OH^-(aq) \longrightarrow Cl^-(aq) + ClO^-(aq) + H_2O(l)$$

If high-purity NaOH is desired, a slightly different version, called the chlor-alkali *mercury-cell* process, is employed. Mercury is used as the cathode, which creates such a large overvoltage for reduction of H_2O to H_2 that the process *does* favor reduction of Na^+. The sodium dissolves in the mercury to form sodium amalgam, Na(Hg). In the mercury-cell version, the half-reactions are

$$2Cl^-(aq) \longrightarrow Cl_2(g) + 2e^- \quad \text{[anode; oxidation]}$$

$$2Na^+(aq) + 2e^- \xrightarrow{Hg} 2Na(Hg) \quad \text{[cathode; reduction]}$$

To obtain sodium hydroxide, the sodium amalgam is pumped out of the system and treated with H_2O, which is reduced by the Na:

$$2Na(Hg) + 2H_2O(l) \xrightarrow{-Hg} 2Na^+(aq) + 2OH^-(aq) + H_2(g)$$

The mercury released in this step is recycled back to the electrolysis bath. Therefore, *the products are the same in both versions,* but the purity of NaOH from the mercury-cell version is much higher.

Despite the formation of purer NaOH, the mercury-cell method is being steadily phased out in the United States and has been eliminated in Japan for more than a decade. Cost is not the major reason for the phase-out, although the method does consume about 15% more electricity than the diaphragm-cell version. Rather, the problem is that as the mercury is recycled, some is lost in the industrial wastewater. On average, 200 g of Hg is lost per ton of Cl_2 produced. In the 1980s, annual U.S. production via the mercury-cell method was 2.75 million tons of Cl_2; thus, during that decade, 550,000 kg of this toxic heavy metal was flowing into U.S. waterways each year!

The newer chlor-alkali *membrane-cell* process replaces the diaphragm with a polymeric membrane to separate the cell compartments. The membrane allows only cations to move through it and only from anode to cathode compartments. Thus, as Cl^- ions are removed at the anode through oxidation to Cl_2, Na^+ ions

in the anode compartment move through the membrane to the cathode compartment and form an NaOH solution. In addition to forming purer NaOH than the older diaphragm-cell method, the membrane-cell process uses less electricity and eliminates the problem of Hg pollution. As a result, it has been adopted throughout much of the industrialized world.

SECTION SUMMARY

Sulfuric acid production starts with the extraction of sulfur, either by the oxidation of H_2S or the mining of sulfur deposits. The sulfur is roasted to SO_2, which is oxidized to SO_3 by the catalyzed contact process, which optimizes the yield at lower temperatures. Absorption of the SO_3 into H_2SO_4, followed by hydration, forms sulfuric acid. In the diaphragm-cell chlor-alkali process, aqueous NaCl is electrolyzed to form Cl_2, H_2, and low-purity NaOH. The mercury-cell method produces high-purity NaOH but has been almost completely phased out because of mercury pollution. The membrane-cell method requires less electricity and does not use Hg.

Chapter Perspective

In this chapter, we took a realistic approach to the chemistry of the elements that allowed a glimpse at the intertwining natural cycles in which various elements take part, as well as at the ingenious methods that have been developed to extract them. The impact of living systems in general, and of humans in particular, on the origin and distribution of elements reveals a complex, evolving relationship. Understanding of and respect for that relationship are required for a healthy, productive balance between society's needs and the environment.

In the next chapter, we conclude our exploration of the elements with a close look at the transition metals, a fascinating and extremely useful collection of metals. Then, in the final chapter, we dive down to the atom's nuclear core and investigate its properties and its great potential for energy production and medical science.

Learning Objectives

Relevant section numbers appear in parentheses.

Understand These Concepts

1. How gravity, thermal convection, and elemental properties led to the silicate, sulfide, and iron phases and the predominance of certain elements in Earth's crust, mantle, and core (Section 22.1)
2. How organisms affect crustal abundances of elements, especially oxygen, carbon, calcium, and some transition metals; the onset of oxidation as an energy source (Section 22.1)
3. How atomic properties influence which elements have oxide ores and which have sulfide ores (Section 22.1)
4. The central role of CO_2 and the importance of photosynthesis, respiration, and decay in the carbon cycle (Section 22.2)
5. The central role of N_2 and the importance of atmospheric, industrial, and biological fixation in the nitrogen cycle (Section 22.2)
6. The absence of a gaseous component, the interactions of the inorganic and biological cycles, and the impact of humans on the phosphorus cycle (Section 22.2)
7. How pyro-, electro-, and hydrometallurgical processes are employed to extract a metal from its ore; the importance of the reduction step from compound to metal; refining and alloying processes (Section 22.3)
8. Functioning of the Downs cell for Na production and the application of Le Châtelier's principle for K production (Section 22.4)
9. How iron ore is reduced in a blast furnace and how pig iron is purified by the basic-oxygen process (Section 22.4)
10. How Fe is removed from copper ore and impure Cu is electrorefined (Section 22.4)
11. The importance of amphoterism in the Bayer process for isolating Al_2O_3 from bauxite; the significance of cryolite in the electrolytic step; the energy advantage of Al recycling (Section 22.4)
12. The steps in the Dow process for the extraction of Mg from seawater (Section 22.4)
13. How H_2 production, whether by chemical or electrolytic means, is tied to NH_3 production (Section 22.4)
14. How the kinetic isotope effect is applied to produce deuterium (Section 22.4)
15. How the Frasch process is used to obtain sulfur from natural deposits (Section 22.5)
16. The importance of equilibrium and kinetic factors in H_2SO_4 production (Section 22.5)
17. How overvoltage allows electrolysis of aqueous NaCl to form Cl_2 gas in the chlor-alkali process; coproduction of NaOH; comparison of diaphragm-cell, mercury-cell, and membrane-cell methods (Section 22.5)

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

How the Elements Occur in Nature

Concept Review Questions

22.1 Hydrogen is by far the most abundant element cosmically. In interstellar space, it exists mainly as H_2. In contrast, on Earth, it exists very rarely as H_2 and is ninth in abundance in the crust. Why is hydrogen so abundant in the universe? Why is hydrogen so rare as a diatomic gas in Earth's atmosphere?

22.2 Metallic elements can be recovered from ores that are oxides, carbonates, halides, or sulfides. Give an example of each type.

22.3 The location of elements in the regions of Earth has enormous practical importance.
(a) Define the term *differentiation* and explain which physical property of a substance is primarily responsible for this process.
(b) What are the four most abundant elements in the crust?
(c) Which element is abundant in the crust and mantle but not the core?

22.4 How does the position of a metal in the periodic table relate to whether it occurs primarily as an oxide or as a sulfide?

Problems in Context

22.5 What material is the source for commercial production of each of the following elements: (a) aluminum; (b) nitrogen; (c) chlorine; (d) calcium; (e) sodium?

22.6 Aluminum is widely distributed throughout the world in the form of aluminosilicates. What property of these minerals prevents them from being a source of aluminum?

22.7 Describe two ways in which the biosphere has influenced the composition of Earth's crust.

The Cycling of Elements Through the Environment

Concept Review Questions

22.8 Use atomic and molecular properties to explain why life is based on the chemistry of carbon, rather than some other element such as silicon.

22.9 Define the term *fixation*. Name two elements that undergo environmental fixation. What natural forms of them are fixed?

22.10 Carbon dioxide enters the atmosphere by natural processes and as a result of human activity. Why is the latter source a cause of great concern?

22.11 Diagrams of environmental cycles are simplified to show overall changes and omit relatively minor contributors. For example, the production of lime from limestone is not explicitly shown in the cycle for carbon (Figure 22.5, p. 967). Which labeled category in the figure includes this process? Name two other processes that contribute to this category.

22.12 Describe three pathways for the utilization of atmospheric nitrogen. Is human activity a significant factor? Explain.

22.13 Why do the nitrogen-containing species shown in Figure 22.6 (p. 969) not include ring compounds or long-chain compounds with N—N bonds?

22.14 (a) Which region of Earth's crust is not involved in the phosphorus cycle?
(b) Describe two roles organisms play in the phosphorus cycle.

Problems in Context

22.15 Nitrogen fixation requires a great deal of energy because the N_2 bond is strong (activation energy for its breakage is high).
(a) How do the processes of atmospheric and industrial fixation reflect this energy requirement?
(b) How do the thermodynamics of the two processes differ? (*Hint:* Examine the respective heats of formation.)
(c) In view of the mild conditions for biological fixation, what must be the source of the "great deal of energy" for this process?

(d) What would be the most obvious environmental result of a low activation energy for N_2 fixation?

22.16 The following steps are *unbalanced* half-reactions involved in the nitrogen cycle. Balance each half-reaction to show the number of electrons lost or gained, and state whether it is an oxidation or a reduction (all occur in acidic conditions):

(a) $N_2(g) \longrightarrow NO(g)$ (b) $N_2O(g) \longrightarrow NO_2(g)$
(c) $NH_3(aq) \longrightarrow NO_2^-(aq)$ (d) $NO_3^-(aq) \longrightarrow NO_2^-(aq)$
(e) $N_2(g) \longrightarrow NO_3^-(aq)$

22.17 The use of silica to form slag in the production of phosphorus from phosphate rock was introduced by Robert Boyle more than 300 years ago. When fluorapatite [$Ca_5(PO_4)_3F$] is used in phosphorus production, most of the fluorine atoms appear in the slag, but some end up in toxic and corrosive $SiF_4(g)$.

(a) If 15% by mass of the fluorine in 100. kg of $Ca_5(PO_4)_3F$ forms SiF_4, what volume of this gas is collected at 1.00 atm and the industrial furnace temperature of 1450.°C?

(b) In some facilities, the SiF_4 is used to produce sodium hexafluorosilicate (Na_2SiF_6) which is sold for water fluoridation:

$$2SiF_4(g) + Na_2CO_3(s) + H_2O(l) \longrightarrow Na_2SiF_6(aq) + SiO_2(s) + CO_2(g) + 2HF(aq)$$

How many cubic meters of drinking water can be fluoridated to a level of 1.0 ppm of F^- using the SiF_4 produced in part (a)?

22.18 An impurity sometimes found in $Ca_3(PO_4)_2$ is Fe_2O_3, which is removed during the production of phosphorus as *ferrophosphorus* (Fe_2P). (a) Why is this impurity troubling from an economic standpoint? (b) If 50. metric tons of crude $Ca_3(PO_4)_2$ contains 2.0% Fe_2O_3 by mass and the overall yield of phosphorus is 90.%, how many metric tons of P_4 can be isolated?

Metallurgy: Extracting a Metal from Its Ore

Concept Review Questions

22.19 Define: (a) ore; (b) mineral; (c) gangue; (d) brine.

22.20 Define: (a) roasting; (b) smelting; (c) flotation; (d) refining.

22.21 What factors determine which reducing agent is selected for producing a specific metal?

22.22 Use atomic properties to explain the reduction of a less active metal by a more active one: (a) in aqueous solution; (b) in the molten state. Give a specific example of each process.

22.23 What class of element is obtained by oxidation of a mineral? What class of element is obtained by reduction of a mineral?

Problems in Context

22.24 Which group of elements gives each of the following alloys: (a) brass; (b) stainless steel; (c) bronze; (d) sterling silver?

1. Cu, Ag 2. Cu, Sn, Zn 3. Ag, Au
4. Fe, Cr, Ni 5. Fe, V 6. Cu, Zn

Tapping the Crust: Isolation and Uses of the Elements

Concept Review Questions

22.25 How are each of the following involved in iron metallurgy: (a) slag; (b) pig iron; (c) steel; (d) basic-oxygen process?

22.26 What are the distinguishing features of each extraction process: pyrometallurgy, electrometallurgy, and hydrometallurgy? Explain briefly how the types of metallurgy are used in the production of (a) Fe; (b) Na; (c) Au; (d) Al.

22.27 What property allows copper to be purified in the presence of iron and nickel impurities? Explain.

22.28 What is the practical reason for using cryolite in the electrolysis of aluminum oxide?

22.29 (a) What is a kinetic isotope effect?

(b) Do compounds of hydrogen exhibit a relatively large or small kinetic isotope effect? Explain.

(c) Carbon compounds also exhibit a kinetic isotope effect. How do you expect it to compare in magnitude with that for hydrogen compounds? Why?

22.30 How is Le Châtelier's principle involved in the production of elemental potassium?

Problems in Context

22.31 Elemental Li and Na are prepared by electrolysis of a molten salt, whereas K, Rb, and Cs are prepared by chemical reduction.

(a) In general terms, explain why the alkali metals cannot be prepared by electrolysis of their aqueous salt solutions.

(b) Use ionization energies (see the Family Portraits, pp. 560 and 564) to explain why calcium should *not* be able to isolate Rb from molten RbX (X = halide).

(c) Use physical properties to explain why calcium *is* used to isolate Rb from molten RbX.

(d) Can Ca be used to isolate Cs from molten CsX? Explain.

22.32 A Downs cell operating at 75.0 A produces 30.0 kg of Na.

(a) What volume of $Cl_2(g)$ is produced at 1.0 atm and 580.°C?

(b) How many coulombs were passed through the cell?

(c) How long did the cell operate?

22.33 (a) In the industrial production of iron, what is the reducing substance loaded into the blast furnace?

(b) In addition to furnishing the reducing power, what other function does this substance serve?

(c) What is the formula of the active reducing agent in the process?

(d) Write equations for the stepwise reduction of Fe_2O_3 to iron in the furnace.

22.34 One of the substances loaded into a blast furnace is limestone, which produces lime in the furnace.

(a) Give the chemical equation for the reaction forming lime.

(b) Explain the purpose of lime in the furnace. The term *flux* is often used as a label for a substance acting as the lime does. What is the derivation of this word, and how does it relate to the function of the lime?

(c) Write a chemical equation describing the action of lime flux.

22.35 The last step in the Dow process for the production of magnesium metal involves electrolysis of molten $MgCl_2$.

(a) Why isn't the electrolysis carried out with aqueous $MgCl_2$? What are the products of this aqueous electrolysis?

(b) Do the high temperatures required to melt $MgCl_2$ favor products or reactants? (*Hint:* Consider the ΔH_f^0 of $MgCl_2$.)

22.36 Iodine is the only halogen that occurs in a positive oxidation state, in $NaIO_3$ impurities within Chile saltpeter, $NaNO_3$.

(a) Is this mode of occurrence consistent with iodine's location in the periodic table? Explain.

(b) In the production of I_2, IO_3^- reacts with HSO_3^-:

$$IO_3^-(aq) + HSO_3^-(aq) \longrightarrow HSO_4^-(aq) + SO_4^-(aq) + H_2O(l) + I_2(s) \quad \text{[unbalanced]}$$

Identify the oxidizing and reducing agents.

(c) If 0.82 mol % of an $NaNO_3$ deposit is $NaIO_3$, how much I_2 (in g) can be obtained from 1.000 ton (2000. lb) of the deposit?

22.37 Selenium is prepared by the reaction of H_2SeO_3 with gaseous SO_2.

(a) What redox process does the sulfur dioxide undergo? What is the oxidation state of sulfur in the product?

(b) Given that the reaction occurs in acidic aqueous solution, what is the formula of the sulfur-containing species?
(c) Write the balanced redox equation for the process.

22.38 The halogens F_2 and Cl_2 are produced by electrolytic oxidation, whereas Br_2 and I_2 are produced by chemical oxidation of the halide ions in a concentrated aqueous solution (brine) by a more electronegative halogen. State two reasons why Cl_2 is not prepared by this method.

22.39 Silicon is prepared by the reduction of K_2SiF_6 with Al. Write the equation for this reaction. (*Hint:* Can F^- be oxidized in this reaction? Can K^+ be reduced?)

22.40 What is the mass percent of iron in each of the following iron ores: Fe_2O_3, Fe_3O_4, FeS_2?

22.41 Phosphorus is one of the impurities present in pig iron that is removed in the basic-oxygen process. Assuming that the phosphorus is present as P atoms, write equations for its oxidation and subsequent reaction in the basic slag.

22.42 The final step in the smelting of $FeCuS_2$ is

$$Cu_2S(s) + 2Cu_2O(s) \longrightarrow 6Cu(l) + SO_2(g)$$

(a) Give the oxidation states of copper in Cu_2S, Cu_2O, and Cu.
(b) What are the oxidizing and reducing agents in this reaction?

22.43 Use balanced equations to explain how acid-base properties are used to separate iron and titanium oxides from aluminum oxide in the Bayer process.

22.44 A piece of Al with a surface area of 2.3 m^2 is anodized to produce a film of Al_2O_3 that is 20. μ ($20.\times10^{-6}$ m) thick.
(a) How many coulombs flow through the cell in this process (assume that the density of the Al_2O_3 layer is 3.97 g/cm^3)?
(b) If it takes 15 min to produce this film, what current must flow through the cell?

22.45 The production of H_2 gas by the electrolysis of water typically requires about 400 kJ of energy per mole.
(a) Use the relationship between work and cell potential (Section 21.4) to calculate the minimum work needed to form 1.0 mol of H_2 gas at a cell potential of 1.24 V.
(b) What is the energy efficiency of the cell operation?
(c) Calculate the cost of producing 500. mol of H_2 if the cost of electrical energy is exactly \$0.05 per kilowatt·hour (1 watt·second = 1 joule).

22.46 (a) What are the components of the reaction mixture following the water-gas shift reaction? (b) Explain how zeolites (Gallery, p. 581) are used to purify the H_2 formed.

22.47 Metal sulfides are often first converted to oxides by roasting in air and then reduced with carbon to produce the metal. Why are the metal sulfides not reduced directly by carbon to yield CS_2? Give a thermodynamic analysis of both processes for a typical case such as ZnS.

Chemical Manufacturing: Two Case Studies

Concept Review Questions

22.48 Explain in detail why a catalyst is used to produce SO_3.

22.49 Among the exothermic steps in the manufacture of sulfuric acid is the process of hydrating SO_3. (a) Write two chemical reactions that show this process. (b) Why is the direct reaction of SO_3 with water not feasible?

22.50 Why is commercial H_2SO_4 so inexpensive?

22.51 (a) What are the three commercial products formed in the chlor-alkali process? (b) State an advantage and a disadvantage of the mercury-cell method for this process.

Problems in Context

22.52 Consider the oxidation of SO_2 to SO_3 at standard conditions.
(a) Calculate ΔG^0 at 25°C. Is the reaction spontaneous?
(b) Why is the reaction not performed at 25°C?
(c) Is the reaction spontaneous at 500.°C? (Assume that ΔH^0 and ΔS^0 are constant with temperature.)
(d) Compare K at 500.°C and at 25°C.
(e) What is the highest T at which the reaction is spontaneous?

22.53 If a chlor-alkali cell used a current of 3×10^4 A, how many pounds of Cl_2 would be produced in a typical 8-h operating day?

22.54 In the chlor-alkali process, the products chlorine and sodium hydroxide are kept separate from each other.
(a) Why is this necessary when Cl_2 is the desired product?
(b) Hypochlorite or chlorate may form by disproportionation of Cl_2 in basic solution. What determines which product forms?
(c) What mole ratio of Cl_2 to OH^- will produce ClO^-? ClO_3^-?

Comprehensive Problems

22.55 The key step in the manufacture of sulfuric acid is the oxidation of sulfur dioxide in the presence of a catalyst, such as V_2O_5. At 727°C, 0.010 mol of SO_2 is injected into an empty 2.00-L container (K_p = 3.18). (a) What is the equilibrium pressure of O_2 that is needed to maintain a 1:1 mole ratio of SO_3:SO_2? (b) What is the equilibrium pressure of O_2 that is needed to maintain a 95:5 mole ratio of SO_3:SO_2?

22.56 Many metal oxides are converted to the free metal by reduction with other elements, such as C or Si. For each of the following reactions, calculate the temperature at which the reduction occurs spontaneously:
(a) $MnO_2(s) \longrightarrow Mn(s) + O_2(g)$
(b) $MnO_2(s) + 2C(\text{graphite}) \longrightarrow Mn(s) + 2CO(g)$
(c) $MnO_2(s) + C(\text{graphite}) \longrightarrow Mn(s) + CO_2(g)$
(d) $MnO_2(s) + Si(s) \longrightarrow Mn(s) + SiO_2(s)$

22.57 Tetraphosphorus decaoxide (P_4O_{10}) is made from phosphate rock and used as a drying agent in the laboratory.
(a) Write a balanced equation for its reaction with water.
(b) What is the pH of a solution formed from the addition of 5.0 g of P_4O_{10} in sufficient water to form 0.500 L? (See Table 18.5, p. 786, for additional information.)

22.58 Heavy water (D_2O) is used to make deuterated chemicals.
(a) What major species, aside from the starting compounds, do you expect to find in a solution of CH_3OH and D_2O?
(b) Write equations to explain how these various species arise. (*Hint:* Consider the autoionization of both components.)

22.59 A blast furnace uses Fe_2O_3 to produce 8400. t of Fe per day.
(a) What mass of CO_2 is produced each day?
(b) Compare this amount of CO_2 with that produced by 1.0 million automobiles, each burning 5.0 gal of gasoline a day. Assume that gasoline has the formula C_8H_{18} and a density of 0.74 g/mL, and that it burns completely. (Note that U.S. gasoline consumption is over 4×10^8 gal/day.)

22.60 Several decades ago, various empirical rules were used to predict the formation of alloys. Two of the rules propose that stable alloys form if the ratio of the number of valence electrons (*s* plus *p*) to the number of atoms is 3:2 or 21:13. For example, β-brass (CuZn) is a very stable alloy: Cu has one 4*s* and Zn has two 4*s* electrons, for 3 valence electrons; one Cu atom plus one Zn atom gives 2 atoms; thus, a 3:2 ratio of electrons to atoms. What is the electron-to-atom ratio for each of the following alloys: (a) Cu_5Sn; (b) Cu_5Zn_8; (c) $Cu_{31}Sn_8$; (d) $AgZn_3$; (e) Ag_3Al?

22.61 In the production of magnesium, $Mg(OH)_2$ is precipitated by using $Ca(OH)_2$, which itself is "insoluble." (a) Use K_{sp} values to show that $Mg(OH)_2$ can be precipitated from seawater in which $[Mg^{2+}]$ is initially 0.051 *M*. (b) If the seawater is saturated with $Ca(OH)_2$, what fraction of the Mg^{2+} is precipitated?

22.62 The Ostwald process for the production of HNO_3 is

(1) $4NH_3(g) + 5O_2(g) \xrightarrow{\text{Pt/Rh catalyst}} 4NO(g) + 6H_2O(g)$

(2) $2NO(g) + O_2(g) \longrightarrow 2NO_2(g)$

(3) $3NO_2(g) + H_2O(l) \longrightarrow 2HNO_3(aq) + NO(g)$

(a) Describe the nature of the change that occurs in step 3.

(b) Write an overall equation that includes NH_3 and HNO_3 as the only nitrogen-containing species.

(c) Calculate ΔH^0_{rxn} (in kJ/mol N atoms) for this reaction at 25°C.

22.63 Step 1 of the Ostwald process for nitric acid production is

$$4NH_3(g) + 5O_2(g) \xrightarrow{\text{Pt/Rh catalyst}} 4NO(g) + 6H_2O(g)$$

An unwanted side reaction for this step is

$$4NH_3(g) + 3O_2(g) \longrightarrow 2N_2(g) + 6H_2O(g)$$

(a) Calculate K_p for these two NH_3 oxidations at 25°C.

(b) Calculate K_p for these two NH_3 oxidations at 900.°C.

(c) The Pt/Rh catalyst is one of the most efficient in the chemical industry, achieving 96% yield in 1 millisecond of contact with the reactants. However, at normal operating conditions (5 atm and 850°C), about 175 mg of Pt is lost per metric ton (t) of HNO_3 produced. If the annual U.S. production of HNO_3 is 1.01×10^7 t and the market price of Pt is $807/troy oz, what is the annual cost of the lost Pt (1 kg = 32.15 troy oz)?

22.64 The compounds $(NH_4)_2HPO_4$ and $NH_4(H_2PO_4)$ are water-soluble fertilizers. (a) Which has the higher mass % of P? (b) Why might the one with the lower mass % of P be preferred?

22.65 Several transition metals are prepared by reduction of the metal halide with magnesium. Titanium is prepared by the Kroll method, in which ore (ilmenite) is converted to the gaseous chloride, which is then reduced to Ti metal by molten Mg (see p. 988). Assuming yields of 84% for step 1 and 93% for step 2, and an excess of the other reactants, what mass of Ti metal can be prepared from 17.5 metric tons of ilmenite?

22.66 The production of S_8 from the $H_2S(g)$ found in natural gas deposits occurs through the Claus process (Section 22.5):

(a) Use these two unbalanced steps to write an overall balanced equation for this process:

(1) $H_2S(g) + O_2(g) \longrightarrow S_8(g) + SO_2(g) + H_2O(g)$

(2) $H_2S(g) + SO_2(g) \longrightarrow S_8(g) + H_2O(g)$

(b) Write the overall reaction with Cl_2 as the oxidizing agent instead of O_2. Use thermodynamic data to show whether $Cl_2(g)$ can be used to oxidize $H_2S(g)$.

(c) Why is oxidation by O_2 preferred to oxidation by Cl_2?

22.67 Acid mine drainage (AMD) occurs when geologic deposits containing pyrite (FeS_2) are exposed to oxygen and moisture. AMD is generated in a multistep process catalyzed by acidophilic (acid-loving) bacteria. Balance each step and identify those that increase acidity:

(1) $FeS_2(s) + O_2(g) \longrightarrow Fe^{2+}(aq) + SO_4{}^{2-}(aq)$

(2) $Fe^{2+}(aq) + O_2(g) \longrightarrow Fe^{3+}(aq) + H_2O(l)$

(3) $Fe^{3+}(aq) + H_2O(l) \longrightarrow Fe(OH)_3(s) + 12H^+(aq)$

(4) $FeS_2(s) + Fe^{3+}(aq) \longrightarrow Fe^{2+}(aq) + SO_4{}^{2-}(aq)$

22.68 Based on a concentration of 0.065 g Br^-/L, the ocean is estimated to have $244,000,000 of Br_2/mi^3 at recent prices.

(a) What is the price per gram of Br_2 in the ocean?

(b) Find the mass (in g) of $AgNO_3$ needed to precipitate 90.0% of the Br^- in 1.00 L of ocean water.

(c) Use Appendix C to find how low $[Cl^-]$ must be to prevent the unwanted precipitation of AgCl.

(d) Given a $[Cl^-]$ of about 0.3 *M*, is precipitation with silver ion a practical way to obtain bromine from the ocean? Explain.

22.69 Below 912°C, pure iron crystallizes in a body-centered cubic structure (ferrite) with a density of 7.86 g/cm^3; from 912°C to 1394°C, it adopts a face-centered cubic structure (austenite) with a density of 7.40 g/cm^3. Both types of iron form interstitial alloys with carbon. The maximum amount of carbon is 0.0218 mass% in ferrite and 2.08 mass% in austenite. Calculate the density of each alloy.

22.70 Why is nitric acid not produced by oxidizing atmospheric nitrogen directly in the following way?

(1) $N_2(g) + 2O_2(g) \longrightarrow 2NO_2(g)$

(2) $3NO_2(g) + H_2O(l) \longrightarrow 2HNO_3(aq) + NO(g)$

(3) $2NO(g) + O_2(g) \longrightarrow 2NO_2(g)$

$$3N_2(g) + 6O_2(g) + 2H_2O(l) \longrightarrow 4HNO_3(aq) + 2NO(g)$$

(*Hint:* Evaluate the thermodynamics of each step.)

22.71 Before the development of the Downs cell, the Castner cell was used for the industrial production of Na metal. The Castner cell was based on the electrolysis of molten NaOH.

(a) Write balanced cathode and anode half-reactions for this cell.

(b) A major problem with this cell was that the water produced at one electrode diffused to the other and reacted with the Na. If all the water produced reacted with Na, what would be the maximum efficiency of the Castner cell expressed as moles of Na produced per mole of electrons flowing through the cell?

22.72 When gold ores are leached with CN^- solutions, gold forms a complex ion, $Au(CN)_2{}^-$. (a) Find E_{cell} for the oxidation in air (P_{O_2} = 0.21) of Au to Au^+ in basic (pH 13.55) solution with $[Au^+]$ = 0.50 *M*. Is the reaction $Au^+(aq) + e^- \longrightarrow Au(s)$, E^0 = 1.68 V, spontaneous? (b) How does formation of the complex ion change E^0 so that the oxidation can be accomplished?

22.73 Nitric oxide is an important species in the tropospheric nitrogen cycle, but it destroys ozone in the stratosphere.

(a) Write a balanced equation for its reversible reaction with ozone. (b) Given that the forward and reverse steps are first order in each component, write general rate laws for them. (c) Calculate ΔG^0 for this reaction at 280. K, the average temperature in the stratosphere. (Assume that the ΔH^0 and S^0 values in Appendix B do not change with temperature.) (d) Calculate the ratio of rate constants for the reaction at this temperature.

22.74 A key part of the carbon cycle is the fixation of CO_2 by photosynthesis to produce carbohydrates and oxygen gas.

(a) Using the formula $(CH_2O)_n$ to represent a carbohydrate, write a balanced equation for the photosynthetic reaction.

(b) If a tree fixes 45 g of CO_2 a day, what volume of O_2 gas measured at 1.0 atm and 80.°F does the tree produce per day?

(c) What volume of air (0.033 mol % CO_2) at the same conditions contains this amount of CO_2?

22.75 Farmers use ammonium sulfate as a fertilizer. In the soil, nitrifying bacteria oxidize $NH_4{}^+$ to $NO_3{}^-$, a groundwater contaminant that causes methemoglobinemia ("blue baby" syndrome). The World Health Organization standard for maximum $[NO_3{}^-]$ in groundwater is 45 mg/L. A farmer adds 200. kg of $(NH_4)_2SO_4$ to a field and 35% is oxidized to $NO_3{}^-$. What is the groundwater $[NO_3{}^-]$ (in mg/L) if 1000. m^3 of the water is contaminated?

22.76 In the 1980s, U.S. Fish and Wildlife Service researchers found high mortality among newborn coots and ducks in parts of California. U.S. Geological Survey scientists later found the cause to be a high selenium concentration in agricultural drainage water. Balance these half-reactions in the selenium cycle:
(a) $Se^{2-}(aq) \longrightarrow Se(s)$
(b) $SeO_3^{2-}(aq) \longrightarrow SeO_4^{2-}(aq)$
(c) $SeO_4^{2-}(aq) \longrightarrow Se(s)$

22.77 The key reaction (unbalanced) in the manufacture of synthetic cryolite for aluminum electrolysis is

$$HF(g) + Al(OH)_3(s) + NaOH(aq) \longrightarrow Na_3AlF_6(aq) + H_2O(l)$$

Assuming a 96.6% yield of dried, crystallized product, what mass (in kg) of cryolite can be obtained from the reaction of 353 kg of $Al(OH)_3$, 1.10 m^3 of 50.0% by mass aqueous NaOH (d = 1.53 g/mL), and 225 m^3 of gaseous HF at 315 kPa and 89.5°C? (Assume that the ideal gas law holds.)

22.78 Because of their different molar masses, H_2 and D_2 effuse at different rates (Section 5.6). (a) If it takes 14.5 min for 0.10 mol of H_2 to effuse, how long does it take for 0.10 mol of D_2 to do so in the same apparatus at the same T and P? (b) How many effusion steps does it take to separate an equimolar mixture of D_2 and H_2 to 99 mol % purity?

22.79 The disproportionation of carbon monoxide to graphite and carbon dioxide is thermodynamically favored but slow.
(a) What does this mean in terms of the magnitudes of the equilibrium constant (K), rate constant (k), and activation energy (E_a)?
(b) Write a balanced equation for the disproportionation of CO.
(c) Calculate K_c at 298 K. (d) Calculate K_p at 298 K.

22.80 The overall cell reaction for aluminum production is

$$2Al_2O_3(\text{in } Na_3AlF_6) + 3C(\text{graphite}) \longrightarrow 4Al(l) + 3CO_2(g)$$

(a) Assuming 100% efficiency, how many metric tons (t) of Al_2O_3 are consumed per metric ton of Al produced?
(b) Assuming 100% efficiency, how many metric tons of the graphite anode are consumed per metric ton of Al produced?
(c) Actual conditions in an aluminum plant require 1.89 t of Al_2O_3 and 0.45 t of graphite per metric ton of Al. What is the percent yield of Al with respect to Al_2O_3?
(d) What is the percent yield of Al with respect to graphite?
(e) What volume of CO_2 (in m^3) is produced per metric ton of Al at operating conditions of 960.°C and exactly 1 atm?

22.81 World production of chromite ($FeCr_2O_4$), the main ore of chromium, was 1.5×10^7 metric tons in 2003. To isolate chromium, a mixture of chromite and sodium hydroxide is heated in air to form sodium chromate, iron(III) oxide, and water vapor. The sodium chromate is dissolved in water, and this solution is acidified with sulfuric acid to produce the less soluble sodium dichromate. The sodium dichromate is filtered out and reduced with carbon to produce chromium(III) oxide, sodium carbonate, and carbon monoxide. The chromium(III) oxide is then reduced to chromium with aluminum metal. (a) Write balanced equations for each step. (b) What mass of chromium (in kg) could be prepared from the 2003 world production of chromite?

22.82 The following nitrogen-containing species play roles in the nitrogen cycle: NH_3, N_2O, NO, NO_2, NO_2^-, NO_3^-. Draw a Lewis structure for each species, showing minimal formal charges, and indicate the shape, including ideal bond angles.

22.83 Even though most metal sulfides are sparingly soluble in water, their solubilities differ by several orders of magnitude. This difference is sometimes used to separate the metals by controlling the pH. Use the following data to find the pH at which you can separate 0.10 M Cu^{2+} and 0.10 M Ni^{2+}:
Saturated H_2S = 0.10 M
K_{a1} of $H_2S = 9\times10^{-8}$ K_{a2} of $H_2S = 1\times10^{-17}$
K_{sp} of $NiS = 1.1\times10^{-18}$ K_{sp} of $CuS = 8\times10^{-34}$

22.84 Ores with as little as 0.25% by mass of copper are used as sources of the metal. (a) How many kilograms of such an ore would be needed for another Statue of Liberty, which contains 2.0×10^5 lb of copper? (b) If the mineral in the ore is chalcopyrite ($FeCuS_2$), what is the mass % of chalcopyrite in the ore?

22.85 How does acid rain affect the leaching of phosphate into groundwater from terrestrial phosphate rock? Calculate the solubility of $Ca_3(PO_4)_2$ in each of the following: (a) Pure water, pH 7.0 (Assume that PO_4^{3-} does not react with water.) (b) Moderately acidic rainwater, pH 4.5 (*Hint:* Assume that all the phosphate exists in the form that predominates at this pH.)

22.86 The lead(IV) oxide used in car batteries is prepared by coating the electrode plate with PbO and then oxidizing it to PbO_2. Despite its formula, PbO_2 has a nonstoichiometric ratio of lead to oxygen of about 1:1.888. In fact, the holes in the PbO_2 crystal structure due to missing O atoms are responsible for the oxide's conductivity. (a) What is the mole % of O missing from the PbO_2 structure? (b) What is the molar mass of the nonstoichiometric compound?

22.87 Chemosynthetic bacteria reduce CO_2 by "splitting" $H_2S(g)$ instead of the $H_2O(g)$ used by photosynthetic organisms. Compare the free energy change for splitting H_2S with that for splitting H_2O. Is there an advantage to using H_2S instead of H_2O?

22.88 Silver has a face-centered cubic structure with a unit cell edge length of 408.6 pm. Sterling silver is a substitutional alloy that contains 7.5% copper atoms. Assuming the unit cell remains the same, find the density of silver and of sterling silver.

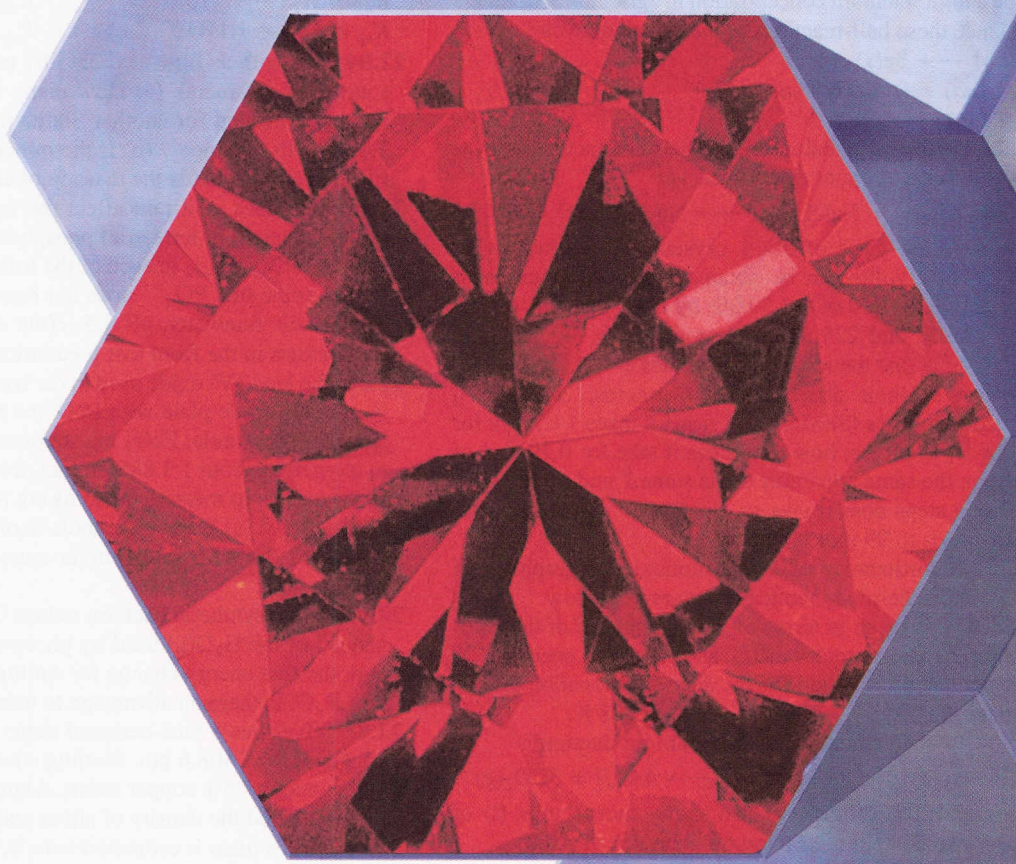
22.89 Earth's mass is estimated to be 5.98×10^{24} kg, and titanium represents 0.05% by mass of this total. (a) How many moles of Ti are present? (b) If half of the Ti is found as ilmenite ($FeTiO_3$), what mass of ilmenite is present? (c) If the airline and auto industries use 1.00×10^5 tons of Ti per year, how many years would it take to use up all the Ti (1 ton = 2000 lb)?

22.90 In 1790, Nicolas Leblanc found a way to form Na_2CO_3 from NaCl. His process, now obsolete, consisted of three steps:

$$2NaCl(s) + H_2SO_4(aq) \longrightarrow Na_2SO_4(aq) + 2HCl(g)$$
$$Na_2SO_4(s) + 2C(s) \longrightarrow Na_2S(s) + 2CO_2(g)$$
$$Na_2S(s) + CaCO_3(s) \longrightarrow Na_2CO_3(s) + CaS(s)$$

(a) Write a balanced overall equation for the process.
(b) Calculate the ΔH_f^0 of CaS if ΔH_{rxn}^0 is 351.8 kJ/mol.
(c) Is the overall process spontaneous at standard-state conditions and 298 K?
(d) How many grams of Na_2CO_3 form from 100. g of NaCl if the process is 78% efficient?

22.91 Limestone ($CaCO_3$) is the second most abundant mineral on Earth after SiO_2. For many of its uses, it is first decomposed thermally to quicklime (CaO). MgO is prepared similarly from $MgCO_3$. (a) Find the temperature at which each decomposition is spontaneous. (b) Quicklime reacts with SiO_2 to form a slag ($CaSiO_3$) used in steelmaking. In 2003, the total steelmaking capacity of the U.S. steel industry was 2,370,000 tons per week, but only 84% of this capacity was utilized. If 50 kg of slag is needed per ton of steel, what mass (in kg) of limestone was used to make slag in 2003?



The colors of rocks Much of the color in the mineral world comes from transition-metal ions. In fact, it is the Cr^{3+} within the crystal structure of otherwise colorless aluminum oxide that makes rubies red. In this chapter, we examine the transition metals and some of their numerous applications as well as the structures and properties of their compounds.

23.5 **Theoretical Basis for the Bonding and Properties of Complexes**
Valence Bond Theory
Crystal Field Theory

Our exploration of the elements to this point is far from complete; in fact, we have skirted the majority of them and some of the most familiar. Whereas most important uses of the main-group elements involve their compounds, the transition elements are remarkably useful in their uncombined form. Figure 23.1 shows that the **transition elements** *(transition metals)* make up the *d* block (B groups) and *f* block *(inner transition elements)*.

In Chapter 22, you saw how two of the most important—copper and iron—are extracted from their ores. Aside from those two, with their countless essential uses, many other transition elements are indispensable as well: chromium in automobile parts, gold and silver in jewelry, tungsten in lightbulb filaments, platinum in automobile catalytic converters, titanium in bicycle frames and aircraft parts, and zinc in batteries, to mention just a few of the better known elements. You may be less aware of zirconium in nuclear-reactor liners, vanadium in axles and crankshafts, molybdenum in boiler plates, nickel in coins, tantalum in organ-replacement parts, palladium in telephone-relay contacts—the list goes on and on. As ions, many of these elements also play vital roles in living organisms.

IN THIS CHAPTER . . . We first discuss some atomic, physical, and chemical properties of the transition elements and then focus on the chemistry of four familiar ones: chromium, manganese, silver, and mercury. Next, we concentrate on the most distinctive feature of transition element chemistry, the formation of coordination compounds, substances that contain complex ions. We consider two models that explain the striking colors of these compounds, as well as their magnetic properties and structures, and then end with some essential biochemical functions of transition metal ions.

Concepts & Skills to Review

before you study this chapter

- properties of light (Section 7.1)
- electron shielding of nuclear charge (Section 8.2)
- electron configuration, ionic size, and magnetic behavior (Sections 8.3 to 8.5)
- valence bond theory (Section 11.1)
- constitutional, geometric, and optical isomerism (Section 15.2)
- Lewis acid-base concepts (Section 18.9)
- complex-ion formation (Section 19.4)
- redox behavior and standard electrode potentials (Section 21.3)

Figure 23.2 The Period 4 transition metals. Samples of all ten elements appear as pure metals, in chunk or powder form, in periodic-table order on this and the facing page.

23.1 PROPERTIES OF THE TRANSITION ELEMENTS

The transition elements differ considerably in physical and chemical behavior from the main-group elements. In some ways, they are more uniform: main-group elements in each period change from metal to nonmetal, but *all transition elements are metals*. In other ways, the transition elements are more diverse: most main-group ionic compounds are colorless and diamagnetic, but *many transition metal compounds are highly colored and paramagnetic*. We first discuss electron configurations of the atoms and ions, and then examine certain key properties of transition elements, with an occasional comparison to the main-group elements.

Electron Configurations of the Transition Metals and Their Ions

As with any of the elements, the properties of the transition elements and their compounds arise largely from the electron configurations of their atoms (Section 8.3) and ions (Section 8.5). The *d*-block (B-group) elements occur in four series that lie within Periods 4 through 7 between the last *ns*-block element [Group 2A(2)] and the first *np*-block element [Group 3A(13)]. Each series represents the filling of five *d* orbitals and, thus, contains ten elements. In 1996 and 1997, elements 110 through 112 were synthesized in particle accelerators, so the Period 7 series is complete; thus, all 40 *d*-block transition elements are known. Lying between the first and second members of the *d*-block transition series in Periods 6 and 7 are the inner transition elements, whose *f* orbitals are being filled.

Even though there are several exceptions, in general, the *condensed* ground-state electron configuration for the elements in each *d*-block series is

$$[\text{noble gas}]\ ns^2(n-1)d^x, \text{ with } n = 4 \text{ to } 7 \text{ and } x = 1 \text{ to } 10$$

In Periods 6 and 7, the condensed configuration includes the *f* sublevel:

$$[\text{noble gas}]\ ns^2(n-2)f^{14}(n-1)d^x, \text{ with } n = 6 \text{ or } 7$$

The *partial* (valence-level) electron configuration for the *d*-block elements excludes the noble gas core and the filled inner *f* sublevel:

$$ns^2(n-1)d^x$$

The first transition series occurs in Period 4 and consists of scandium (Sc) through zinc (Zn) (Figure 23.2 and Table 23.1). Scandium has the electron configuration [Ar] $4s^23d^1$, and the addition of one electron at a time (along with one proton in the nucleus) first half-fills, then fills, the 3*d* orbitals across the periodic table to zinc. Recall that chromium and copper are two exceptions to this general pattern: the 4*s* and 3*d* orbitals in Cr are both half-filled to give [Ar] $4s^13d^5$, and the 4*s* in Cu is half-filled to give [Ar] $4s^13d^{10}$. The reasons for these exceptions involve the change in relative energies of the 4*s* and 3*d* orbitals as electrons are added across the series and the unusual stability of half-filled and filled sublevels.

Transition metal ions form through *the loss of the ns electrons before the (n − 1)d electrons*. Therefore, the electron configuration of Ti^{2+} is [Ar] $3d^2$, *not* [Ar] $4s^2$, and Ti^{2+} is referred to as a d^2 ion. Ions of different metals with the same configuration often have similar properties. For example, both Mn^{2+} and Fe^{3+} are d^5 ions; both have pale colors in aqueous solution and, as we'll discuss later, form complex ions with similar magnetic properties.

Table 23.1 shows a general pattern in number of unpaired electrons (or half-filled orbitals) across the Period 4 transition series. Note that the number increases

Iron, Fe; 8B(8)

Cobalt, Co; 8B(9)

Nickel, Ni; 8B(10)

Copper, Cu; 1B(11)

Zinc, Zn; 2B(12)

Table 23.1 Orbital Occupancy of the Period 4 Transition Metals

Element	Partial Orbital Diagram			Unpaired Electrons
	4*s*	3*d*	4*p*	
Sc	↑↓	↑		1
Ti	↑↓	↑ ↑		2
V	↑↓	↑ ↑ ↑		3
Cr	↑	↑ ↑ ↑ ↑ ↑		6
Mn	↑↓	↑ ↑ ↑ ↑ ↑		5
Fe	↑↓	↑↓ ↑ ↑ ↑ ↑		4
Co	↑↓	↑↓ ↑↓ ↑ ↑ ↑		3
Ni	↑↓	↑↓ ↑↓ ↑↓ ↑ ↑		2
Cu	↑	↑↓ ↑↓ ↑↓ ↑↓ ↑↓		1
Zn	↑↓	↑↓ ↑↓ ↑↓ ↑↓ ↑↓		0

in the first half of the series and, when pairing begins, decreases through the second half. As you'll see, it is the electron configuration of the transition metal *atom* that correlates with physical properties of the *element,* such as density and magnetic behavior, whereas it is the electron configuration of the *ion* that determines the properties of the *compounds*.

SAMPLE PROBLEM 23.1 Writing Electron Configurations of Transition Metal Atoms and Ions

Problem Write *condensed* electron configurations for the following: **(a)** Zr; **(b)** V^{3+}; **(c)** Mo^{3+}. (Assume that elements in higher periods behave like those in Period 4.)

Plan We locate the element in the periodic table and count its position in the respective transition series. These elements are in Periods 4 and 5, so the general configuration is [noble gas] $ns^2(n-1)d^x$. For the ions, we recall that *ns* electrons are lost first.

Solution **(a)** Zr is the second element in the 4*d* series: [Kr] $5s^24d^2$.

(b) V is the third element in the 3*d* series: [Ar] $4s^23d^3$. In forming V^{3+}, three electrons are lost (two 4*s* and one 3*d*), so V^{3+} is a d^2 ion: [Ar] $3d^2$.

(c) Mo lies below Cr in Group 6B(6), so we expect the same exception as for Cr. Thus, Mo is [Kr] $5s^14d^5$. To form the ion, Mo loses the one 5*s* and two of the 4*d* electrons, so Mo^{3+} is a d^3 ion: [Kr] $4d^3$.

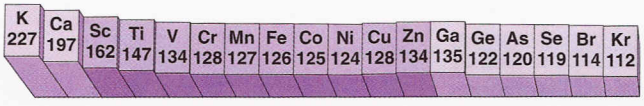
Check Figure 8.11 (p. 302) shows we're correct for the atoms. Be sure that charge plus number of *d* electrons in the ion equals the sum of outer *s* and *d* electrons in the atom.

FOLLOW-UP PROBLEM 23.1 Write *partial* electron configurations for the following: **(a)** Ag^+; **(b)** Cd^{2+}; **(c)** Ir^{3+}.

Atomic and Physical Properties of the Transition Elements

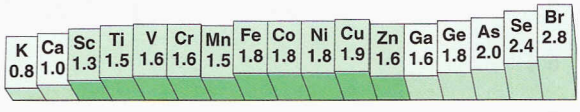
The atomic properties of the transition elements contrast in several ways with those of a comparable set of main-group elements.

Trends Across a Period Consider the variations in atomic size, electronegativity, and ionization energy across Period 4 (Figure 23.3):



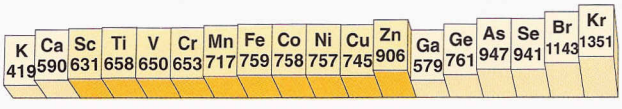
A Atomic radius (pm)

- *Atomic size.* Atomic size decreases overall across the period (Figure 23.3A). However, there is a smooth, steady decrease across the main groups because the electrons are added to *outer* orbitals, which shield the increasing nuclear charge poorly. This steady decrease is suspended throughout the transition series, where *atomic size decreases at first but then remains fairly constant.* Recall that the *d* electrons fill *inner* orbitals, so they shield outer electrons from the increasing nuclear charge very efficiently. As a result, the outer 4*s* electrons are not pulled closer.



B Electronegativity

- *Electronegativity.* Electronegativity generally increases across the period but, once again, the transition elements exhibit a relatively *small change in electronegativity* (Figure 23.3B), consistent with the relatively small change in size. In contrast, the main groups show a steady, much steeper increase between the metal potassium (0.8) and the nonmetal bromine (2.8). The transition elements all have intermediate electronegativity values, much like the large, metallic members of Groups 3A(13) to 5A(15).



C First ionization energy (kJ/mol)

Figure 23.3 Horizontal trends in key atomic properties of the Period 4 elements. The atomic radius (**A**), electronegativity (**B**), and first ionization energy (**C**) of the elements in Period 4 are shown as posts of different heights, with darker shades for the transition series. The transition elements exhibit smaller, less regular changes for these properties than do the main-group elements.

- *Ionization energy.* The ionization energies of the Period 4 main-group elements rise steeply from left to right, more than tripling from potassium (419 kJ/mol) to krypton (1351 kJ/mol), as electrons become more difficult to remove from the poorly shielded, increasing nuclear charge. In the transition metals, however, the *first ionization energies increase relatively little* because the inner 3*d* electrons shield effectively (Figure 23.3C); thus, the outer 4*s* electron experiences only a slightly higher effective nuclear charge. [Recall from Section 8.4 that the drop at Group 3A(13) occurs because it is relatively easy to remove the first electron from the outer *np* orbital.]

Trends Within a Group Vertical trends for transition elements are also different from those for the main groups.

- *Atomic size.* As expected, atomic size increases from Period 4 to 5, as it does for the main-group elements, but there is virtually *no size increase from Period 5 to 6* (Figure 23.4A). Remember that the lanthanides, with their buried 4*f* sublevel, appear between the 4*d* (Period 5) and 5*d* (Period 6) series. Therefore, an element in Period 6 is separated from the one above it in Period 5 by 32 elements (ten 4*d*, six 5*p*, two 6*s*, and fourteen 4*f* orbitals) instead of just 18. The extra shrinkage that results from the increase in nuclear charge due to the addition of 14 protons is called the **lanthanide contraction.** By coincidence, this *decrease* is about equal to the normal *increase* between periods, so the Periods 5 and 6 transition elements have about the same atomic sizes.
- *Electronegativity.* The vertical trend in electronegativity seen in most transition groups is opposite the trend in main groups. Here, we see an *increase* in electronegativity from Period 4 to Period 5, but then no further increase in Period 6 (Figure 23.4B). The heavier elements, especially gold (EN = 2.4), become quite electronegative, with values exceeding those of most metalloids and even some nonmetals (e.g., EN of Te and of P = 2.1). (In fact, gold forms the salt-like CsAu and the Au^- ion, which exists in liquid ammonia.) Although the

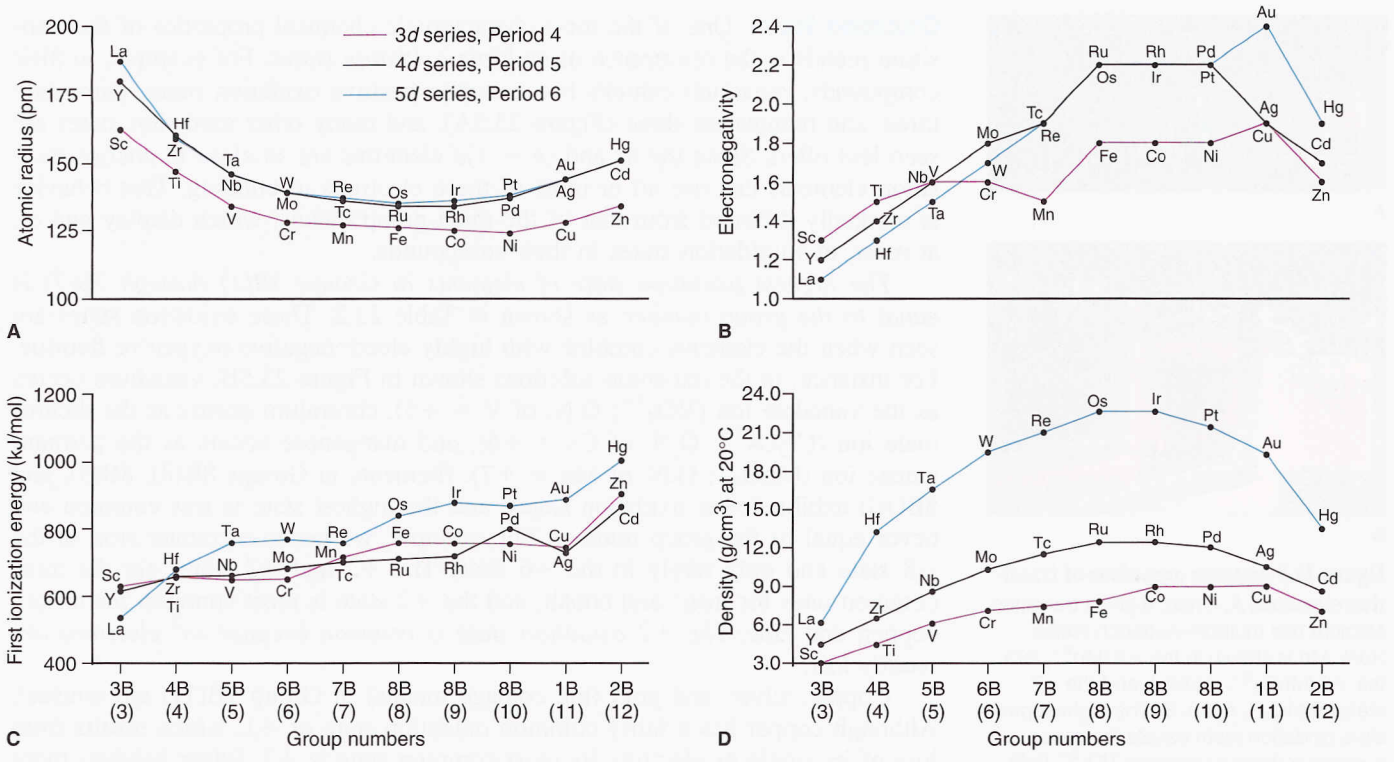


Figure 23.4 Vertical trends in key properties within the transition elements. The trends are unlike those for the main-group elements in several ways: **A,** The second and third members of a transition metal group are nearly the same size. **B,** Electronegativity increases down a transition group. **C,** First ionization energies are highest at the bottom of a transition group. **D,** Densities increase down a transition group because mass increases faster than volume.

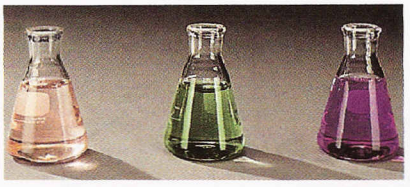
atomic size increases slightly from the top to the bottom of a group, the nuclear charge increases much more. Therefore, the heavier transition metals exhibit more covalent character in their bonds and attract electrons more strongly than do main-group metals.

- *Ionization energy.* The relatively small increase in size combined with the relatively large increase in nuclear charge also explains why *the first ionization energy generally increases* down a transition group (Figure 23.4C). This trend also runs counter to the pattern in the main groups, in which heavier members are so much larger that their outer electron is easier to remove.
- *Density.* Atomic size, and therefore volume, is inversely related to density. Across a period, densities increase, then level off, and finally dip a bit at the end of a series (Figure 23.4D). Down a transition group, densities increase dramatically because atomic volumes change little from Period 5 to 6, but atomic masses increase significantly. As a result, the Period 6 series contains some of the densest elements known: tungsten, rhenium, osmium, iridium, platinum, and gold have densities about 20 times that of water and twice that of lead.

Chemical Properties of the Transition Metals

Like their atomic and physical properties, the chemical properties of the transition elements are very different from those of the main-group elements. Let's examine the key properties in the Period 4 transition series and then see how behavior changes within a group.



A

B

Figure 23.5 Aqueous oxoanions of transition elements. A, Often, a given transition element has multiple oxidation states. Here, Mn is shown in the +2 (Mn^{2+}, *left*), the +6 (MnO_4^{2-}, *middle*), and the +7 states (MnO_4^-, *right*). **B,** The highest possible oxidation state equals the group number in these oxoanions: VO_4^{3-} (*left*), $Cr_2O_7^{2-}$ (*middle*), and MnO_4^- (*right*).

Oxidation States One of the most characteristic chemical properties of the transition metals is the occurrence of *multiple oxidation states*. For example, in their compounds, vanadium exhibits two common positive oxidation states, chromium three, and manganese three (Figure 23.5A), and many other oxidation states are seen less often. Since the *ns* and $(n - 1)d$ electrons are so close in energy, transition elements can use all or most of these electrons in bonding. This behavior is markedly different from that of the main-group metals, which display one or, at most, two oxidation states in their compounds.

The highest oxidation state of elements in Groups 3B(3) through 7B(7) is equal to the group number, as shown in Table 23.2. These oxidation states are seen when the elements combine with highly electronegative oxygen or fluorine. For instance, in the oxoanion solutions shown in Figure 23.5B, vanadium occurs as the vanadate ion (VO_4^{3-}; O.N. of V = +5), chromium occurs as the dichromate ion ($Cr_2O_7^{2-}$; O.N. of Cr = +6), and manganese occurs as the permanganate ion (MnO_4^-; O.N. of Mn = +7). Elements in Groups 8B(8), 8B(9), and 8B(10) exhibit fewer oxidation states, and the highest state is less common and never equal to the group number. For example, we never encounter iron in the +8 state and only rarely in the +6 state. The +2 and +3 states are the most common ones for iron* and cobalt, and the +2 state is most common for nickel, copper, and zinc. *The +2 oxidation state is common because ns^2 electrons are readily lost.*

Copper, silver, and gold (the coinage metals) in Group 1B(11) are unusual. Although copper has a fairly common oxidation state of +1, which results from loss of its single 4*s* electron, its most common state is +2. Silver behaves more predictably, exhibiting primarily the +1 oxidation state. Gold exhibits the +3 state and, less often, the +1 state. Zinc, cadmium, and mercury in Group 2B(12) exhibit the +2 state, but mercury also exhibits the +1 state in the Hg_2^{2+} ion, with its Hg—Hg bond.†

*Iron may seem to have unusual oxidation states in the common ores magnetite (Fe_3O_4) and pyrite (FeS_2), but this is not really the case. In magnetite, one-third of the metal ions are Fe^{2+} and two-thirds are Fe^{3+}, which is equivalent to a 1:1 ratio of FeO:Fe_2O_3 and gives an overall formula of Fe_3O_4. Pyrite contains Fe^{2+} combined with the disulfide ion, S_2^{2-}.

†Some evidence suggests that the Hg_2^{2+} ion may exist as an Hg atom bonded to an Hg^{2+} ion, with the atom donating its two 6*s* electrons for the covalent bond.

Table 23.2 Oxidation States and *d*-Orbital Occupancy of the Period 4 Transition Metals*

Oxidation State	3B (3) Sc	4B (4) Ti	5B (5) V	6B (6) Cr	7B (7) Mn	8B (8) Fe	8B (9) Co	8B (10) Ni	1B (11) Cu	2B (12) Zn
0	d^1	d^2	d^3	d^5	d^5	d^6	d^7	d^8	d^{10}	d^{10}
+1			d^3	d^5	d^5	d^6	d^7	d^8	d^{10}	
+2		d^2	d^3	d^4	d^5	d^6	d^7	d^8	d^9	d^{10}
+3	d^0	d^1	d^2	d^3	d^4	d^5	d^6	d^7	d^8	
+4		d^0	d^1	d^2	d^3	d^4	d^5	d^6		
+5			d^0	d^1	d^2		d^4			
+6				d^0	d^1	d^2				
+7					d^0					

*The most important orbital occupancies are in color.

Metallic Behavior and Reducing Strength Atomic size and oxidation state have a major effect on the nature of bonding in transition metal compounds. Like the metals in Groups 3A(13), 4A(14), and 5A(15), the transition elements in their *lower* oxidation states behave chemically more like metals. That is, *ionic bonding is more prevalent for the lower oxidation states, and covalent bonding is more prevalent for the higher states.* For example, at room temperature, $TiCl_2$ is an ionic solid, whereas $TiCl_4$ is a molecular liquid. In the higher oxidation states, the atoms have higher charge densities, so they polarize the electron clouds of the nonmetal ions more strongly and the bonding becomes more covalent. For the same reason, the oxides become less basic as the oxidation state increases: TiO is weakly basic in water, whereas TiO_2 is amphoteric (reacts with both acid and base).

Table 23.3 shows the standard electrode potentials of the Period 4 transition metals in their +2 oxidation state in acid solution. Note that, in general, reducing strength decreases across the series. All the Period 4 transition metals, except copper, are active enough to reduce H^+ from aqueous acid to form hydrogen gas. In contrast to the rapid reaction at room temperature of the Group 1A(1) and 2A(2) metals with water, however, the transition metals have an oxide coating that allows rapid reaction only with hot water or steam.

Table 23.3 Standard Electrode Potentials of Period 4 M^{2+} Ions

Half-Reaction	E° (V)
$Ti^{2+}(aq) + 2e^- \rightleftharpoons Ti(s)$	−1.63
$V^{2+}(aq) + 2e^- \rightleftharpoons V(s)$	−1.19
$Cr^{2+}(aq) + 2e^- \rightleftharpoons Cr(s)$	−0.91
$Mn^{2+}(aq) + 2e^- \rightleftharpoons Mn(s)$	−1.18
$Fe^{2+}(aq) + 2e^- \rightleftharpoons Fe(s)$	−0.44
$Co^{2+}(aq) + 2e^- \rightleftharpoons Co(s)$	−0.28
$Ni^{2+}(aq) + 2e^- \rightleftharpoons Ni(s)$	−0.25
$Cu^{2+}(aq) + 2e^- \rightleftharpoons Cu(s)$	0.34
$Zn^{2+}(aq) + 2e^- \rightleftharpoons Zn(s)$	−0.76

Color and Magnetism of Compounds *Most main-group ionic compounds are colorless* because the metal ion has a filled outer level (noble gas electron configuration). With only much higher energy orbitals available to receive an excited electron, the ion does not absorb visible light. In contrast, electrons in a partially filled *d* sublevel can absorb visible wavelengths and move to slightly higher energy *d* orbitals. As a result, *many transition metal compounds have striking colors.* Exceptions are the compounds of scandium, titanium(IV), and zinc, which are colorless because their metal ions have either an empty *d* sublevel (Sc^{3+} or Ti^{4+}: [Ar] $3d^0$) or a filled one (Zn^{2+}: [Ar] $3d^{10}$) (Figure 23.6).

Magnetic properties are also related to sublevel occupancy (Section 8.5). Recall that a *paramagnetic* substance has atoms or ions with unpaired electrons, which cause it to be attracted to an external magnetic field. A *diamagnetic* substance has only paired electrons, so it is unaffected (or slightly repelled) by a magnetic field. *Most main-group metal ions are diamagnetic* for the same reason they are colorless: all their electrons are paired. In contrast, *many transition metal compounds are paramagnetic because of their unpaired d electrons.* For example, $MnSO_4$ is paramagnetic, but $CaSO_4$ is diamagnetic. The Ca^{2+} ion has the electron configuration of argon, whereas Mn^{2+} has a d^5 configuration. Transition metal ions with a d^0 or d^{10} configuration are also colorless and diamagnetic.

Figure 23.6 Colors of representative compounds of the Period 4 transition metals. Staggered from left to right, the compounds are scandium oxide *(white),* titanium(IV) oxide *(white),* vanadyl sulfate dihydrate *(light blue),* sodium chromate *(yellow),* manganese(II) chloride tetrahydrate *(light pink),* potassium ferricyanide *(red-orange),* cobalt(II) chloride hexahydrate *(violet),* nickel(II) nitrate hexahydrate *(green),* copper(II) sulfate pentahydrate *(blue),* and zinc sulfate heptahydrate *(white).*

Chemical Behavior Within a Group The *increase* in reactivity going down a group of main-group metals, as shown by the *decrease* in first ionization energy (IE_1), does *not* occur going down a group of transition metals. Consider the chromium (Cr) group [6B(6)], which shows a typical pattern (Table 23.4). IE_1 *increases* down the group, which makes the two heavier metals *less* reactive than the lightest one. Chromium is also a much stronger reducing agent than molybdenum (Mo) or tungsten (W), as shown by the standard electrode potentials.

Table 23.4 Some Properties of Group 6B(6) Elements

Element	Atomic Radius (pm)	IE_1 (kJ/mol)	E^0 (V) for $M^{3+}(aq)\|M(s)$
Cr	128	653	−0.74
Mo	139	685	−0.20
W	139	770	−0.11

The similarity in atomic size of Period 5 and 6 members also leads to similar chemical behavior, a fact that has some important practical consequences. Because Mo and W compounds behave similarly, for example, their ores often occur together in nature, which makes the elements very difficult to separate from each other. The same situation occurs with zirconium and hafnium in Group 4B(4) and with niobium and tantalum in Group 5B(5).

SECTION SUMMARY

All transition elements are metals. Atoms of the *d*-block elements have $(n - 1)d$ orbitals being filled, and their ions have an empty *ns* orbital. Unlike the trends in the main-group elements, atomic size, electronegativity, and first ionization energy change relatively little across a transition series. Because of the lanthanide contraction, atomic size changes little from Period 5 to 6 in a transition metal group; thus, electronegativity, first ionization energy, and density *increase* down a group. Transition metals typically have several oxidation states, with the +2 state most common. The elements exhibit more metallic behavior in their lower states. Most Period 4 transition metals are active enough to reduce hydrogen ion from acid solution. Many transition metal compounds are colored and paramagnetic because the metal ion has unpaired *d* electrons.

A Remarkable Laboratory Feat The discovery of the lanthanides is a testimony to the remarkable laboratory skills of 19th-century chemists. The two mineral sources, ceria and yttria, are mixtures of compounds of all 14 lanthanides; yttria also includes oxides of Sc, Y, and La. Purification of these elements was so difficult that many claims of new elements turned out to be mixtures of similar elements. To confuse matters, the periodic table of the time had space for only one element between Ba and Hf, which turned out to be La. Not until 1913, when the atomic-number basis of the table was established, did chemists realize that 14 new elements could fit, and in 1918, Niels Bohr proposed that the $n = 4$ level be expanded to include the *f* sublevel.

23.2 THE INNER TRANSITION ELEMENTS

The 14 **lanthanides**—cerium (Ce; $Z = 58$) through lutetium (Lu; $Z = 71$)—lie between lanthanum ($Z = 57$) and hafnium ($Z = 72$) in the third *d*-block transition series. Below them are the 14 radioactive **actinides,** thorium (Th; $Z = 90$) through lawrencium (Lr; $Z = 103$), which lie between actinium (Ac; $Z = 89$) and rutherfordium (Rf; $Z = 104$). The lanthanides and actinides are called **inner transition elements** because, in most cases, their seven inner $4f$ or $5f$ orbitals are being filled.

The Lanthanides

The lanthanides are sometimes called the *rare earth elements,* a term referring to their presence in unfamiliar oxides, but they are actually not rare at all. Cerium (Ce), for instance, ranks 26th in natural abundance (by mass %) and is five times more abundant than lead. All the lanthanides are silvery, high-melting (800°C to 1600°C) metals. Their chemical properties represent an extreme case of the small variations typical of transition elements in a period or a group, which makes the lanthanides very difficult to separate.

The natural co-occurrence of the lanthanides arises because they exist as M^{3+} ions of very similar radii in their common ores. Most lanthanides have the ground-state electron configuration [Xe] $6s^2 4f^x 5d^0$, where x varies across the series. The three exceptions (Ce, Gd, and Lu) have a single electron in one of their $5d$ orbitals: Ce ([Xe] $6s^2 4f^1 5d^1$) forms a stable 4+ ion with an empty (f^0) sublevel, and the Gd^{3+} and Lu^{3+} ions have a stable half-filled (f^7) or filled (f^{14}) sublevel.

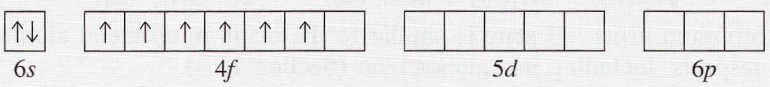
Lanthanide compounds and their mixtures have many uses. Several oxides are used for tinting sunglasses and welder's goggles and for adding color to the fluorescent powder coatings in TV screens. High-quality camera lenses incorporate La_2O_3 because of its extremely high index of refraction. Samarium forms an alloy with cobalt, $SmCo_5$, that is used in the strongest known permanent magnet (see Sample Problem 23.2). Two industrial uses account for more than 60% of rare earth applications. In gasoline refining, the zeolite catalysts (Gallery, p. 581) used to "crack" hydrocarbon components into smaller molecules contain 5% by mass rare earth oxides. In steelmaking, a mixture of lanthanides, called *misch metal,* is used to remove carbon impurities from molten iron and steel.

SAMPLE PROBLEM 23.2 Finding the Number of Unpaired Electrons

Problem The alloy $SmCo_5$ forms a permanent magnet because both samarium and cobalt have unpaired electrons. How many unpaired electrons are in the Sm atom ($Z = 62$)?

Plan We write the condensed electron configuration of Sm and then, using Hund's rule and the aufbau principle, place the electrons in a partial orbital diagram and count the unpaired electrons.

Solution Samarium is the eighth element after Xe. Two electrons go into the $6s$ sublevel. In general, the $4f$ sublevel fills before the $5d$ (among the lanthanides, only Ce, Gd, and Lu have $5d$ electrons), so the remaining electrons go into the $4f$. Thus, Sm is [Xe] $6s^2 4f^6$. There are seven f orbitals, so each of the six f electrons enters a separate orbital:



Thus, Sm has six unpaired electrons.

Check Six $4f$ e^- plus two $6s$ e^- plus the 54 e^- in Xe gives 62, the atomic number of Sm.

FOLLOW-UP PROBLEM 23.2 How many unpaired electrons are in the Er^{3+} ion?

The Actinides

All actinides are radioactive. Like the lanthanides, they share very similar physical and chemical properties. Thorium and uranium occur in nature, but the transuranium elements, those with Z greater than 92, have been synthesized in high-energy particle accelerators, some in only tiny amounts (Section 24.3). In fact, macroscopic samples of mendelevium (Md), nobelium (No), and lawrencium (Lr) have never been seen. The actinides that have been isolated are silvery and chemically reactive and, like the lanthanides, form highly colored compounds. The actinides and lanthanides have similar outer-electron configurations. Although the +3 oxidation state is characteristic of the actinides, as it is for the lanthanides, other states also occur. For example, uranium exhibits +3 through +6 states, with the +6 state the most prevalent; thus, the most common oxide of uranium is UO_3.

SECTION SUMMARY

There are two series of inner transition elements. The lanthanides ($4f$ series) have a common +3 oxidation state and exhibit very similar properties. The actinides ($5f$ series) are radioactive. All actinides have a +3 oxidation state; several, including uranium, have higher states as well.

23.3 HIGHLIGHTS OF SELECTED TRANSITION METALS

Let's investigate several transition elements, focusing on the general patterns in the aqueous chemistry of each. We examine chromium and manganese from Period 4, silver from Period 5, and mercury from Period 6.

Chromium

Chromium is a very shiny, silvery metal, whose name (from the Greek *chroma,* "color") refers to its many colorful compounds. A solution of Cr^{3+} is deep violet, for example, and a trace of Cr^{3+} in the Al_2O_3 crystal structure gives ruby its beautiful red hue (see photo p. 1002). Chromium readily forms a thin, adherent, transparent coating of Cr_2O_3 in air, making the metal extremely useful as an attractive protective coating on easily corroded metals, such as iron. "Stainless" steels often contain as much as 18% chromium by mass and are highly resistant to corrosion.

With six valence electrons ([Ar] $4s^1 3d^5$), chromium occurs in all possible positive oxidation states, but the three most important are +2, +3, and +6 (see Table 23.2). In its three common oxides, chromium exhibits the pattern seen in many elements: *nonmetallic character and oxide acidity increase with metal oxidation state*. Chromium(II) oxide (CrO) is basic and largely ionic. It forms an insoluble hydroxide in neutral or basic solution but dissolves in acidic solution to yield the Cr^{2+} ion:

$$CrO(s) + 2H^+(aq) \longrightarrow Cr^{2+}(aq) + H_2O(l)$$

Chromium(III) oxide (Cr_2O_3) is amphoteric, dissolving in acid to yield the violet Cr^{3+} ion,

$$Cr_2O_3(s) + 6H^+(aq) \longrightarrow 2Cr^{3+}(aq) + 3H_2O(l)$$

and in base to form the green $Cr(OH)_4^-$ ion:

$$Cr_2O_3(s) + 3H_2O(l) + 2OH^-(aq) \longrightarrow 2Cr(OH)_4^-(aq)$$

Thus, chromium in its +3 state is similar to the main-group metal aluminum in several respects, including its amphoterism (Section 19.4).

Deep-red chromium(VI) oxide (CrO_3) is covalent and acidic, forming chromic acid (H_2CrO_4) in water,

$$CrO_3(s) + H_2O(l) \longrightarrow H_2CrO_4(aq)$$

which yields the yellow chromate ion (CrO_4^{2-}) in base:

$$H_2CrO_4(aq) + 2OH^-(aq) \longrightarrow CrO_4^{2-}(aq) + 2H_2O(l)$$

In acidic solution, the chromate ion immediately forms the orange dichromate ion ($Cr_2O_7^{2-}$):

$$2CrO_4^{2-}(aq) + 2H^+(aq) \rightleftharpoons Cr_2O_7^{2-}(aq) + H_2O(l)$$

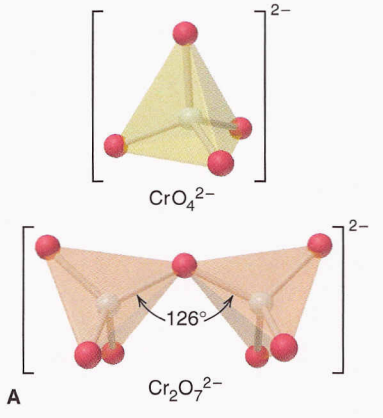
Because both ions contain chromium(VI), this is not a redox reaction; rather, it is a dehydration-condensation, as you can see from the structures in Figure 23.7. Hydrogen-ion concentration controls the equilibrium position: yellow CrO_4^{2-} predominates at high pH and orange $Cr_2O_7^{2-}$ at low pH. The bright colors of chromium(VI) compounds lead to their wide use in pigments for artist's paints and ceramic glazes. Lead chromate (chrome yellow) is used as an oil-paint color, and also in the yellow stripes that delineate traffic lanes.

Chromium metal and the Cr^{2+} ion are potent reducing agents. The metal displaces hydrogen from dilute acids to form blue $Cr^{2+}(aq)$, which reduces O_2 in air within minutes to form the violet Cr^{3+} ion:

$$4Cr^{2+}(aq) + O_2(g) + 4H^+(aq) \longrightarrow 4Cr^{3+}(aq) + 2H_2O(l) \qquad E^0_{overall} = 1.64\ V$$

Chromium(VI) compounds in acid solution are strong oxidizing agents (concentrated solutions are *extremely* corrosive!), the chromium(VI) being readily reduced to chromium(III):

$$Cr_2O_7^{2-}(aq) + 14H^+(aq) + 6e^- \longrightarrow 2Cr^{3+}(aq) + 7H_2O(l) \qquad E^0 = 1.33\ V$$



A

B

Figure 23.7 The bright colors of chromium(VI) compounds. A, Structures of the chromate (CrO_4^{2-}) and dichromate ($Cr_2O_7^{2-}$) ions. **B,** Samples of K_2CrO_4 (*yellow*) and $K_2Cr_2O_7$ (*orange*).

This reaction is often used to determine the iron content of a water or soil sample by oxidizing Fe^{2+} to Fe^{3+} ion. In basic solution, the CrO_4^{2-} ion, which is a much weaker oxidizing agent, predominates:

$$CrO_4^{2-}(aq) + 4H_2O(l) + 3e^- \longrightarrow Cr(OH)_3(s) + 5OH^-(aq) \qquad E^0 = -0.13\ V$$

The Concept of Valence-State Electronegativity Why does oxide acidity increase with oxidation state? And how can a metal, like chromium, form an oxoanion? To answer such questions, we must apply the concept of electronegativity to the various oxidation states of an element. A metal in a higher oxidation state is more positively charged, which increases its attraction for electrons; in effect, its *electronegativity increases*. This effective electronegativity, called *valence-state electronegativity,* also has numerical values. The electronegativity of chromium metal is 1.6, close to that of aluminum (1.5), another active metal. For chromium(III), the value increases to 1.7, still characteristic of a metal. However, the electronegativity of chromium(VI) is 2.3, close to the values of some nonmetals, such as phosphorus (2.1), selenium (2.4), and carbon (2.5). Thus, like P in PO_4^{3-}, Cr in chromium(VI) compounds often occurs covalently bonded at the center of the oxoanion of a relatively strong acid.

Manganese

Elemental manganese is hard and shiny and, like vanadium and chromium, is used mostly to make steel alloys. A small amount of Mn (<1%) makes steel easier to roll, forge, and weld. Steel made with 12% Mn is tough enough to be used for naval armor, front-end loader buckets (see photo), and other extremely hard steel objects. Small amounts of manganese are added to aluminum beverage cans and bronze alloys to make them stiffer and tougher as well.

Front-end loader parts are made of steel containing manganese.

The chemistry of manganese resembles that of chromium in some respects. The free metal is quite reactive and readily reduces H^+ from acids, forming the pale-pink Mn^{2+} ion:

$$Mn(s) + 2H^+(aq) \longrightarrow Mn^{2+}(aq) + H_2(g) \qquad E^0 = 1.18\ V$$

Like chromium, manganese can use all its valence electrons in its compounds, exhibiting every possible positive oxidation state, with the +2, +4, and +7 states most common (Table 23.5). As the oxidation state of manganese rises, its valence-state electronegativity increases and its oxides change from basic to acidic. Manganese(II) oxide (MnO) is basic, and manganese(III) oxide (Mn_2O_3) is amphoteric. Manganese(IV) oxide (MnO_2) is insoluble and shows no acid-base properties. [It is used in dry cells and alkaline batteries as the oxidizing agent in a redox reaction with zinc (Chapter 21, p. 932).] Manganese(VII) oxide (Mn_2O_7),

Table 23.5 Some Oxidation States of Manganese

Oxidation state*	**Mn(II)**	Mn(III)	**Mn(IV)**	Mn(VI)	**Mn(VII)**
Example	Mn^{2+}	Mn_2O_3	MnO_2	MnO_4^{2-}	MnO_4^-
Orbital occupancy	d^5	d^4	d^3	d^1	d^0
Oxide acidity	BASIC				ACIDIC

*Most common states in **boldface.**

Sharing the Ocean's Wealth At their current rate of usage, known reserves of many key transition metals will be depleted in less than 50 years. Other sources must be found. One promising source is nodules strewn over large portions of the ocean floor. Varying from a few millimeters to a few meters in diameter, these chunks consist mainly of manganese and iron oxides, with oxides of other elements present in smaller amounts. Billions of tons exist, but mining them presents major technical and political challenges. Global agreements have designated the ocean floor as international property, so cooperation will be required to mine the nodules and share the mineral rewards.

which forms by reaction of Mn with pure O_2, reacts with water to form permanganic acid ($HMnO_4$), which is as strong as perchloric acid ($HClO_4$).

All manganese species with oxidation states greater than +2 act as oxidizing agents, but the purple permanganate (MnO_4^-) ion is particularly powerful. Like ions with chromium in its highest oxidation state, MnO_4^- is a much stronger oxidizing agent in acidic than in basic solution:

$$MnO_4^-(aq) + 4H^+(aq) + 3e^- \longrightarrow MnO_2(s) + 2H_2O(l) \qquad E^0 = 1.68\ V$$

$$MnO_4^-(aq) + 2H_2O(l) + 3e^- \longrightarrow MnO_2(s) + 4OH^-(aq) \qquad E^0 = 0.59\ V$$

Unlike Cr^{2+} and Fe^{2+}, the Mn^{2+} ion resists oxidation in air. The Cr^{2+} ion is a d^4 species and readily loses a $3d$ electron to form the d^3 ion Cr^{3+}, which is more stable. The Fe^{2+} ion is a d^6 species, and removing a $3d$ electron yields the stable, half-filled d^5 configuration of Fe^{3+}. Removing an electron from Mn^{2+} disrupts its stable d^5 configuration.

Silver

Silver, the second member of the coinage metals [Group 1B(11)], has been admired for thousands of years and is still treasured for use in jewelry and fine flatware. Because the pure metal is too soft for these purposes, however, it is alloyed with copper to form the harder sterling silver. In former times, silver was used in coins, but it has been replaced almost universally by copper-nickel alloys. Silver has the *highest electrical conductivity of any element* but is not used in wiring because copper is cheaper and more plentiful. In the past, silver was found in nuggets and veins of rock, often mixed with gold, because both elements are chemically inert enough to exist uncombined. Nearly all of those deposits have been mined, so most silver is now obtained from the anode mud formed during the electrorefining of copper (Section 22.4).

The only important oxidation state of silver is +1. Its most important *soluble* compound is silver nitrate, used for electroplating and in the manufacture of the halides used for photographic film. Although silver forms no oxide in air, it tarnishes to black Ag_2S by reaction with traces of sulfur-containing compounds. Some polishes remove the Ag_2S, along with some silver, by physically abrading the surface. An alternative "home remedy" that removes the tarnish and restores the metal involves heating the object in a solution of table salt or baking soda ($NaHCO_3$) in an aluminum pan. Aluminum, a strong reducing agent, reduces the Ag^+ ions back to the metal:

$$2Al(s) + 3Ag_2S(s) + 6H_2O(l) \longrightarrow 2Al(OH)_3(s) + 6Ag(s) + 3H_2S(g) \qquad E^0 = 0.86\ V$$

The Chemistry of Black-and-White Photography The most widespread use of silver compounds—particularly the three halides AgCl, AgBr, and AgI—is in black-and-white photography, an art that applies transition metal chemistry and solution kinetics. The photographic film itself is simply a flexible plastic support for the light-sensitive emulsion, which consists of AgBr microcrystals dispersed in gelatin. The five steps in obtaining a final photograph are exposing the film, developing the image, fixing the image, washing the negative, and printing the image. Figure 23.8 summarizes the first four of these steps. The process depends on several key chemical properties of silver and its compounds:

- Silver halides undergo a redox reaction when exposed to visible light.
- Silver chloride, bromide, and iodide are *not* water soluble.
- Ag^+ is easily reduced: $Ag^+(aq) + e^- \longrightarrow Ag(s)$; $E^0 = 0.80$ V.
- Ag^+ forms several stable, water-soluble complex ions.

1. *Exposing the film.* Light reflected from the objects in a scene—more light from bright objects than from dark ones—enters the camera lens and strikes the film. Exposed AgBr crystals absorb photons ($h\nu$) in a very localized redox reac-

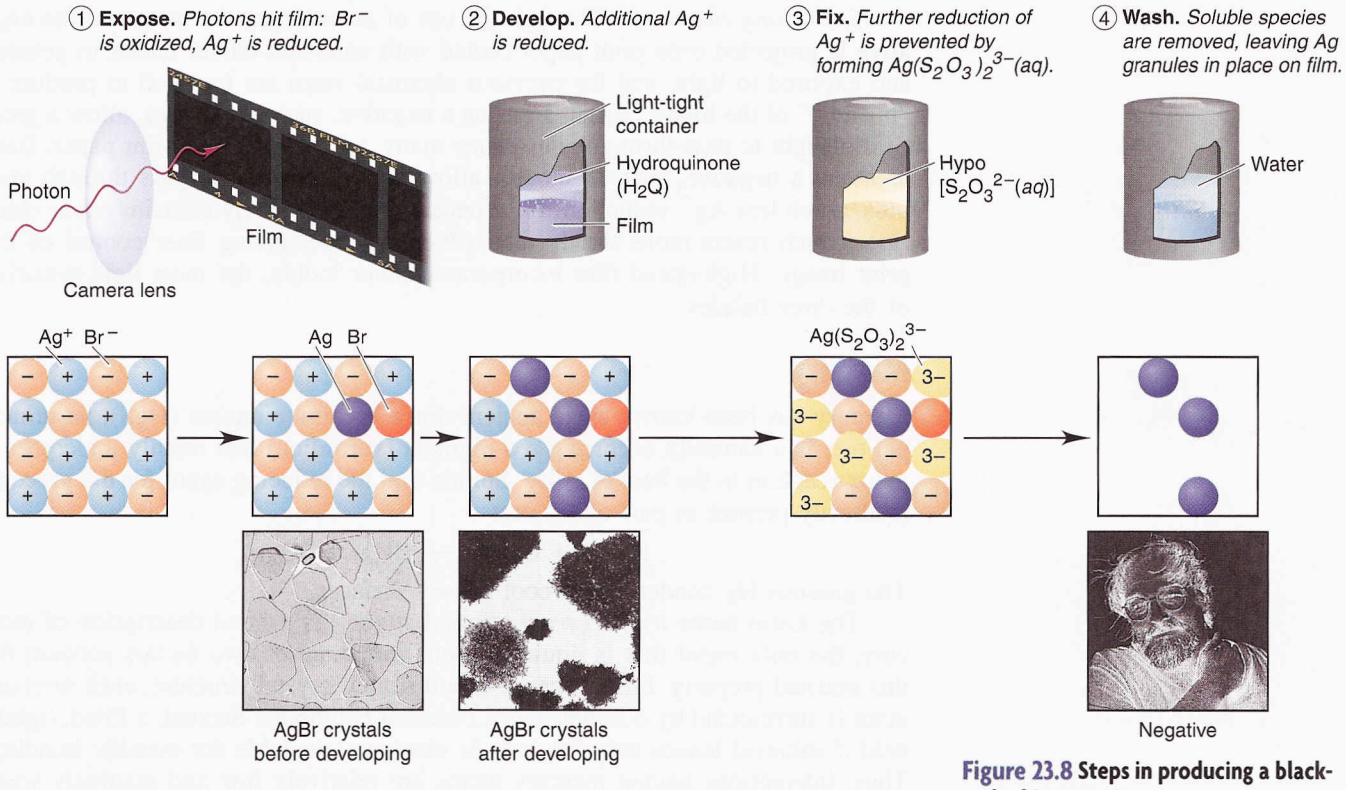


Figure 23.8 Steps in producing a black-and-white negative.

tion. A Br^- ion is excited by a photon and oxidized, and the released electron almost immediately reduces a nearby Ag^+ ion:

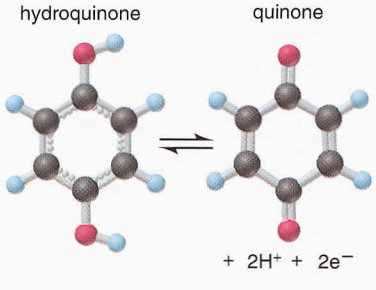
$$\begin{aligned} Br^- &\xrightarrow{h\nu} Br + e^- \\ Ag^+ + e^- &\longrightarrow Ag \\ \hline Ag^+ + Br^- &\xrightarrow{h\nu} Ag + Br \end{aligned}$$

Wherever more light strikes a microcrystal, more Ag atoms form. The exposed crystals are called a *latent image* because the few scattered atoms of photoreduced Ag are not yet visible. Nevertheless, their presence as crystal defects within the AgBr crystal makes it highly susceptible to further reduction.

2. *Developing the image.* The latent image is developed into the actual image by reducing more of the silver ions in the crystal in a controlled manner. Developing is a rate-dependent step: crystals with many photoreduced Ag atoms react more quickly than those with only a few. The developer is a weak reducing agent, such as the organic substance hydroquinone ($H_2C_6H_4O_2$; H_2Q) (see margin):

$$2Ag^+(s) + H_2Q(aq;\ \text{reduced form}) \longrightarrow 2Ag(s) + Q(aq;\ \text{oxidized form}) + 2H^+(aq)$$

The reaction rate depends on H_2Q concentration, solution temperature, and the length of time the emulsion is bathed in the solution. After developing, approximately 10^6 as many Ag atoms are present on the film as there were in the latent image, and they form very small, black clusters of silver.



3. *Fixing the image.* After the image is developed, it must be "fixed"; that is, the reduction of Ag^+ must be stopped, or the entire film will blacken on exposure to more light. Fixing involves removing the remaining Ag^+ chemically by converting it to a soluble complex ion with sodium thiosulfate solution ("hypo"):

$$AgBr(s) + 2S_2O_3^{2-}(aq) \longrightarrow Ag(S_2O_3)_2^{3-}(aq) + Br^-(aq)$$

4. *Washing the negative.* The water-soluble ions are washed away in water. Washing is the final step in producing a photographic *negative,* in which dark objects in the scene appear bright in the image, and vice versa.

5. *Printing the image.* Through the use of an enlarger, the image on the negative is projected onto print paper coated with emulsion (silver halide in gelatin) and exposed to light, and the previous chemical steps are repeated to produce a "positive" of the image. Bright areas on a negative, such as car tires, allow a great deal of light to pass through and reduce many Ag^+ ions on the print paper. Dark areas on a negative, such as clouds, allow much less light to pass through and, thus, much less Ag^+ reduction. Print-paper emulsion usually contains silver chloride, which reacts more slowly than silver bromide, giving finer control of the print image. High-speed film incorporates silver iodide, the most light-sensitive of the three halides.

Mercury

Mercury has been known since ancient times because cinnabar (HgS), its principal ore, is a naturally occurring red pigment (vermilion) that readily undergoes a redox reaction in the heat of a fire. Sulfide ion, the reducing agent for the process, is already present as part of the ore:

$$HgS(s) + O_2(g) \longrightarrow Hg(g) + SO_2(g)$$

The gaseous Hg condenses on cool nearby surfaces.

The Latin name *hydrargyrum* ("liquid silver") is a good description of mercury, the only metal that is liquid at room temperature. Two factors account for this unusual property. First, because of a distorted crystal structure, each mercury atom is surrounded by 6 rather than 12 nearest neighbors. Second, a filled, tightly held *d* sublevel leaves only the two 6*s* electrons available for metallic bonding. Thus, interactions among mercury atoms are relatively few and relatively weak and, as a result, the solid form breaks down at −38.9°C.

Many of mercury's uses arise from its unusual physical properties. Its liquid range (−39°C to 357°C) encompasses most everyday temperatures, so Hg is commonly used in thermometers. As you might expect from its position in Period 6 following the lanthanide contraction, mercury is quite dense (13.5 g/mL), which makes it convenient for use in barometers and manometers. Mercury's fluidity and conductivity make it useful for "silent" switches in thermostats. At high pressures, mercury vapor can be excited electrically to emit the bright white light seen in sports stadium and highway lights.

Mercury is a good solvent for other metals, and many *amalgams* (alloys of mercury) exist. In mercury batteries, a zinc amalgam acts as the anode and mercury(II) oxide acts as the cathode (Chapter 21, p. 933). In the mercury-cell version of the chlor-alkali process (Chapter 22, p. 995), mercury acts as the cathode and as the solvent for the sodium metal that forms. Recall that, when treated with water, the resulting sodium amalgam, Na(Hg), forms two important by-products:

$$2Na(Hg) + 2H_2O(l) \xrightarrow{-Hg} 2NaOH(aq) + H_2(g)$$

The mercury is released in this step and reused in the electrolytic cell. In view of mercury's toxicity, which we discuss shortly, a newer method involving a polymeric membrane is replacing the mercury-cell method. Nevertheless, past contamination of wastewater from the chlor-alkali process and the disposal of old mercury batteries remain serious environmental concerns.

The chemical properties of mercury are unique within Group 2B(12). The other members, zinc and cadmium, occur in the +2 oxidation state as d^{10} ions, but mercury occurs in the +1 state as well, with the condensed electron configuration [Xe] $6s^1 4f^{14} 5d^{10}$. We can picture the unpaired 6*s* electron allowing two Hg(I) species to form the *diatomic ion* $[Hg—Hg]^{2+}$ (written Hg_2^{2+}), one of the

first species known with a covalent metal-metal bond (but also see the footnote on p. 1008). Mercury's more common oxidation state is +2. Whereas HgF_2 is largely ionic, many other compounds, such as $HgCl_2$, contain bonds that are predominantly covalent. Most mercury(II) compounds are insoluble in water.

The common ions Zn^{2+}, Cd^{2+}, and Hg^{2+} are biopoisons. Zinc oxide is used as an external antiseptic ointment. The Cd^{2+} and Hg^{2+} ions are two of the so-called toxic heavy-metal ions. The cadmium in solder may be more responsible than the lead for solder's high toxicity. Mercury compounds have been used in agriculture as fungicides and pesticides and in medicine as internal drugs, but these uses have been largely phased out.

Because most mercury(II) compounds are insoluble in water, they were once thought to be harmless in the environment; but we now know otherwise. Microorganisms in sludge and river sediment convert mercury atoms and ions to the methyl mercury ion, $CH_3—Hg^+$, and then to organomercury compounds, such as dimethylmercury, $CH_3—Hg—CH_3$. These toxic compounds are nonpolar and, like chlorinated hydrocarbons, become increasingly concentrated in fatty tissues, as they move up a food chain from microorganisms to worms to fish and, finally, to birds and mammals. Indeed, fish living in a mercury-polluted lake or coastal estuary can have a mercury concentration thousands of times higher than that of the water itself.

The mechanism for the toxicity of mercury and other heavy-metal ions is not fully understood. It is thought that the ions migrate from fatty tissue and bind strongly to thiol (—SH) groups of amino acids in proteins, thereby disrupting the proteins' structure and function. Because the brain has a high fat content, small amounts of lead, cadmium, and mercury ions circulating in the blood become deposited in the brain's fatty tissue, interact with its proteins, and often cause devastating neurological and psychological effects.

Mad as a Hatter The felt top hat and zany manner of the Mad Hatter in *Alice in Wonderland* are literary references to the toxicity of mercury compounds. Mercury(II) nitrate and chloride were used with HNO_3 to make felt for hats from animal hair. Inhalation of the dust generated by the process led to "hatter's shakes," abnormal behavior, and other neurological and psychological symptoms.

SECTION SUMMARY

Chromium and manganese add corrosion resistance and hardness to steels. They are typical of transition metals in having several oxidation states. Valence-state electronegativity refers to the ability of an element in its various oxidation states to attract bonding electrons. It increases with oxidation number, which is the reason elements act more metallic (more ionic compounds, more basic oxides) in lower states and more nonmetallic (more acidic oxides, oxoanions of acids) in higher states. Cr and Mn produce H_2 in acid. Cr(VI) undergoes a pH-sensitive dehydration-condensation reaction. Both Cr(VI) and Mn(VII) are stronger oxidizing agents in acid than in base. The only important oxidation state for silver is +1. The silver halides are light sensitive and are used in photography. Mercury, the only metal that is liquid at room temperature, dissolves many other metals in important applications. The mercury(I) ion is diatomic and has a metal-metal covalent bond. The element and its compounds are toxic and become concentrated as they move up a food chain.

23.4 COORDINATION COMPOUNDS

The most distinctive aspect of transition metal chemistry is the formation of **coordination compounds** (also called *complexes*). These are substances that contain at least one **complex ion,** a species consisting of *a central metal cation (either a transition metal or a main-group metal) that is bonded to molecules and/or anions called* ***ligands.*** In order to maintain charge neutrality in the coordination compound, the complex ion is typically associated with other ions, called **counter ions.**

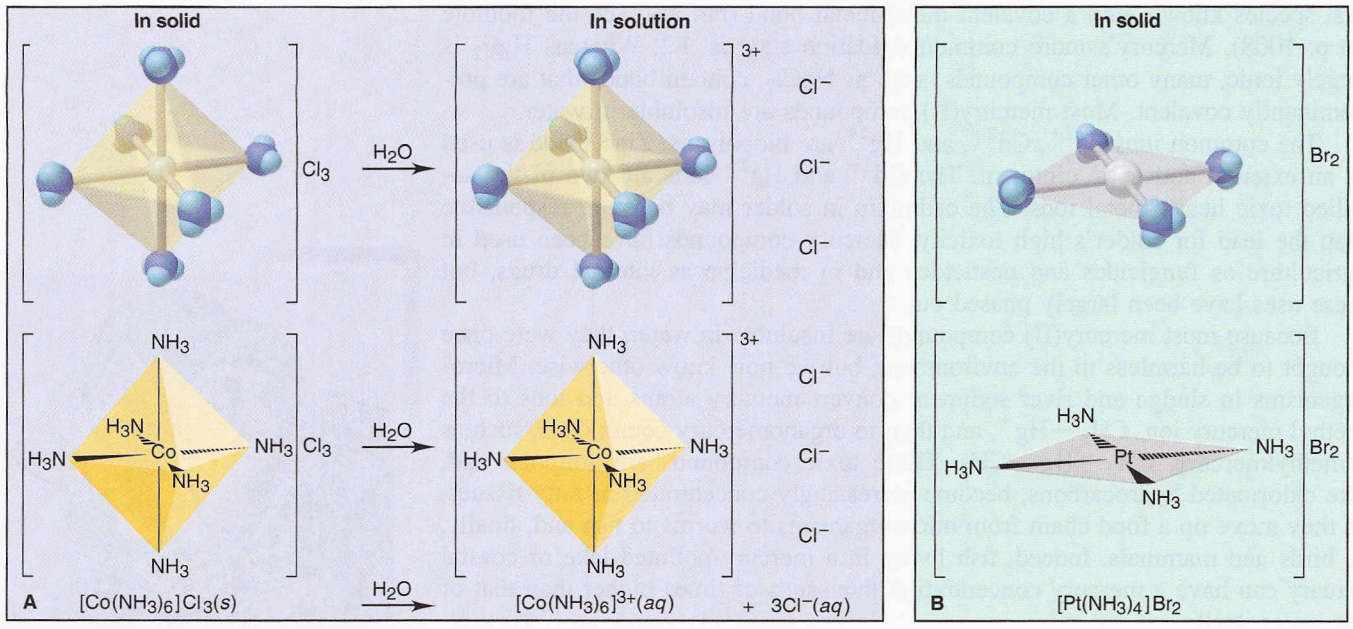


Figure 23.9 Components of a coordination compound. Coordination compounds, shown here as models (*top*), perspective drawings (*middle*), and chemical formulas (*bottom*), typically consist of a complex ion and counter ions to neutralize the charge. The complex ion has a central metal ion surrounded by ligands. **A,** When solid $[Co(NH_3)_6]Cl_3$ dissolves, the complex ion and the counter ions separate, but the ligands remain bound to the metal ion. Six ligands around the metal ion give the complex ion an octahedral geometry. **B,** Complex ions with a central d^8 metal ion have four ligands and a square planar geometry.

A typical coordination compound appears in Figure 23.9A: the coordination compound is $[Co(NH_3)_6]Cl_3$, the complex ion (always enclosed in square brackets) is $[Co(NH_3)_6]^{3+}$, the six NH_3 molecules bonded to the central Co^{3+} are ligands, and the three Cl^- ions are counter ions. *A coordination compound behaves like an electrolyte in water:* the complex ion and counter ions separate from each other. But the complex ion behaves like a polyatomic ion: *the ligands and central metal ion remain attached.* Thus, as Figure 23.9A shows, 1 mol of $[Co(NH_3)_6]Cl_3$ yields 1 mol of $[Co(NH_3)_6]^{3+}$ ions and 3 mol of Cl^- ions.

We discussed the Lewis acid-base properties of hydrated metal ions, which are a type of complex ion, in Section 18.9, and we examined complex-ion equilibria in Section 19.4. In this section, we consider the bonding, structure, and properties of complex ions.

Complex Ions: Coordination Numbers, Geometries, and Ligands

A complex ion is described by the metal ion and the number and types of ligands attached to it. Its structure is related to three characteristics—coordination number, geometry, and number of donor atoms per ligand:

- *Coordination number.* The **coordination number** is the *number of ligand atoms* that are bonded directly to the central metal ion and is *specific* for a given metal ion in a particular oxidation state and compound. The coordination number of the Co^{3+} ion in $[Co(NH_3)_6]^{3+}$ is 6 because six ligand atoms (N from NH_3) are bonded to it. The coordination number of the Pt^{2+} ion in many of its complexes is 4, whereas that of the Pt^{4+} ion in its complexes is 6. Copper(II) may have a coordination number of 2, 4, or 6 in different complex ions. In general, *the most common coordination number in complex ions is 6,* but 2 and 4 are often seen, and some higher ones are also known.
- *Geometry. The geometry (shape) of a complex ion depends on the coordination number and nature of the metal ion.* Table 23.6 shows the geometries associated with the coordination numbers 2, 4, and 6, with some examples of each. A complex ion whose metal ion has a coordination number of 2, such as $[Ag(NH_3)_2]^+$, is *linear.* The coordination number 4 gives rise to either of two geometries—square planar or tetrahedral. Most d^8 metal ions form *square planar* complex ions, depicted in Figure 23.9B. The d^{10} ions are among those that

Table 23.6 Coordination Numbers and Shapes of Some Complex Ions

Coordination Number	Shape		Examples
2	Linear		$[CuCl_2]^-$, $[Ag(NH_3)_2]^+$, $[AuCl_2]^-$
4	Square planar		$[Ni(CN)_4]^{2-}$, $[PdCl_4]^{2-}$, $[Pt(NH_3)_4]^{2+}$, $[Cu(NH_3)_4]^{2+}$
4	Tetrahedral		$[Cu(CN)_4]^{3-}$, $[Zn(NH_3)_4]^{2+}$, $[CdCl_4]^{2-}$, $[MnCl_4]^{2-}$
6	Octahedral		$[Ti(H_2O)_6]^{3+}$, $[V(CN)_6]^{4-}$, $[Cr(NH_3)_4Cl_2]^+$, $[Mn(H_2O)_6]^{2+}$, $[FeCl_6]^{3-}$, $[Co(en)_3]^{3+}$

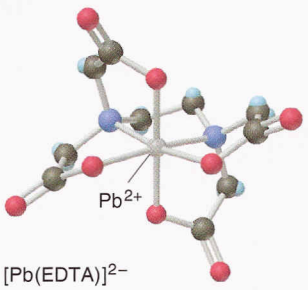
form *tetrahedral* complex ions. A coordination number of 6 results in an *octahedral* geometry, as shown by $[Co(NH_3)_6]^{3+}$ in Figure 23.9A. Note the similarity with some of the molecular shapes in VSEPR theory (Section 10.2).

- *Donor atoms per ligand.* The ligands of complex ions are *molecules or anions* with one or more **donor atoms** that each *donate a lone pair of electrons* to the metal ion to form a covalent bond. Because they have at least one lone pair, donor atoms often come from Group 5A(15), 6A(16), or 7A(17).

Ligands are classified in terms of the number of donor atoms, or "teeth," that each uses to bond to the central metal ion. *Monodentate* (Latin, "one-toothed") ligands, such as Cl^- and NH_3, use a single donor atom. *Bidentate* ligands have two donor atoms, each of which bonds to the metal ion. *Polydentate* ligands have more than two donor atoms. Table 23.7 shows some common ligands in coordination compounds; note that each ligand has one or more donor atoms (colored type), each with a lone pair of electrons to donate. Bidentate and polydentate

Table 23.7 Some Common Ligands in Coordination Compounds

Ligand Type	Examples							
Monodentate	$H_2\ddot{O}:$ water	$:\ddot{F}:^-$	fluoride ion	$[:C\equiv N:]^-$	cyanide ion	$[:\ddot{O}—H]^-$	hydroxide ion	
	$:NH_3$ ammonia	$:\ddot{Cl}:^-$	chloride ion	$[:\ddot{S}=C=\ddot{N}:]^-$ (or $[:S\equiv C—\ddot{N}:]^-$)	thiocyanate ion	$[:\ddot{O}—N=\ddot{O}:]^-$ (or $[:\ddot{O}—N\equiv O:]^+$)	nitrite ion	
Bidentate	 ethylenediamine (en)	 oxalate ion						
Polydentate	 diethylenetriamine	 triphosphate ion				 ethylenediaminetetraacetate ion ($EDTA^{4-}$)		



[Pb(EDTA)]$^{2-}$

Grabbing Ions Because it has 6 donor atoms, the ethylenediaminetetraacetate ($EDTA^{4-}$) ion forms very stable complexes with many metal ions. This property makes EDTA useful in treating heavy-metal poisoning. Once ingested by the patient, the ion acts as a scavenger to remove lead and other heavy-metal ions from the blood and other body fluids.

ligands give rise to *rings* in the complex ion. For instance, ethylenediamine (abbreviated *en* in formulas) has a chain of four atoms (:N—C—C—N:), so it forms a five-membered ring, with the two electron-donating N atoms bonding to the metal atom. Such ligands seem to grab the metal ion like claws, so a complex ion that contains them is also called a **chelate** (pronounced "KEY-late"; Greek *chela,* "crab's claw").

Formulas and Names of Coordination Compounds

There are three important rules for writing the formulas of coordination compounds, the first two being the same for writing formulas of any ionic compound:

1. *The cation is written before the anion.*
2. *The charge of the cation(s) is balanced by the charge of the anion(s).*
3. *In the complex ion, neutral ligands are written before anionic ligands, and the formula for the whole ion is placed in brackets.*

Let's apply these rules as we examine the combinations of ions in coordination compounds. *The whole complex ion may be a cation or an anion.* A complex cation has anionic counter ions, and a complex anion has cationic counter ions. It's easy to find the charge of the central metal ion. For example, in $K_2[Co(NH_3)_2Cl_4]$, two K^+ counter ions balance the charge of the complex anion $[Co(NH_3)_2Cl_4]^{2-}$, which contains two NH_3 molecules and four Cl^- ions as ligands. The two NH_3 are neutral, the four Cl^- have a total charge of 4−, and the entire complex ion has a charge of 2−, so the central metal ion must be Co^{2+}:

$$\text{Charge of complex ion} = \text{Charge of metal ion} + \text{total charge of ligands}$$
$$2- = \text{Charge of metal ion} + [(2 \times 0) + (4 \times 1-)]$$
$$\text{So,} \quad \text{Charge of metal ion} = (2-) - (4-) = 2+$$

In the compound $[Co(NH_3)_4Cl_2]Cl$, the complex ion is $[Co(NH_3)_4Cl_2]^+$ and one Cl^- is the counter ion. The four NH_3 ligands are neutral, the two Cl^- ligands have a total charge of 2−, and the complex cation has a charge of 1+, so the central metal ion must be Co^{3+} [that is, 1+ = (3+) + (2−)]. Some coordination compounds have a complex cation *and* a complex anion, as in $[Co(NH_3)_5Br]_2[Fe(CN)_6]$. In this compound, the complex cation is $[Co(NH_3)_5Br]^{2+}$, with Co^{3+}, and the complex anion is $[Fe(CN)_6]^{4-}$, with Fe^{2+}.

Coordination compounds were originally named after the person who first prepared them or from their color, and some of these common names are still used, but most coordination compounds are named systematically through a set of rules:

1. *The cation is named before the anion.* In naming $[Co(NH_3)_4Cl_2]Cl$, for example, we name the $[Co(NH_3)_4Cl_2]^+$ ion before the Cl^- ion. Thus, the name is

   tetraamminedichlorocobalt(III) chloride

   The only space in the name appears between the cation and the anion.
2. *Within the complex ion, the ligands are named, in alphabetical order,* ***before*** *the metal ion.* Note that in the $[Co(NH_3)_4Cl_2]^+$ ion of the compound named in rule 1, the four NH_3 and two Cl^- are named before the Co^{3+}.
3. *Neutral ligands generally have the molecule name,* but there are a few exceptions (Table 23.8). *Anionic ligands drop the -ide and add -o after the root name;* thus, the name *fluoride* for the F^- ion becomes the ligand name *fluoro*. The two ligands in $[Co(NH_3)_4Cl_2]^+$ are *ammine* (NH_3) and *chloro* (Cl^-) with *ammine* coming before *chloro* alphabetically.
4. *A numerical prefix indicates the number of ligands of a particular type.* For example, *tetra*ammine denotes *four* NH_3, and *di*chloro denotes *two* Cl^-. Other prefixes are *tri-, penta-,* and *hexa-*. These prefixes do *not* affect the alphabetical order; thus, *tetraammine* comes before *dichloro*. Because some ligand

Table 23.8 Names of Some Neutral and Anionic Ligands

Neutral		Anionic	
Name	**Formula**	**Name**	**Formula**
Aqua	H_2O	Fluoro	F^-
Ammine	NH_3	Chloro	Cl^-
Carbonyl	CO	Bromo	Br^-
Nitrosyl	NO	Iodo	I^-
		Hydroxo	OH^-
		Cyano	CN^-

names already contain a numerical prefix (such as ethylene*di*amine), we use *bis* (2), *tris* (3), or *tetrakis* (4) to indicate the number of such ligands, followed by the ligand name in parentheses. Therefore, a complex ion that has two ethylenediamine ligands has *bis(ethylenediamine)* in its name.

5. *The oxidation state of the central metal ion is given by a Roman numeral (in parentheses) only* if the metal ion can have more than one state, as in the compound named in rule 1.
6. *If the complex ion is an anion, we drop the ending of the metal name and add -ate.* Thus, the name for $K[Pt(NH_3)Cl_5]$ is

potassium amminepentachloroplatinate(IV)

(Note that there is one K^+ counter ion, so the complex anion has a charge of 1−. The five Cl^- ligands have a total charge of 5−, so Pt must be in the +4 oxidation state.) For some metals, we use the Latin root with the *-ate* ending, shown in Table 23.9. For example, the name for $Na_4[FeBr_6]$ is

sodium hexabromoferrate(II)

Table 23.9 Names of Some Metal Ions in Complex Anions

Metal	Name in Anion
Iron	Ferrate
Copper	Cuprate
Lead	Plumbate
Silver	Argentate
Gold	Aurate
Tin	Stannate

SAMPLE PROBLEM 23.3 Writing Names and Formulas of Coordination Compounds

Problem **(a)** What is the systematic name of $Na_3[AlF_6]$?
(b) What is the systematic name of $[Co(en)_2Cl_2]NO_3$?
(c) What is the formula of tetraamminebromochloroplatinum(IV) chloride?
(d) What is the formula of hexaamminecobalt(III) tetrachloroferrate(III)?

Plan We use the rules that were presented above and refer to Tables 23.8 and 23.9.

Solution **(a)** The complex ion is $[AlF_6]^{3-}$. There are six *(hexa-)* F^- ions *(fluoro)* as ligands, so we have *hexafluoro*. The complex ion is an anion, so the ending of the metal ion (aluminum) must be changed to *-ate:* hexafluoroaluminate. Aluminum has only the +3 oxidation state, so we do *not* use a Roman numeral. The positive counter ion is named first and separated from the anion by a space: sodium hexafluoroaluminate.

(b) Listed alphabetically, there are two Cl^- *(dichloro)* and two en [*bis(ethylenediamine)*] as ligands. The complex ion is a cation, so the metal name is unchanged, but we specify its oxidation state because cobalt can have several. One NO_3^- balances the 1+ cation charge: with 2− for two Cl^- and 0 for two en, the metal must be *cobalt(III)*. The word *nitrate* follows a space: dichlorobis(ethylenediamine)cobalt(III) nitrate.

(c) The central metal ion is written first, followed by the neutral ligands and then (in alphabetical order) by the negative ligands. *Tetraammine* is four NH_3, *bromo* is one Br^-, *chloro* is one Cl^-, and *platinate(IV)* is Pt^{4+}, so the complex ion is $[Pt(NH_3)_4BrCl]^{2+}$. Its 2+ charge is the sum of 4+ for Pt^{4+}, 0 for four NH_3, 1− for one Br^-, and 1− for one Cl^-. To balance the 2+ charge, we need two Cl^- counter ions: $[Pt(NH_3)_4BrCl]Cl_2$.

(d) This compound consists of two different complex ions. In the cation, *hexaammine* is six NH_3 and *cobalt(III)* is Co^{3+}, so the cation is $[Co(NH_3)_6]^{3+}$. The 3+ charge is the sum of 3+ for Co^{3+} and 0 for six NH_3. In the anion, *tetrachloro* is four Cl^-, and *ferrate(III)* is Fe^{3+}, so the anion is $[FeCl_4]^-$. The 1− charge is the sum of 3+ for Fe^{3+} and 4− for four Cl^-. In the neutral compound, one 3+ cation is balanced by three 1− anions: $[Co(NH_3)_6][FeCl_4]_3$.

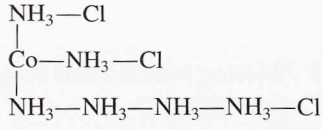
Check Reverse the process to be sure you obtain the name or formula asked for in the problem.

FOLLOW-UP PROBLEM 23.3 **(a)** What is the name of $[Cr(H_2O)_5Br]Cl_2$? **(b)** What is the formula of barium hexacyanocobaltate(III)?

A Historical Perspective: Alfred Werner and Coordination Theory

The substances we now call coordination compounds had been known for almost 200 years when the young Swiss chemist Alfred Werner began studying them in the 1890s. He investigated a series of compounds such as the cobalt series shown in Table 23.10, each of which contains one cobalt(III) ion, three chloride ions, and a given number of ammonia molecules. At the time, which was 30 years before the idea of atomic orbitals was proposed, no structural theory could explain how compounds with similar, even identical, formulas could have widely different properties.

Werner measured the conductivity of each compound in aqueous solution to determine the total number of ions that became dissociated. He treated the solutions with excess $AgNO_3$ to precipitate released Cl^- ions as AgCl and thus determine the number of free Cl^- ions per formula unit. Previous studies had established that the NH_3 molecules were not free in solution. Werner's data, summarized in Table 23.10, could not be explained by the accepted, traditional formulas of the compounds. Other chemists had proposed "chain" structures, like those of organic compounds, to explain such data. For example, a proposed structure for $[Co(NH_3)_6]Cl_3$ was



However, these models proved inadequate.

Werner's novel idea was the coordination complex, a central metal ion surrounded by a *constant total number* of covalently bonded molecules and/or anions. The coordination complex could be neutral or charged; if charged, it combined with oppositely charged counter ions, in this case Cl^-, to form the neutral compound.

Table 23.10 Some Coordination Compounds of Cobalt Studied by Werner

Traditional Formula	Werner's Data*		Modern Formula	Charge of Complex Ion
	Total Ions	Free Cl^-		
$CoCl_3 \cdot 6NH_3$	4	3	$[Co(NH_3)_6]Cl_3$	3+
$CoCl_3 \cdot 5NH_3$	3	2	$[Co(NH_3)_5Cl]Cl_2$	2+
$CoCl_3 \cdot 4NH_3$	2	1	$[Co(NH_3)_4Cl_2]Cl$	1+
$CoCl_3 \cdot 3NH_3$	0	0	$[Co(NH_3)_3Cl_3]$	—

*Moles per mole of compound.

Werner proposed two types of valence, or *combining ability,* for metal ions. *Primary valence,* now called *oxidation state,* is the positive charge on the metal ion that must be satisfied by an equivalent negative charge. In Werner's cobalt series, the primary valence is +3, and it is always balanced by three Cl^- ions. These anions can be bonded covalently to Co as part of the complex ion and/or associated with it as counter ions. *Secondary valence,* now called *coordination number,* is the constant total number of connections (anionic or neutral ligands) *within* the complex ion. The secondary valence in this series of Co compounds is 6.

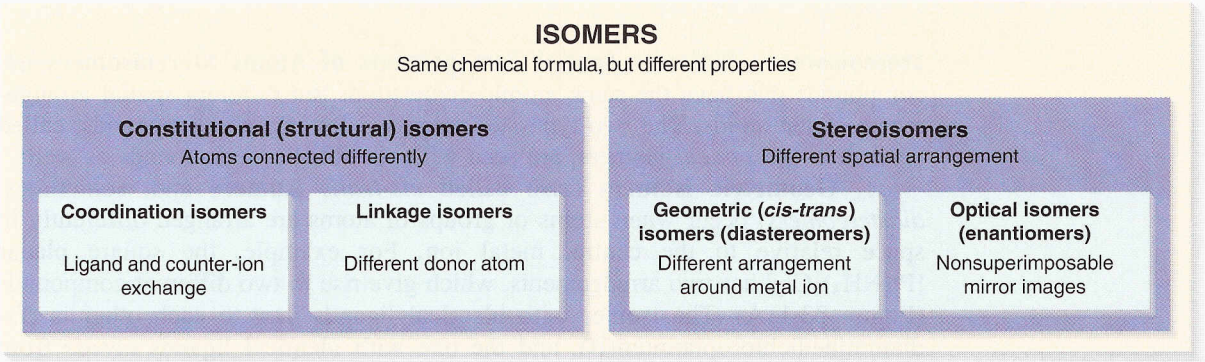
As you can see, Werner's data are satisfied if the total number of ligands remains the same for each compound, even though the numbers of Cl^- ions and NH_3 molecules in the different complex ions vary. For example, the first compound, $[Co(NH_3)_6]Cl_3$, has a total of four ions: one $[Co(NH_3)_6]^{3+}$ and three Cl^-. All three Cl^- ions are free to form AgCl. The last compound, $[Co(NH_3)_3Cl_3]$, contains no separate ions.

Surprisingly, Werner was an organic chemist, and his work on coordination compounds, which virtually revolutionized his contemporaries' understanding of chemical bonding, was his attempt to demonstrate the unity of chemistry. For these pioneering studies, especially his prediction of optical isomerism (discussed next), Werner received the Nobel Prize in chemistry in 1913.

Isomerism in Coordination Compounds

Isomers are compounds with the same chemical formula but different properties. We discussed many aspects of isomerism in the context of organic compounds in Section 15.2; it may be helpful to review that section now. Figure 23.10 presents an overview of the most common types of isomerism in coordination compounds.

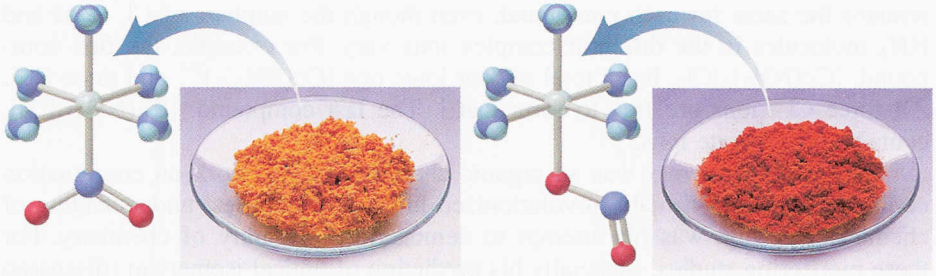
Figure 23.10 Important types of isomerism in coordination compounds.



Constitutional Isomers: Same Atoms Connected Differently Two compounds with the same formula, but with the atoms connected differently, are called **constitutional (structural) isomers.** Coordination compounds exhibit the following two types of constitutional isomers: one involves a difference in the composition of the complex ion, the other in the donor atom of the ligand.

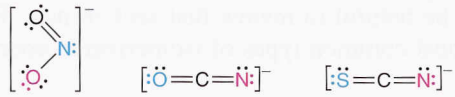
1. **Coordination isomers** occur when the composition of the complex ion changes but not that of the compound. One way this type of isomerism occurs is when ligand and counter ion exchange positions, as in $[Pt(NH_3)_4Cl_2](NO_2)_2$ and $[Pt(NH_3)_4(NO_2)_2]Cl_2$. In the first compound, the Cl^- ions are the ligands, and the NO_2^- ions are counter ions; in the second, the roles are reversed. Another way that this type of isomerism occurs is in compounds of two complex ions in which the two sets of ligands in one compound are reversed in the other, as in $[Cr(NH_3)_6][Co(CN)_6]$ and $[Co(NH_3)_6][Cr(CN)_6]$; note that NH_3 is a ligand of Cr^{3+} in one compound and of Co^{3+} in the other.

2. **Linkage isomers** occur when the composition of the complex ion remains the same but the attachment of the ligand donor atom changes. Some ligands can bind to the metal ion through *either of two donor atoms*. For example, the nitrite ion can bind through a lone pair on either the N atom (*nitro*, O_2N:) or one of the O atoms (*nitrito*, ONO:) to give linkage isomers, as in the orange compound pentaammine*nitro*cobalt(III) chloride $[Co(NH_3)_5(NO_2)]Cl_2$ *(below left)* and its red linkage isomer pentaammine*nitrito*cobalt(III) chloride $[Co(NH_3)_5(ONO)]Cl_2$ *(below right)*:



Nitro isomer ***Nitrito*** isomer

Another example is the cyanate ion, which can attach via a lone pair on the O atom (*cyanato*, NCO:) or the N atom (*isocyanato*, OCN:); the thiocyanate ion behaves similarly, attaching via the S atom or the N atom:



nitrite cyanate thiocyanate

Stereoisomers: Different Spatial Arrangements of Atoms **Stereoisomers** are compounds that have the same atomic connections but different spatial arrangements of the atoms. The two types we discussed for organic compounds, called *geometric* and *optical* isomers, are seen with coordination compounds as well:

1. **Geometric isomers** (also called ***cis-trans* isomers** and, sometimes, *diastereomers*) occur when atoms or groups of atoms are arranged differently in space relative to the central metal ion. For example, the square planar $[Pt(NH_3)_2Cl_2]$ has two arrangements, which give rise to two different compounds (Figure 23.11A). The isomer with identical ligands *next* to each other is *cis*-diamminedichloroplatinum(II), and the one with identical ligands *across* from each other is *trans*-diamminedichloroplatinum(II); their biological behaviors are remarkably different. Octahedral complexes also exhibit *cis-trans* isomerism (Figure 23.11B). The *cis* isomer of the $[Co(NH_3)_4Cl_2]^+$ ion has the two Cl^- ligands next to each other and is violet, whereas the *trans* isomer has these two ligands across from each other and is green.

2. **Optical isomers** (also called *enantiomers*) occur when a molecule and its mirror image cannot be superimposed (see Figures 15.8 to 15.10, pp. 627–628). Unlike other types of isomers, which have distinct physical properties, optical isomers are physically identical in all ways but one: *the direction in which they rotate the plane of polarized light*. Octahedral complex ions show many examples of optical isomerism, which we can observe by rotating one isomer and seeing if it is superimposable on the other isomer (its mirror image). For example, as you can see in Figure 23.12A, the two structures (I and II) of $[Co(en)_2Cl_2]^+$, the *cis*-dichlorobis(ethylenediamine)cobalt(III) ion, are mirror images of each other. Rotate structure I 180° around a vertical axis, and you obtain III. The Cl^- li-

Anticancer Geometric Isomers In the mid-1960s, Barnett Rosenberg and his colleagues found that *cis*-$[Pt(NH_3)_2Cl_2]$ (cisplatin) was a highly effective antitumor agent. This compound and several closely related platinum(II) complexes are still among the most effective treatments for certain types of cancer. The geometric isomer, *trans*-$[Pt(NH_3)_2Cl_2]$, however, has no antitumor effect. Cisplatin may work by lying within the cancer cell's DNA double helix, such that a donor atom on each strand replaces a Cl^- ligand and binds the platinum(II) strongly, preventing DNA replication (Section 15.6).

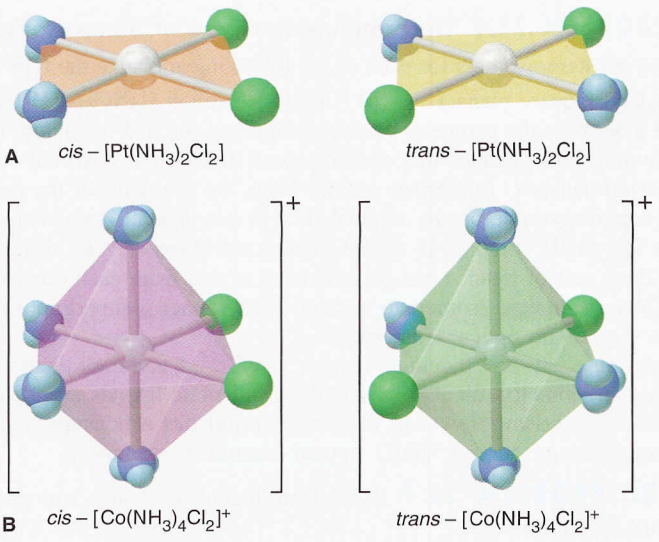


Figure 23.11 Geometric *(cis-trans)* isomerism. A, The *cis* and *trans* isomers of the square planar coordination compound $[Pt(NH_3)_2Cl_2]$. **B,** The *cis* and *trans* isomers of the octahedral complex ion $[Co(NH_3)_4Cl_2]^+$. The colored shapes represent the actual colors of the species.

gands of III match those of II, but the en ligands do not: II and III (rotated I) are not superimposable; therefore, they are optical isomers. One isomer is designated *d*-$[Co(en)_2Cl_2]^+$ and the other is *l*-$[Co(en)_2Cl_2]^+$, depending on whether it rotates polarized light to the right (*d*- for "dextro-") or to the left (*l*- for "levo-"). (The *d*- or *l*- designation can only be determined experimentally, *not* by examination of the structure.) In contrast, as shown in Figure 23.12B, the two structures of the *trans*-dichlorobis(ethylenediamine)cobalt(III) ion are *not* optical isomers: rotate I 90° around a vertical axis and you obtain III, which *is* superimposable on II.

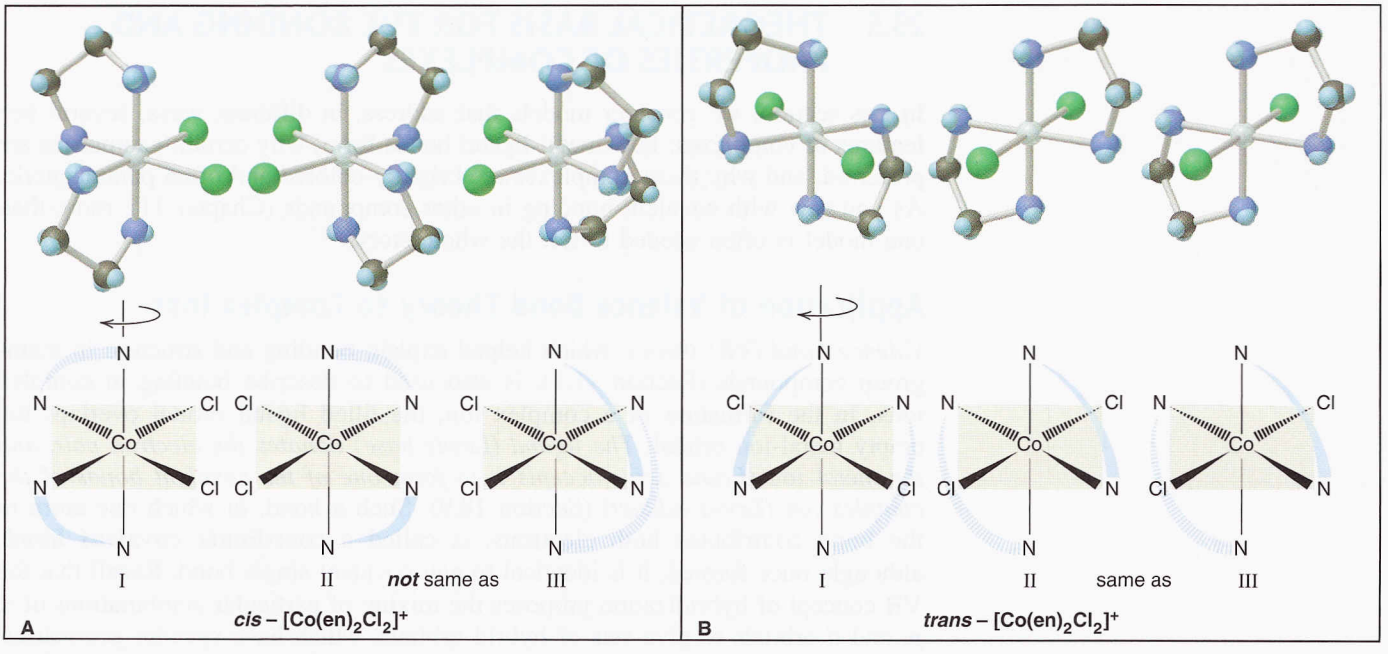

Figure 23.12 Optical isomerism in an octahedral complex ion. A, Structure I and its mirror image, structure II, are optical isomers of *cis*-$[Co(en)_2Cl_2]^+$. Rotating structure I gives structure III, which is *not* the same as structure II. (The curved wedges represent the bidentate ligand ethylenediamine, $H_2N—CH_2—CH_2—NH_2$.) **B,** The *trans* isomer does *not* have optical isomers. Rotating structure I gives III, which is *identical* to II, the mirror image of i.

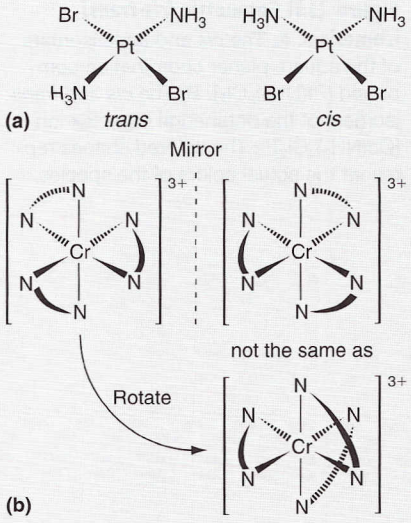

SAMPLE PROBLEM 23.4 Determining the Type of Stereoisomerism

Problem Draw all stereoisomers for each of the following and state the type of isomerism:
(a) $[Pt(NH_3)_2Br_2]$ (square planar) **(b)** $[Cr(en)_3]^{3+}$ (en = $H_2\ddot{N}CH_2CH_2\ddot{N}H_2$)

Plan We first determine the geometry around each metal ion and the nature of the ligands. If there are two different ligands that can be placed in different positions relative to each other, geometric *(cis-trans)* isomerism occurs. Then, we see whether the mirror image of an isomer is superimposable on the original. If it is *not*, optical isomerism occurs.

Solution **(a)** The Pt(II) complex is square planar, and there are two different monodentate ligands. Each pair of ligands can lie next to or across from each other (see structures in margin). Thus, geometric isomerism occurs. Each isomer *is* superimposable on its mirror image, so there is no optical isomerism.

(b) Ethylenediamine (en) is a bidentate ligand. The Cr^{3+} has a coordination number of 6 and an octahedral geometry, like Co^{3+}. The three bidentate ligands are identical, so there is no geometric isomerism. However, the complex ion has a nonsuperimposable mirror image (see structures in margin). Thus, optical isomerism occurs.

FOLLOW-UP PROBLEM 23.4 What stereoisomers, if any, are possible for the $[Co(NH_3)_2(en)Cl_2]^+$ ion?

SECTION SUMMARY

Coordination compounds consist of a complex ion and charge-balancing counter ions. The complex ion has a central metal ion bonded to neutral and/or anionic ligands, which have one or more donor atoms that each provide a lone pair of electrons. The most common geometry is octahedral (six ligand atoms bonding). Formulas and names of coordination compounds follow systematic rules. Werner established the structural basis of coordination compounds. These compounds can exhibit constitutional isomerism (coordination and linkage) and stereoisomerism (geometric and optical).

23.5 THEORETICAL BASIS FOR THE BONDING AND PROPERTIES OF COMPLEXES

In this section, we consider models that address, in different ways, several key features of complexes: how metal-ligand bonds form, why certain geometries are preferred, and why these complexes are brightly colored and often paramagnetic. As you saw with covalent bonding in other compounds (Chapter 11), more than one model is often needed to tell the whole story.

Application of Valence Bond Theory to Complex Ions

Valence bond (VB) theory, which helped explain bonding and structure in main-group compounds (Section 11.1), is also used to describe bonding in complex ions. In the formation of a complex ion, the filled ligand orbital overlaps the empty metal-ion orbital. *The ligand (Lewis base) donates the electron pair, and the metal ion (Lewis acid) accepts it to form one of the covalent bonds of the complex ion (Lewis adduct)* (Section 18.9). Such a bond, in which one atom in the bond contributes both electrons, is called a **coordinate covalent bond,** although, once formed, it is identical to any covalent single bond. Recall that the VB concept of hybridization proposes the mixing of particular combinations of *s*, *p*, and *d* orbitals to give sets of hybrid orbitals, which have specific geometries. Similarly, for coordination compounds, the model proposes that *the number and type of metal-ion hybrid orbitals occupied by ligand lone pairs determine the geometry of the complex ion.* Let's discuss the orbital combinations that lead to octahedral, square planar, and tetrahedral geometries.

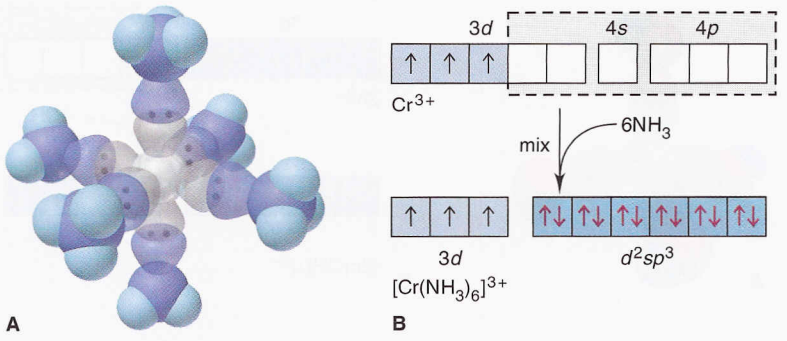

Figure 23.13 Hybrid orbitals and bonding in the octahedral $[Cr(NH_3)_6]^{3+}$ ion. **A,** VB depiction of the $Cr(NH_3)_6^{3+}$ ion. **B,** The partial orbital diagrams depict the mixing of two 3*d*, one 4*s*, and three 4*p* orbitals in Cr^{3+} to form six d^2sp^3 hybrid orbitals, which are filled with six NH_3 lone pairs (*red*).

Octahedral Complexes The hexaamminechromium(III) ion, $[Cr(NH_3)_6]^{3+}$, illustrates the application of VB theory to an *octahedral complex* (Figure 23.13). The six lowest energy empty orbitals of the Cr^{3+} ion—two 3*d*, one 4*s*, and three 4*p*—mix and become six equivalent d^2sp^3 hybrid orbitals that point toward the corners of an octahedron.* Six NH_3 molecules donate lone pairs from their nitrogens to form six metal-ligand bonds. The three unpaired 3*d* electrons of the central Cr^{3+} ion ([Ar] $3d^3$), which make the complex ion paramagnetic, remain in unhybridized orbitals.

Square Planar Complexes Metal ions with a d^8 configuration usually form *square planar complexes* (Figure 23.14). In the $[Ni(CN)_4]^{2-}$ ion, for example, the model proposes that one 3*d*, one 4*s*, and two 4*p* orbitals of Ni^{2+} mix and form four dsp^2 hybrid orbitals, which point to the corners of a square and accept one electron pair from each of four CN^- ligands.

A look at the ground-state electron configuration of the Ni^{2+} ion, however, raises a key question: how can the Ni^{2+} ion ([Ar] $3d^8$) offer an empty 3*d* orbital for accepting a lone pair, if its eight 3*d* electrons lie in three filled and two half-filled orbitals? Apparently, in the d^8 configuration of Ni^{2+}, electrons in the half-filled orbitals pair up and leave one 3*d* orbital empty. This explanation is consistent with the fact that the complex is diamagnetic (no unpaired electrons). Moreover, it requires that the energy *gained* by using a 3*d* orbital for bonding in the hybrid orbital is greater than the energy *required* to overcome repulsions from pairing the 3*d* electrons.

*Note the distinction between the hybrid-orbital designation here and that for octahedral molecules like SF_6. The designation gives the orbitals in energy order within a given *n* value. In the $[Cr(NH_3)_6]^{3+}$ complex ion, the *d* orbitals have a *lower n* value than the *s* and *p* orbitals, so the hybrid orbitals are d^2sp^3. For the orbitals in SF_6, the *d* orbitals have the *same n* value as the *s* and *p*, so the hybrid orbitals are sp^3d^2.

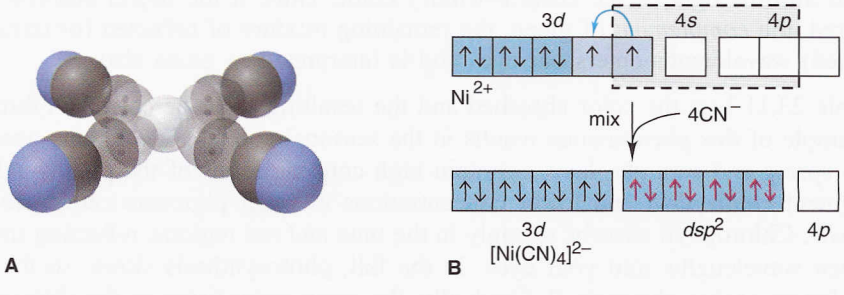

Figure 23.14 Hybrid orbitals and bonding in the square planar $[Ni(CN)_4]^{2-}$ ion. **A,** VB depiction of $[Ni(CN)_4]^{2-}$. **B,** Two lone 3*d* electrons pair up and free one 3*d* orbital for hybridization with the 4*s* and two of the 4*p* orbitals to form four dsp^2 orbitals, which become occupied with lone pairs (*red*) from four CN^- ligands.

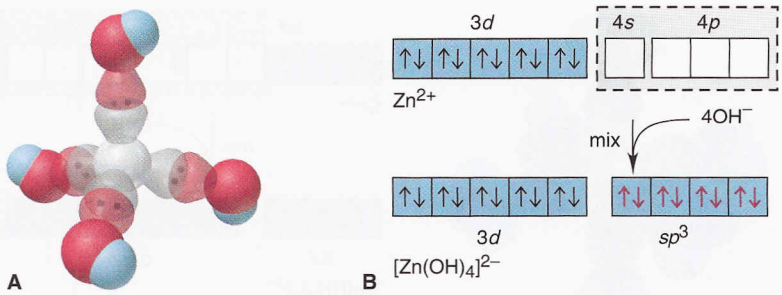

Figure 23.15 Hybrid orbitals and bonding in the tetrahedral $[Zn(OH)_4]^{2-}$ ion. **A,** VB depiction of $[Zn(OH)_4]^{2-}$. **B,** Mixing one 4*s* and three 4*p* orbitals gives four sp^3 hybrid orbitals available for accepting lone pairs (*red*) from OH^- ligands.

Tetrahedral Complexes Metal ions that have a filled *d* sublevel, such as Zn^{2+} ([Ar] $3d^{10}$), often form *tetrahedral complexes* (Figure 23.15). For the complex ion $[Zn(OH)_4]^{2-}$, for example, VB theory proposes that the lowest available Zn^{2+} orbitals—one 4*s* and three 4*p*—mix to become four sp^3 hybrid orbitals that point to the corners of a tetrahedron and are occupied by four lone pairs, one from each of four OH^- ligands.

Crystal Field Theory

The VB model is easy to picture and rationalizes bonding and shape, but it treats the orbitals as little more than empty "slots" for accepting electron pairs. Consequently, it gives no insight into the colors of coordination compounds and sometimes predicts their magnetic properties incorrectly. In contrast to the VB approach, **crystal field theory** provides little insight about metal-ligand bonding but explains color and magnetism clearly. To do so, it highlights the *effects on the d-orbital energies of the metal ion as the ligands approach*. Before we discuss this theory, let's consider what causes a substance to be colored.

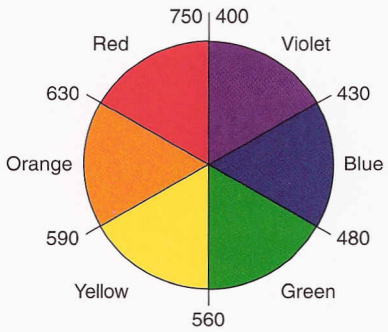

Figure 23.16 An artist's wheel. Colors, with approximate wavelength ranges (in nm), are shown as wedges. Complementary colors, such as red and green, lie opposite each other.

What Is Color? White light is electromagnetic radiation consisting of all wavelengths (λ) in the visible range (Section 7.1). It can be dispersed into a spectrum of colors, each of which has a narrower range of wavelengths. Objects appear colored in white light because they absorb certain wavelengths and reflect or transmit others: an opaque object *reflects* light, whereas a clear one *transmits* it. The reflected or transmitted light enters the eye and the brain perceives a color. If an object absorbs all visible wavelengths, it appears black; if it reflects all, it appears white.

Each color has a *complementary* color. For example, green and red are complementary colors. A mixture of complementary colors absorbs all visible wavelengths and appears black. Figure 23.16 shows these relationships on an artist's color wheel, where complementary colors appear as wedges opposite each other.

An object has a particular color for one of two reasons:

- It reflects (or transmits) light of *that* color. Thus, if an object absorbs all wavelengths *except* green, the reflected (or transmitted) light enters our eyes and is interpreted as green.
- It absorbs light of the *complementary* color. Thus, if the object absorbs only red, the *complement* of green, the remaining mixture of reflected (or transmitted) wavelengths enters our eyes and is interpreted as green also.

Table 23.11 lists the color absorbed and the resulting color perceived. A familiar example of this phenomenon results in the seasonal colors of deciduous trees. In the spring and summer, leaves contain high concentrations of the photosynthetic pigment *chlorophyll* and lower concentrations of other pigments called *xanthophylls*. Chlorophyll absorbs strongly in the blue and red regions, reflecting mostly green wavelengths into your eyes. In the fall, photosynthesis slows, so the leaf no longer makes chlorophyll. Gradually, the green color fades as the chlorophyll decomposes, revealing the xanthophylls that were present all along but masked

Table 23.11 Relation Between Absorbed and Observed Colors

Absorbed Color	λ (nm)	Observed Color	λ (nm)
Violet	400	Green-yellow	560
Blue	450	Yellow	600
Blue-green	490	Red	620
Yellow-green	570	Violet	410
Yellow	580	Dark blue	430
Orange	600	Blue	450
Red	650	Green	520

Foliage changing color in autumn.

by the chlorophyll. Xanthophylls absorb green and blue strongly, reflecting the bright yellows and reds of autumn (see photo).

Splitting of *d* Orbitals in an Octahedral Field of Ligands The crystal field model explains that the properties of complexes result from the splitting of *d*-orbital energies, which arises from electrostatic interactions between metal ion and ligands. The model assumes that a complex ion forms as a result of *electrostatic attractions between the metal cation and the negative charge of the ligands*. This negative charge is either partial, as in a polar neutral ligand like NH_3, or full, as in an anionic ligand like Cl^-. The ligands approach the metal ion along the mutually perpendicular *x*, *y*, and *z* axes, which minimizes the overall energy of the system.

Picture what happens as the ligands approach. Figure 23.17A shows six ligands moving toward a metal ion to form an octahedral complex. Let's see how the various *d* orbitals of the metal ion are affected as the complex forms. As the ligands approach, their electron pairs repel electrons in the five *d* orbitals. In the isolated metal ion, the *d* orbitals have equal energies despite their different orientations. In the electrostatic field of ligands, however, the *d* electrons are *repelled unequally because their orbitals have different orientations*. Because the ligands move along the *x*, *y*, and *z* axes, they approach *directly toward* the lobes of the $d_{x^2-y^2}$ and d_{z^2} orbitals (Figure 23.17B and C) but *between* the lobes of the d_{xy}, d_{xz}, and d_{yz} orbitals (Figure 23.17D to F). Thus, electrons in the $d_{x^2-y^2}$ and d_{z^2} orbitals experience *stronger* repulsions than those in the d_{xy}, d_{xz}, and d_{yz} orbitals.

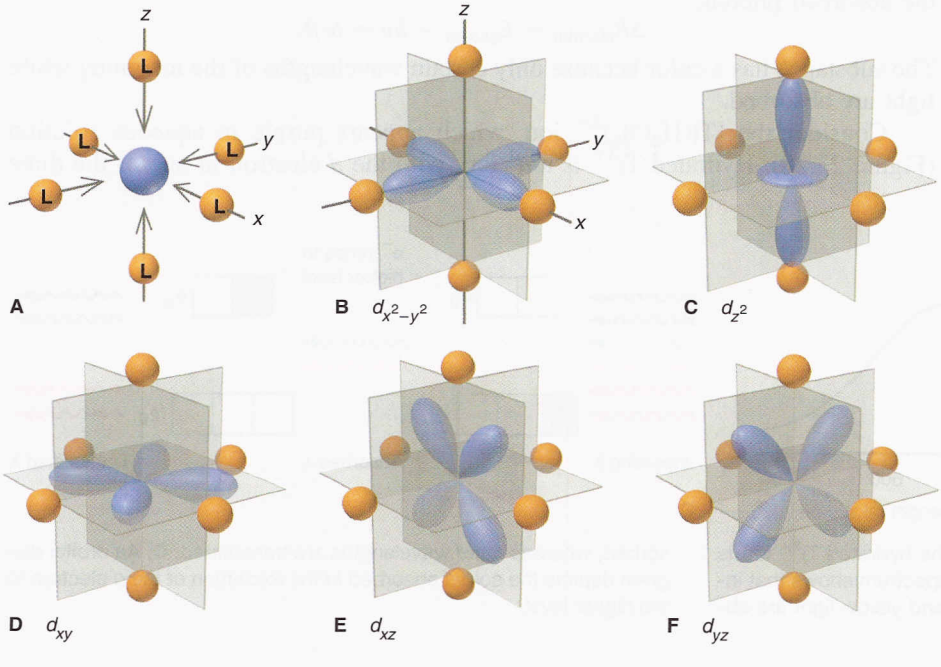

Figure 23.17 The five *d* orbitals in an octahedral field of ligands. The direction of ligand approach influences the strength of repulsions of electrons in the five metal *d* orbitals. **A,** We assume that ligands approach a metal ion along the three linear axes in an octahedral orientation. **B** and **C,** Lobes of the $d_{x^2-y^2}$ and d_{z^2} orbitals lie *directly in line* with the approaching ligands, so repulsions are stronger. **D** to **F,** Lobes of the d_{xy}, d_{xz}, and d_{yz} orbitals lie *between* the approaching ligands, so repulsions are weaker.

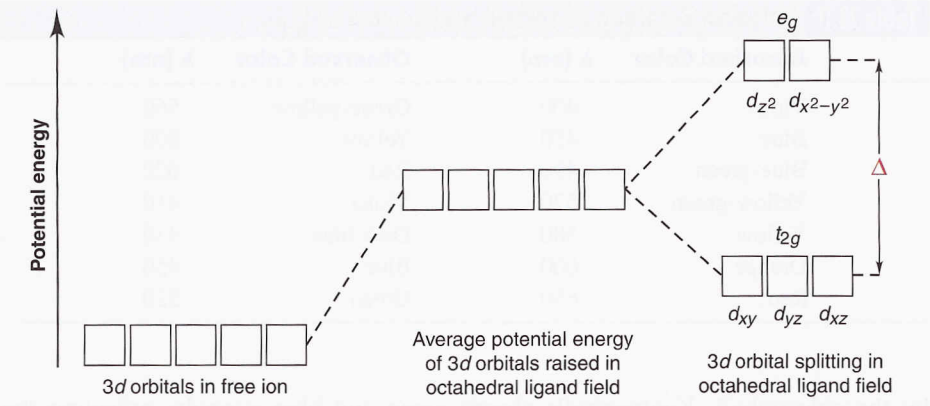

Figure 23.18 Splitting of *d*-orbital energies by an octahedral field of ligands. Electrons in the *d* orbitals of the free metal ion experience an *average* net repulsion in the negative ligand field that increases all *d*-orbital energies. Electrons in the d_{xy}, d_{yz}, and d_{xz} orbitals, which form the t_{2g} set, are repelled less than those in the $d_{x^2-y^2}$ and d_{z^2} orbitals, which form the e_g set. The energy difference between these two sets is the crystal field splitting energy, Δ.

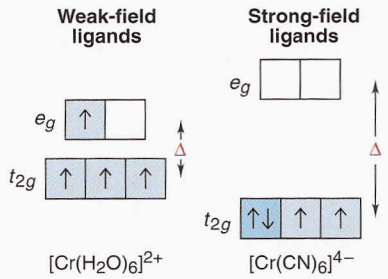

Figure 23.19 The effect of the ligand on splitting energy. Ligands interacting strongly with metal-ion *d* orbitals, such as CN^-, produce a larger Δ than those interacting weakly, such as H_2O.

An energy diagram of the orbitals shows that all five *d* orbitals are higher in energy in the forming complex than in the free metal ion because of repulsions from the approaching ligands, but *the orbital energies split, with two d orbitals higher in energy than the other three* (Figure 23.18). The two higher energy orbitals are called ***e_g* orbitals,** and the three lower energy ones are ***t_{2g}* orbitals.** (These designations refer to features of the orbitals that need not concern us here.)

The splitting of orbital energies is called the *crystal field effect,* and the difference in energy between the e_g and t_{2g} sets of orbitals is the **crystal field splitting energy (Δ).** Different ligands create crystal fields of different strength and, thus, cause the *d*-orbital energies to split to different extents. **Strong-field ligands** lead to a *larger* splitting energy (larger Δ); **weak-field ligands** lead to a *smaller* splitting energy (smaller Δ). For instance, H_2O is a weak-field ligand, and CN^- is a strong-field ligand (Figure 23.19). The magnitude of Δ relates directly to the color and magnetic properties of a complex.

Explaining the Colors of Transition Metals The remarkably diverse colors of coordination compounds are determined by the energy difference (Δ) between the t_{2g} and e_g orbital sets in their complex ions. When the ion absorbs light in the visible range, electrons are excited ("jump") from the lower energy t_{2g} level to the higher e_g level. Recall that the *difference* between two electronic energy levels in the ion is equal to the energy (and inversely related to the wavelength) of the absorbed photon:

$$\Delta E_{\text{electron}} = E_{\text{photon}} = h\nu = hc/\lambda$$

The substance has a color because only certain wavelengths of the incoming white light are absorbed.

Consider the $[Ti(H_2O)_6]^{3+}$ ion, which appears purple in aqueous solution (Figure 23.20). Hydrated Ti^{3+} is a d^1 ion, with the *d* electron in one of the three

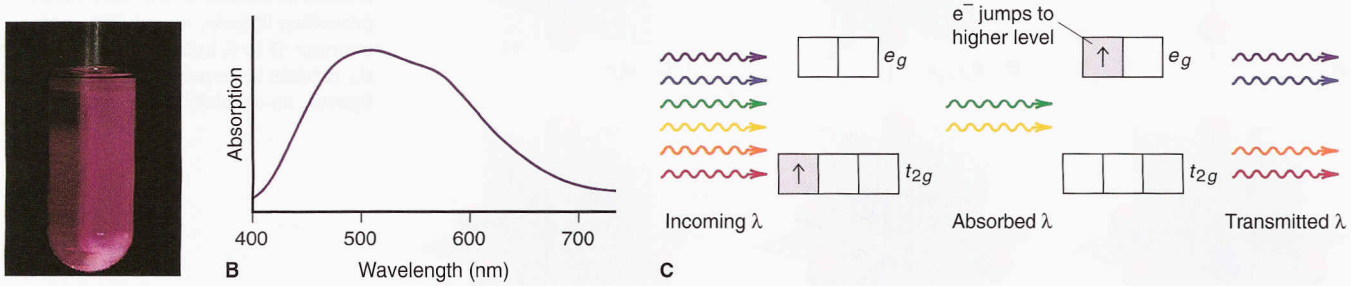

Figure 23.20 The color of $[Ti(H_2O)_6]^{3+}$. A, The hydrated Ti^{3+} ion is purple in aqueous solution. **B,** An absorption spectrum shows that incoming wavelengths corresponding to green and yellow light are absorbed, whereas other wavelengths are transmitted. **C,** An orbital diagram depicts the colors absorbed in the excitation of the *d* electron to the higher level.

lower energy t_{2g} orbitals. The energy difference (Δ) between the t_{2g} and e_g orbitals in this ion corresponds to the energy of photons spanning the green and yellow range. When white light shines on the solution, these colors of light are absorbed, and the electron jumps to one of the e_g orbitals. Red, blue, and violet light are transmitted, so the solution appears purple.

Absorption spectra show the wavelengths absorbed by a given metal ion with different ligands and by different metal ions with the same ligand. From such data, we relate the energy of the absorbed light to the Δ values, and two important observations emerge:

1. *For a given ligand, the color depends on the oxidation state of the metal ion.* A solution of $[V(H_2O)_6]^{2+}$ ion is violet, and a solution of $[V(H_2O)_6]^{3+}$ ion is yellow (Figure 23.21A).
2. *For a given metal ion, the color depends on the ligand.* Even a single ligand substitution can have a major effect on the wavelengths absorbed and, thus, the color, as you can see for two Cr^{3+} complex ions in Figure 23.21B.

The second observation allows us to rank ligands into a **spectrochemical series** with regard to their ability to split *d*-orbital energies. An abbreviated series, moving from weak-field ligands (small splitting, small Δ) to strong-field ligands (large splitting, large Δ), is shown in Figure 23.22. Using this series, we can predict the *relative* size of Δ for a series of octahedral complexes of the same metal ion. Although it is difficult to predict the actual color of a given complex, we can determine whether a complex will absorb longer or shorter wavelengths than other complexes in the series.

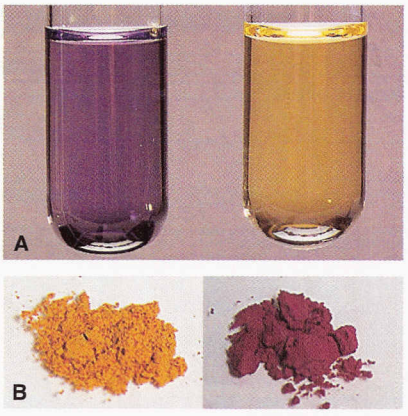

Figure 23.21 Effects of the metal oxidation state and of ligand identity on color. **A,** Solutions of $[V(H_2O)_6]^{2+}$ (*left*) and $[V(H_2O)_6]^{3+}$ (*right*) ions have different colors. **B,** A change in even a single ligand can influence the color. The $[Cr(NH_3)_6]^{3+}$ ion is yellow-orange (*left*); the $[Cr(NH_3)_5Cl]^{2+}$ ion is purple (*right*).

SAMPLE PROBLEM 23.5 Ranking Crystal Field Splitting Energies for Complex Ions of a Given Metal

Problem Rank the ions $[Ti(H_2O)_6]^{3+}$, $[Ti(NH_3)_6]^{3+}$, and $[Ti(CN)_6]^{3-}$ in terms of the relative value of Δ and of the energy of visible light absorbed.

Plan The formulas show that titanium's oxidation state is +3 in the three ions. From Figure 23.22, we rank the ligands in terms of crystal field strength: the stronger the ligand, the greater the splitting, and the higher the energy of light absorbed.

Solution The ligand field strength is in the order $CN^- > NH_3 > H_2O$, so the relative size of Δ and energy of light absorbed is

$$Ti(CN)_6^{3-} > Ti(NH_3)_6^{3+} > Ti(H_2O)_6^{3+}$$

FOLLOW-UP PROBLEM 23.5 Which complex ion absorbs visible light of higher energy, $[V(H_2O)_6]^{3+}$ or $[V(NH_3)_6]^{3+}$?

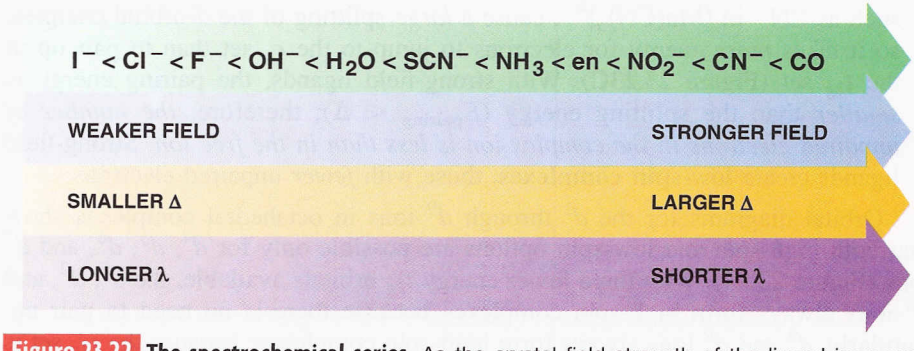

Figure 23.22 The spectrochemical series. As the crystal field strength of the ligand increases, the splitting energy (Δ) increases, so shorter wavelengths (λ) of light must be absorbed to excite electrons. Water is usually a weak-field ligand.

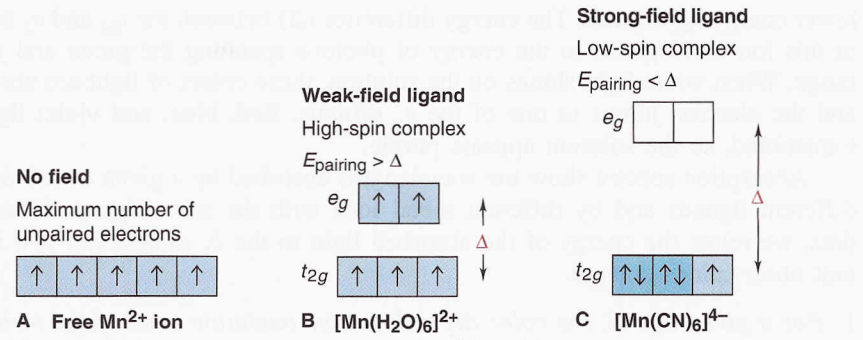

Figure 23.23 High-spin and low-spin complex ions of Mn^{2+}. **A,** The free Mn^{2+} ion has five unpaired electrons. **B,** Bonded to weak-field ligands (smaller Δ), Mn^{2+} still has five unpaired electrons (high-spin complex). **C,** Bonded to strong-field ligands (larger Δ), Mn^{2+} has only one unpaired electron (low-spin complex).

Explaining the Magnetic Properties of Transition Metal Complexes The splitting of energy levels influences magnetic properties by affecting the number of *unpaired* electrons in the metal ion's *d* orbitals. Based on Hund's rule, electrons occupy orbitals one at a time as long as orbitals of equal energy are available. When all lower energy orbitals are half-filled, the next electron can

- enter a half-filled orbital and pair up by overcoming a repulsive *pairing energy* ($E_{pairing}$), or
- enter an empty, higher energy orbital by overcoming the crystal field splitting energy (Δ).

Thus, *the relative sizes of $E_{pairing}$ and Δ determine the occupancy of the d orbitals.* The orbital occupancy pattern, in turn, determines the number of unpaired electrons and, thus, the paramagnetic behavior of the ion.

As an example, the isolated Mn^{2+} ion ([Ar] $3d^5$) has five unpaired electrons in 3*d* orbitals of equal energy (Figure 23.23A). In an octahedral field of ligands, the orbital energies split. The orbital occupancy is affected by the ligand in one of two ways:

- *Weak-field ligands and high-spin complexes.* Weak-field ligands, such as H_2O in $[Mn(H_2O)_6]^{2+}$, cause a *small* splitting energy, so it takes *less* energy for *d* electrons to jump to the e_g set than to pair up in the t_{2g} set. Therefore, the *d* electrons remain unpaired (Figure 23.23B). Thus, with weak-field ligands, the pairing energy is *greater* than the splitting energy ($E_{pairing} > \Delta$); therefore, *the number of unpaired electrons in the complex ion is the **same** as in the free ion.* Weak-field ligands create **high-spin complexes,** those with the *maximum* number of unpaired electrons.
- *Strong-field ligands and low-spin complexes.* In contrast, strong-field ligands, such as CN^- in $[Mn(CN)_6]^{4-}$, cause a *large* splitting of the *d*-orbital energies, so it takes *more* energy for electrons to jump to the e_g set than to pair up in the t_{2g} set (Figure 23.23C). With strong-field ligands, the pairing energy is *smaller* than the splitting energy ($E_{pairing} < \Delta$); therefore, *the number of unpaired electrons in the complex ion is **less** than in the free ion.* Strong-field ligands create **low-spin complexes,** those with *fewer* unpaired electrons.

Orbital diagrams for the d^1 through d^9 ions in octahedral complexes show that both high-spin and low-spin options are possible only for d^4, d^5, d^6, and d^7 ions (Figure 23.24). With three lower energy t_{2g} orbitals available, the d^1, d^2, and d^3 ions always form high-spin complexes because there is no need to pair up. Similarly, d^8 and d^9 ions always form high-spin complexes: because the t_{2g} set is filled with six electrons, the two e_g orbitals *must* have either two (d^8) or one (d^9) unpaired electron.

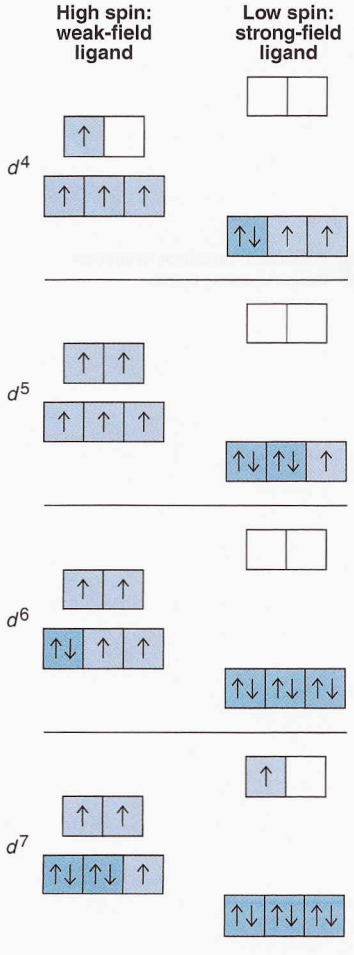

Figure 23.24 Orbital occupancy for high-spin and low-spin complexes of d^4 through d^7 metal ions.

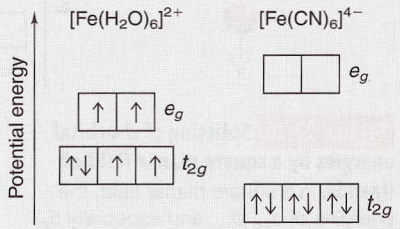
SAMPLE PROBLEM 23.6 Identifying Complex Ions as High Spin or Low Spin

Problem Iron(II) forms an essential complex in hemoglobin. For each of the two octahedral complex ions $[Fe(H_2O)_6]^{2+}$ and $[Fe(CN)_6]^{4-}$, draw an orbital splitting diagram, predict the number of unpaired electrons, and identify the ion as low spin or high spin.

Plan The Fe^{2+} electron configuration gives us the number of *d* electrons, and the spectrochemical series in Figure 23.22 shows the relative strengths of the two ligands. We draw the diagrams, separating the t_{2g} and e_g sets by a greater distance for the strong-field ligand. Then we add electrons, noting that a weak-field ligand gives the *maximum* number of unpaired electrons and a high-spin complex, whereas a strong-field ligand leads to electron pairing and a low-spin complex.

Solution Fe^{2+} has the [Ar] $3d^6$ configuration. According to Figure 23.22, H_2O produces smaller splitting than CN^-. The diagrams are shown in the margin. The $[Fe(H_2O)_6]^{2+}$ ion has four unpaired electrons (high spin), and the $[Fe(CN)_6]^{4-}$ ion has no unpaired electrons (low spin).



Comment **1.** H_2O is a weak-field ligand, so it almost always forms high-spin complexes. **2.** These results are correct, but we cannot confidently predict the spin of a complex without having actual values for Δ and $E_{pairing}$. **3.** Cyanide ions and carbon monoxide are highly toxic because they interact with the iron cations in proteins.

FOLLOW-UP PROBLEM 23.6 How many unpaired electrons do you expect for $[Mn(CN)_6]^{3-}$? Is this a high-spin or low-spin complex ion?

Crystal Field Splitting in Tetrahedral and Square Planar Complexes Four ligands around a metal ion also cause *d*-orbital splitting, but the magnitude and pattern of the splitting depend on whether the ligands are in a tetrahedral or a square planar arrangement.

- *Tetrahedral complexes.* With the ligands approaching from the corners of a tetrahedron, none of the five *d* orbitals is directly in their paths (Figure 23.25). Thus, splitting of *d*-orbital energies is *less* in a tetrahedral complex than in an octahedral complex having the same ligands:

$$\Delta_{tetrahedral} < \Delta_{octahedral}$$

Minimal repulsions arise if the ligands approach the d_{xy}, d_{yz}, and d_{xz} orbitals closer than they approach the d_{z^2} and $d_{x^2-y^2}$ orbitals. This situation is the *opposite of the octahedral case,* and the relative *d*-orbital energies are reversed: the d_{xy}, d_{yz}, and d_{xz} orbitals become *higher* in energy than the d_{z^2} and $d_{x^2-y^2}$ orbitals. *Only high-spin tetrahedral complexes are known* because the magnitude of Δ is so small.

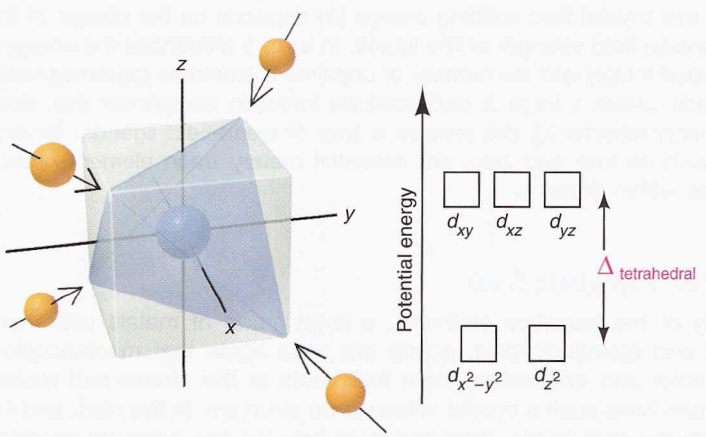


Figure 23.25 Splitting of *d*-orbital energies by a tetrahedral field of ligands. Electrons in d_{xy}, d_{yz}, and d_{xz} orbitals experience greater repulsions than those in $d_{x^2-y^2}$ and d_{z^2}, so the tetrahedral splitting pattern is the opposite of the octahedral pattern.

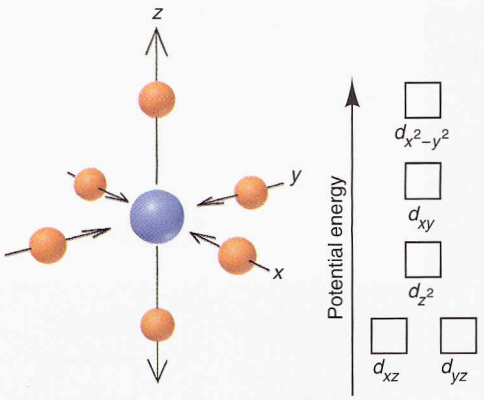

Figure 23.26 Splitting of *d*-orbital energies by a square planar field of ligands. In a square planar field, the energies of d_{xz}, d_{yz}, and especially d_{z^2} orbitals decrease relative to the octahedral pattern.

- *Square planar complexes.* The effects of the ligand field in the square planar case are easier to picture if we imagine starting with an octahedral geometry and then remove the two ligands along the *z*-axis, as depicted in Figure 23.26. With no *z*-axis interactions present, the d_{z^2} orbital energy decreases greatly, and the energies of the other orbitals with a *z*-axis component, the d_{xz} and d_{yz}, also decrease. As a result, the two *d* orbitals in the *xy* plane interact most strongly with the ligands, and because the $d_{x^2-y^2}$ orbital has its lobes *on* the axes, its energy is highest. As a consequence of this splitting pattern, square planar complexes with d^8 metal ions, such as $[PdCl_4]^{2-}$, are diamagnetic, with four pairs of *d* electrons filling the four lowest energy orbitals. Thus, as a general rule, *square planar complexes are low spin.*

At this point, a final word about bonding theories may be helpful. As you have seen in our discussions of several other topics, no one model is satisfactory in every respect. The VB approach offers a simple picture of bond formation but does not even attempt to explain color. The crystal field model predicts color and magnetic behavior beautifully but treats the metal ion and ligands as points of opposite charge and thus offers no insight about the covalent nature of metal-ligand bonding.

Despite its complexity, chemists now rely on a more refined model, called *ligand field–molecular orbital theory.* This theory combines aspects of the previous two models with MO theory (Section 11.3). We won't explore this model here, but it is a powerful predictive tool, yielding information on bond properties that result from the overlap of metal ion and ligand orbitals as well as information on the spectral and magnetic properties that result from the splitting of a metal ion's *d* orbitals.

In addition to their important chemical applications, complexes of the transition elements play vital roles in living systems, as the following Chemical Connections essay describes.

SECTION SUMMARY

Valence bond theory pictures bonding in complex ions as arising from coordinate covalent bonding between Lewis bases (ligands) and Lewis acids (metal ions). Ligand lone pairs occupy hybridized metal-ion orbitals to form complex ions with characteristic shapes.

Crystal field theory explains the color and magnetism of complexes. As the result of a surrounding field of ligands, the *d*-orbital energies of the metal ion split. The magnitude of this crystal field splitting energy (Δ) depends on the charge of the metal ion and the crystal field strength of the ligand. In turn, Δ influences the energy of the photon absorbed (color) and the number of unpaired *d* electrons (paramagnetism). Strong-field ligands create a large Δ and produce low-spin complexes that absorb light of higher energy (shorter λ); the reverse is true of weak-field ligands. Several transition metals, such as iron and zinc, are essential dietary trace elements that function in complexes within proteins.

Chapter Perspective

Our study of the transition elements, a large group of metals with many essential industrial and biological roles, points out once again that macroscopic properties, such as color and magnetism, have their roots at the atomic and molecular levels, which in turn have such a crucial influence on structure. In the next, and final, chapter we explore the core of the atom and learn how we can apply its enormous power.

CHEMICAL CONNECTIONS to Nutritional Science

Transition Metals as Essential Dietary Trace Elements

Living things consist primarily of water and complex organic compounds of four building-block elements: carbon, oxygen, hydrogen, and nitrogen (see Figure 2.18, p. 61). All organisms also contain seven other elements, known as *macro*nutrients because they occur in fairly high concentrations. In order of increasing atomic number, they are sodium, magnesium, phosphorus, sulfur, chlorine, potassium, and calcium. In addition, organisms contain a surprisingly large number of other elements in much lower concentrations, and most of these *micro*nutrients, or *trace elements,* are transition metals.

With the exception of scandium and titanium, all Period 4 transition elements are essential for organisms, and plants require molybdenum (from Period 5) as well. The transition metal ion usually occurs at a bend of a protein chain covalently bonded to surrounding amino acid groups whose N and O atoms act as ligands. Despite the structural complexity of biomolecules, the principles of bonding and *d*-orbital splitting are the same as in simple inorganic systems. Table B23.1 (on the next page) is a list of the Period 4 transition metals known, or thought, to be essential in human nutrition. In this discussion we focus on iron and zinc.

Iron plays a crucial role in oxygen transport in all vertebrates. The oxygen-transporting protein hemoglobin (Figure B23.1A) consists of four folded protein chains called *globins,* each cradling the iron-containing complex *heme*. Heme is a porphyrin, a complex derived from a metal ion and the tetradentate ring ligand known as *porphin*. Iron(II) is centered in the plane of the porphin ring, forming coordinate covalent bonds with four N lone pairs, resulting in a square planar complex. When heme is bound in hemoglobin (Figure B23.1B), the complex is *octahedral,* with the fifth ligand of iron(II) being an N atom from a nearby amino acid (histidine), and the sixth an O atom from either an O_2 (shown) or an H_2O molecule.

Hemoglobin exists in two forms, depending on the nature of the sixth ligand. In the blood vessels of the lungs, where O_2 concentration is high, heme binds O_2 to form *oxyhemoglobin,* which is transported in the arteries to O_2-depleted tissues. At these tissues, the O_2 is released and replaced by an H_2O molecule to form *deoxyhemoglobin,* which is transported in the veins back to the lungs. The H_2O is a weak-field ligand, so the d^6 ion Fe^{2+} in deoxyhemoglobin is part of a high-spin complex. Because of the relatively small *d*-orbital splitting, deoxyhemoglobin absorbs light at the red (low-energy) end of the spectrum and looks purplish blue, which accounts for the dark color of venous blood. On the other hand, O_2 is a strong-field ligand, so it increases the splitting energy, which gives rise to a low-spin complex. For this reason, oxyhemoglobin absorbs at the blue (high-energy) end of the spectrum, which accounts for the bright red color of arterial blood.

The position of the Fe^{2+} ion relative to the plane of the porphin ring also depends on this sixth ligand. Bound to O_2, Fe^{2+} is *in* the porphin plane; bound to H_2O, it moves *out of* the plane slightly. This tiny ($\sim$60 pm = 6×10^{-11} m) change in the position of Fe^{2+} on release or attachment of O_2 influences the shape of its globin chain, which in turn alters the shape of a neighboring globin chain, triggering the release or attachment of *its* O_2, and so on to the other two globin chains. The very survival of vertebrate life is the result of this cooperative "teamwork" by the four globin

(continued)

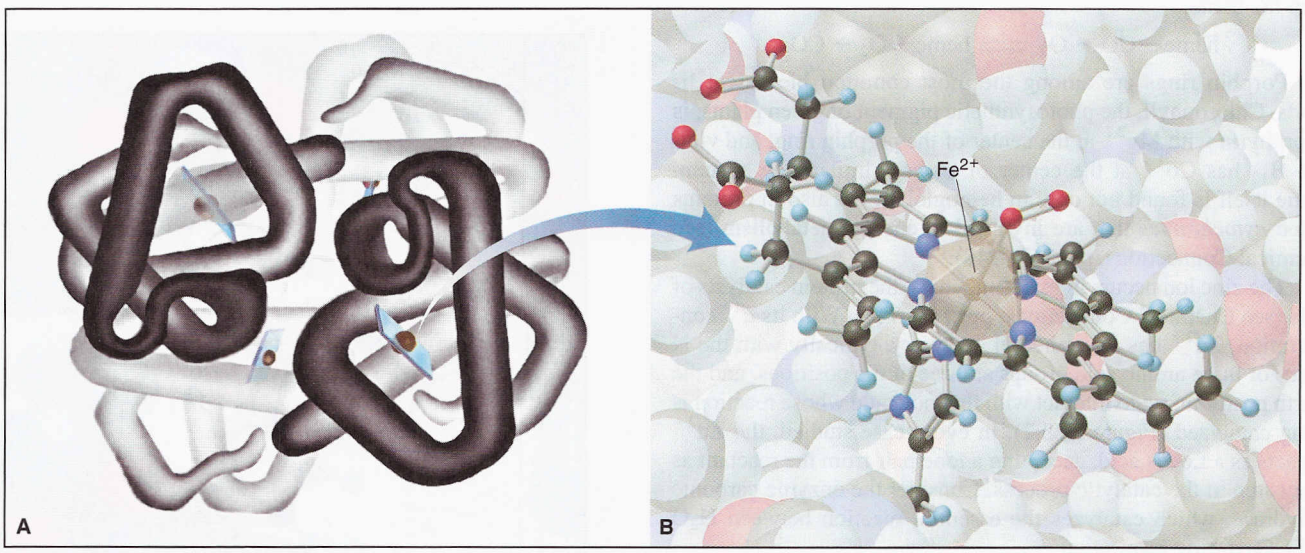

Figure B23.1 Hemoglobin and the octahedral complex in heme. **A,** Hemoglobin consists of four protein chains, each with a bound heme. (Illustration by Irving Geis. Rights owned by Howard Hughes Medical Institute. Table B23.1 Some Transition Metal Trace Elements in Humans

Element	Biomolecule Containing Element	Function of Biomolecule
Vanadium	Protein (?)	Redox couple in fat metabolism (?)
Chromium	Glucose tolerance factor	Glucose utilization
Manganese	Isocitrate dehydrogenase	Cell respiration
Iron	Hemoglobin and myoglobin	Oxygen transport
	Cytochrome *c*	Cell respiration; ATP formation
	Catalase	Decomposition of H_2O_2
Cobalt	Cobalamin (vitamin B_{12})	Development of red blood cells
Copper	Ceruloplasmin	Hemoglobin synthesis
	Cytochrome oxidase	Cell respiration; ATP formation
Zinc	Carbonic anhydrase	Elimination of CO_2
	Carboxypeptidase A	Protein digestion
	Alcohol dehydrogenase	Metabolism of ethanol

chains because it allows hemoglobin to pick up O_2 rapidly from the lungs and unload it rapidly in the tissues.

Carbon monoxide is highly toxic because it binds to the Fe^{2+} ion in heme about 200 times more tightly than O_2, thereby eliminating the heme group from functioning in the circulation. Like O_2, CO is a strong-field ligand and produces a bright red, "healthy" look in the individual. Because heme binding is an equilibrium process, CO poisoning can be reversed by breathing extremely high concentrations of O_2, which effectively displaces CO from the heme:

$$\text{heme}{-}\text{CO} + O_2 \rightleftharpoons \text{heme}{-}O_2 + \text{CO}$$

Porphin rings are among the most common biological ligands. Chlorophyll, the photosynthetic pigment of green plants, is a porphyrin with Mg^{2+} at the center of the porphin ring, and vitamin B_{12} has Co^{3+} at the center of a very similar ring system. Heme itself is found not only in hemoglobin, but also in proteins called *cytochromes* that are involved in energy metabolism (see Chemical Connections, pp. 947–948).

The zinc ion occurs in many enzymes, the protein catalysts of cells (see Chemical Connections, pp. 709–710). With its d^{10} configuration, Zn^{2+} has a tetrahedral geometry, typically with the N atoms of three amino acid groups at three of the positions, and the fourth position free to interact with the molecule whose reaction is being catalyzed (Figure B23.2). In every case studied, the Zn^{2+} ion acts as a Lewis acid, accepting a lone pair from the reactant as a key step in the catalytic process. Consider the enzyme carbonic anhydrase, which catalyzes the essential reaction between H_2O and CO_2 during respiration:

$$CO_2(g) + H_2O(l) \rightleftharpoons H^+(aq) + HCO_3^-(aq)$$

The Zn^{2+} ion at the enzyme's active site binds three histidine N atoms and the H_2O reactant as the fourth ligand. By withdrawing electron density from the O—H bonds, the Zn^{2+} makes the H_2O acidic enough to lose a proton. In the rate-determining step, the resulting bound OH^- ion attacks the partially positive C atom of CO_2 much more vigorously than could the lone pair of a free water molecule; thus, the reaction rate is higher. One reason the Cd^{2+} ion is toxic is that it competes with Zn^{2+} for fitting into the carbonic anhydrase active site.

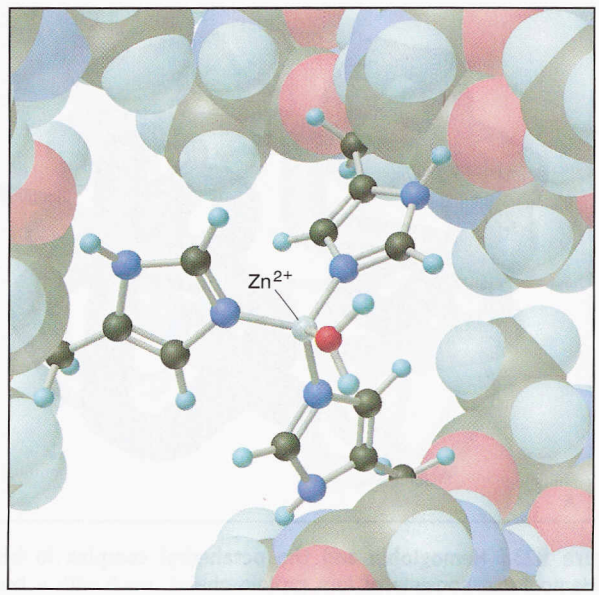

Figure B23.2 The tetrahedral Zn^{2+} complex in carbonic anhydrase.

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. The positions of the *d*- and *f*-block elements and the general forms of their atomic and ionic electron configurations (Section 23.1)
2. How atomic size, ionization energy, and electronegativity vary across a period and down a group of transition elements and how these trends differ from those of the main-group elements; why the densities of Period 6 transition elements are so high (Section 23.1)
3. Why the transition elements often have multiple oxidation states and why the +2 state is common (Section 23.1)
4. Why metallic behavior (prevalence of ionic bonding and basic oxides) decreases as oxidation state increases (Section 23.1)
5. Why many transition metal compounds are colored and paramagnetic (Section 23.1)
6. The common +3 oxidation state of lanthanides and the similarity in their M^{3+} radii; the radioactivity of actinides (Section 23.2)
7. How valence-state electronegativity explains why oxides become more covalent and acidic as the O.N. of the metal increases (Section 23.3)
8. Why Cr and Mn oxoanions are stronger oxidizing agents in acidic than in basic solutions (Section 23.3)
9. The role silver halides play in black-and-white photography (Section 23.3)
10. How the high density and low melting point of mercury account for its common uses; the toxicity of organomercury compounds (Section 23.3)
11. The coordination numbers, geometries, and ligand structures of complex ions (Section 23.4)
12. How coordination compounds are named and their formulas written (Section 23.4)
13. How Werner correlated the properties and structures of coordination compounds (Section 23.4)
14. The types of constitutional isomerism (coordination and linkage) and stereoisomerism (geometric and optical) of coordination compounds (Section 23.4)
15. How valence bond theory uses hybridization to account for the shapes of octahedral, square planar, and tetrahedral complexes (Section 23.5)
16. How crystal field theory explains that approaching ligands cause *d*-orbital energies to split (Section 23.5)
17. How the relative crystal-field strength of ligands (spectrochemical series) affects the *d*-orbital splitting energy (Δ) (Section 23.5)
18. How the magnitude of Δ accounts for the energy of light absorbed and, thus, the color of a complex (Section 23.5)
19. How the relative sizes of pairing energy and Δ determine the occupancy of *d* orbitals and, thus, the magnetic properties of complexes (Section 23.5)
20. How *d*-orbital splitting in tetrahedral and square planar complexes differs from that in octahedral complexes (Section 23.5)

Master These Skills

1. Writing electron configurations of transition metal atoms and ions (SP 23.1)
2. Using a partial orbital diagram to determine the number of unpaired electrons in a transition-metal atom or ion (SP 23.2)
3. Recognizing the structural components of complex ions (Section 23.4)
4. Naming and writing formulas of coordination compounds (SP 23.3)
5. Determining the type of stereoisomerism in complexes (SP 23.4)
6. Correlating a complex ion's shape with the number and type of hybrid orbitals of the central metal ion (Section 23.5)
7. Using the spectrochemical series to rank complex ions in terms of Δ and the energy of light absorbed (SP 23.5)
8. Using the spectrochemical series to determine if a complex is high or low spin (SP 23.6)

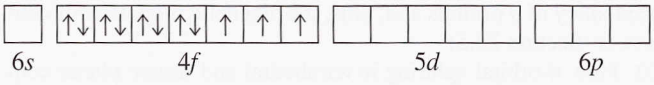
Brief Solutions to Follow-up Problems

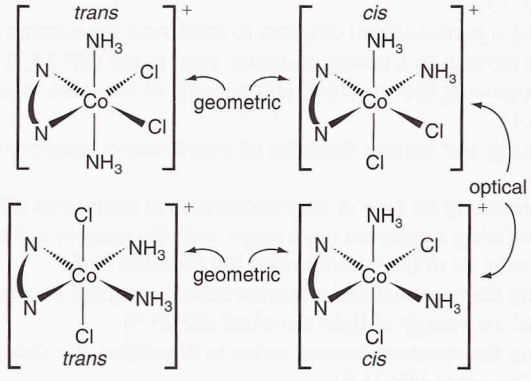
23.1 (a) Ag^+: $4d^{10}$; (b) Cd^{2+}: $4d^{10}$; (c) Ir^{3+}: $5d^6$

23.2 Three; Er^{3+} is [Xe] $4f^{11}$:



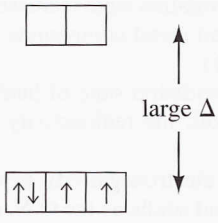
23.3 (a) Pentaaquabromochromium(III) chloride;
(b) $Ba_3[Co(CN)_6]_2$

23.4 Two sets of *cis-trans* isomers, and the two *cis* isomers are optical isomers.



23.5 Both metal ions are V^{3+}; in terms of ligand field energy, $NH_3 > H_2O$, so $[V(NH_3)_6]^{3+}$ absorbs light of higher energy.

23.6 The metal ion is Mn^{3+}: [Ar] $3d^4$.



Two unpaired *d* electrons; low-spin complex

Problems

Problems with **colored** numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

Note: In these problems, the term *electron configuration* refers to the condensed, ground-state electron configuration.

Properties of the Transition Elements

(Sample Problem 23.1)

Concept Review Questions

23.1 How is the *n* value of the *d* sublevel of a transition element related to the period number of the element?

23.2 (a) Write the general electron configuration of a transition element in Period 5.
(b) Write the general electron configuration of a transition element in Period 6.

23.3 What is the general rule concerning the order in which electrons are removed from a transition metal atom to form an ion? Give an example from Group 5B(5). Name two types of measurements used to study electron configurations of ions.

23.4 What is the maximum number of unpaired *d* electrons that an atom or ion can possess? Give an example of an atom and an ion that have this number.

23.5 How does the variation in atomic size across a transition series contrast with the change across the main-group elements of the same period? Why?

23.6 (a) What is the lanthanide contraction?
(b) How does it affect atomic size down a group of transition elements?
(c) How does it influence the densities of the Period 6 transition elements?

23.7 (a) What is the range in electronegativity values across the first (3*d*) transition series?
(b) What is the range across Period 4 of main-group elements?
(c) Explain the difference between the two ranges.

23.8 (a) Explain the major difference between the number of oxidation states of most transition elements and that of most main-group elements.
(b) Why is the +2 oxidation state so common among transition elements?

23.9 (a) What difference in behavior distinguishes a paramagnetic substance from a diamagnetic one?
(b) Why are paramagnetic ions common among the transition elements but not the main-group elements?
(c) Why are colored solutions of metal ions common among the transition elements but not the main-group elements?

Skill-Building Exercises *(grouped in similar pairs)*

23.10 Using the periodic table to locate each element, write the electron configuration of (a) V; (b) Y; (c) Hg.

23.11 Using the periodic table to locate each element, write the electron configuration of (a) Ru; (b) Cu; (c) Ni.

23.12 Using the periodic table to locate each element, write the electron configuration of (a) Os; (b) Co; (c) Ag.

23.13 Using the periodic table to locate each element, write the electron configuration of (a) Zn; (b) Mn; (c) Re.

23.14 Give the electron configuration and the number of unpaired electrons for each of the following ions: (a) Sc^{3+}; (b) Cu^{2+}; (c) Fe^{3+}; (d) Nb^{3+}.

23.15 Give the electron configuration and the number of unpaired electrons for each of the following ions: (a) Cr^{3+}; (b) Ti^{4+}; (c) Co^{3+}; (d) Ta^{2+}.

23.16 What is the highest possible oxidation state for each of the following: (a) Ta; (b) Zr; (c) Mn?

23.17 What is the highest possible oxidation state for each of the following: (a) Nb; (b) Y; (c) Tc?

23.18 Which transition metals have a maximum oxidation state of +6?

23.19 Which transition metals have a maximum oxidation state of +4?

23.20 In which compound does Cr exhibit greater metallic behavior, CrF_2 or CrF_6? Explain.

23.21 VF_5 is a liquid that boils at 48°C, whereas VF_3 is a solid that melts above 800°C. Explain this difference in properties.

23.22 Is it more difficult to oxidize Cr or Mo? Explain.

23.23 Is MnO_4^- or ReO_4^- a stronger oxidizing agent? Explain.

23.24 Which oxide, CrO_3 or CrO, forms a more acidic aqueous solution? Explain.

23.25 Which oxide, Mn_2O_3 or Mn_2O_7, displays more basic behavior? Explain.

Problems in Context

23.26 The green patina of copper-alloy roofs of old buildings is the result of the corrosion (oxidation) of copper in the presence of O_2, H_2O, CO_2, and sulfur compounds. Silver and gold—the other stable members of Group 1B(11)—do not form this patina. Corrosion of copper and silver in the presence of sulfur and its compounds leads to the familiar black tarnish, but gold does not react with sulfur. This pattern is markedly different from that in Group 1A(1), where ease of oxidation *increases* down the group. What causes the different patterns in the two groups?

The Inner Transition Elements

(Sample Problem 23.2)

Concept Review Questions

23.27 What atomic property of the lanthanides leads to their remarkably similar chemical properties?

23.28 (a) What is the maximum number of unpaired electrons exhibited by an ion of a lanthanide?
(b) How does this number relate to occupancy of the 4*f* subshell?

23.29 Which of the actinides are radioactive?

Skill-Building Exercises *(grouped in similar pairs)*

23.30 Write the electron configurations of the following atoms and ions: (a) La; (b) Ce^{3+}; (c) Es; (d) U^{4+}.

23.31 Write the electron configurations of the following atoms and ions: (a) Pm; (b) Lu^{3+}; (c) Th; (d) Fm^{3+}.

23.32 Only a few of the lanthanides show any oxidation state other than +3. Two of these, europium (Eu) and terbium (Tb), are found near the middle of the series, and their unusual oxidation states can be associated with a half-filled *f* subshell.
(a) Write the electron configurations of Eu^{2+}, Eu^{3+}, and Eu^{4+}. Why is Eu^{2+} a common ion, whereas Eu^{4+} is unknown?
(b) Write the electron configurations of Tb^{2+}, Tb^{3+}, and Tb^{4+}. Would you expect Tb to show a +2 or a +4 oxidation state? Explain.

23.33 Cerium (Ce) and ytterbium (Yb) exhibit other oxidation states in addition to +3.
(a) Write the electron configurations of Ce^{2+}, Ce^{3+}, and Ce^{4+}.
(b) Write the electron configurations of Yb^{2+}, Yb^{3+}, and Yb^{4+}.
(c) In addition to the 3+ ions, the ions Ce^{4+} and Yb^{2+} are stable. Suggest a reason for this stability.

Problems in Context

23.34 One of the lanthanides displays the maximum possible number of unpaired electrons both for an atom and for a 3+ ion. Name the element and give the number of unpaired electrons in the atom and the ion.

Highlights of Selected Transition Metals

Concept Review Questions

23.35 What is the chemical reason that chromium is so useful for decorative plating on metals?

23.36 What is valence-state electronegativity? Use the concept to explain the change in acidity of the oxides of Mn with changing O.N. of the metal.

23.37 What property does manganese confer to steel?

23.38 What chemical property of silver leads to its use in jewelry and other decorative objects?

23.39 How is a photographic latent image different from the image you see on a piece of developed film?

23.40 Mercury has an unusual physical property and an unusual 1+ ion. Explain.

Problems in Context

23.41 When a basic solution of $Cr(OH)_4^-$ ion is slowly acidified, solid $Cr(OH)_3$ first precipitates out and then redissolves as excess acid is added. Assuming that $Cr(OH)_4^-$ actually exists as $Cr(H_2O)_2(OH)_4^-$, write equations that represent these two reactions.

23.42 Use the following data to determine if $Cr^{2+}(aq)$ can be prepared by the reaction of $Cr(s)$ with $Cr^{3+}(aq)$:

$$Cr^{3+}(aq) + e^- \longrightarrow Cr^{2+}(aq) \qquad E^0 = -0.41\ V$$
$$Cr^{3+}(aq) + 3e^- \longrightarrow Cr(s) \qquad E^0 = -0.74\ V$$
$$Cr^{2+}(aq) + 2e^- \longrightarrow Cr(s) \qquad E^0 = -0.91\ V$$

23.43 When solid CrO_3 is dissolved in water, the solution is orange rather than the yellow of H_2CrO_4. How does this observation indicate that CrO_3 is an acidic oxide?

23.44 Solutions of $KMnO_4$ are used commonly in redox titrations. The dark purple MnO_4^- ion serves as its own indicator, changing to the almost colorless Mn^{2+} as it is reduced. The end point occurs when a pale purple color remains as the $KMnO_4$ solution is added. If a sample that has reached this end point is allowed to stand for a long period of time, the color fades and a suspension of a small amount of brown, muddy MnO_2 appears. Use standard electrode potentials to explain this result.

Coordination Compounds

(Sample Problems 23.3 and 23.4)

Concept Review Questions

23.45 Describe the makeup of a complex ion, including the nature of the ligands and their interaction with the central metal ion. Explain how a complex ion can be positive or negative and how it occurs as part of a neutral coordination compound.

23.46 What electronic feature must a donor atom of any ligand possess?

23.47 What is the coordination number of a metal ion in a complex ion? How does it differ from oxidation number?

23.48 What structural feature is characteristic of a complex described as a chelate?

23.49 What geometries are associated with the coordination numbers 2, 4, and 6?

23.50 What are the coordination numbers of cobalt(III), platinum(II), and platinum(IV) in complexes?

23.51 In what sense is a complex ion the adduct of a Lewis acid-base reaction?

23.52 What does the ending *-ate* signify in a complex ion name?

23.53 In what order are the metal ion and ligands given in the name of a complex ion?

23.54 Is a linkage isomer a type of constitutional isomer or stereoisomer? Explain.

Skill-Building Exercises *(grouped in similar pairs)*

23.55 Give systematic names for the following formulas:
(a) $[Ni(H_2O)_6]Cl_2$ (b) $[Cr(en)_3](ClO_4)_3$ (c) $K_4[Mn(CN)_6]$

23.56 Give systematic names for the following formulas:
(a) $[Co(NH_3)_4(NO_2)_2]Cl$ (b) $[Cr(NH_3)_6][Cr(CN)_6]$
(c) $K_2[CuCl_4]$

23.57 What are the charge and coordination number of the central metal ion(s) in each compound of Problem 23.55?

23.58 What are the charge and coordination number of the central metal ion(s) in each compound of Problem 23.56?

23.59 Give systematic names for the following formulas:
(a) $K[Ag(CN)_2]$ (b) $Na_2[CdCl_4]$ (c) $[Co(NH_3)_4(H_2O)Br]Br_2$

23.60 Give systematic names for the following formulas:
(a) $K[Pt(NH_3)Cl_5]$ (b) $[Cu(en)(NH_3)_2][Co(en)Cl_4]$
(c) $[Pt(en)_2Br_2](ClO_4)_2$

23.61 What are the charge and coordination number of the central metal ion(s) in each compound of Problem 23.59?

23.62 What are the charge and coordination number of the central metal ion(s) in each compound of Problem 23.60?

23.63 Give formulas corresponding to the following names:
(a) Tetraamminezinc sulfate
(b) Pentaamminechlorochromium(III) chloride
(c) Sodium bis(thiosulfato)argentate(I)

23.64 Give formulas corresponding to the following names:
(a) Dibromobis(ethylenediamine)cobalt(III) sulfate
(b) Hexaamminechromium(III) tetrachlorocuprate(II)
(c) Potassium hexacyanoferrate(II)

23.65 What is the coordination number of the metal ion and the number of individual ions per formula unit in each of the compounds in Problem 23.63?

23.66 What is the coordination number of the metal ion and the number of individual ions per formula unit in each of the compounds in Problem 23.64?

23.67 Give formulas corresponding to the following names:
(a) Hexaaquachromium(III) sulfate
(b) Barium tetrabromoferrate(III)
(c) Bis(ethylenediamine)platinum(II) carbonate

23.68 Give formulas corresponding to the following names:
(a) Potassium tris(oxalato)chromate(III)
(b) Tris(ethylenediamine)cobalt(III) pentacyanoiodomanganate(II)
(c) Diamminediaquabromochloroaluminum nitrate

23.69 What is the coordination number of the metal ion and the number of individual ions per formula unit in each of the compounds in Problem 23.67?

23.70 What is the coordination number of the metal ion and the number of individual ions per formula unit in each of the compounds in Problem 23.68?

23.71 Which of these ligands can participate in linkage isomerism: (a) NO_2^-; (b) SO_2; (c) NO_3^-? Explain with Lewis structures.

23.72 Which of these ligands can participate in linkage isomerism: (a) SCN^-; (b) $S_2O_3^{2-}$ (thiosulfate); (c) HS^-? Explain with Lewis structures.

23.73 For any of the following that can exist as isomers, state the type of isomerism and draw the structures:
(a) $[Pt(CH_3NH_2)_2Br_2]$ (b) $[Pt(NH_3)_2FCl]$
(c) $[Pt(H_2O)(NH_3)FCl]$

23.74 For any of the following that can exist as isomers, state the type of isomerism and draw the structures:
(a) $[Zn(en)F_2]$ (b) $[Zn(H_2O)(NH_3)FCl]$
(c) $[Pd(CN)_2(OH)_2]^{2-}$

23.75 For any of the following that can exist as isomers, state the type of isomerism and draw the structures:
(a) $[PtCl_2Br_2]^{2-}$ (b) $[Cr(NH_3)_5(NO_2)]^{2+}$
(c) $[Pt(NH_3)_4I_2]^{2+}$

23.76 For any of the following that can exist as isomers, state the type of isomerism and draw the structures:
(a) $[Co(NH_3)_5Cl]Br_2$ (b) $[Pt(CH_3NH_2)_3Cl]Br$
(c) $[Fe(H_2O)_4(NH_3)_2]^{2+}$

Problems in Context

23.77 Chromium(III), like cobalt(III), has a coordination number of 6 in many of its complex ions. Compounds are known that have the traditional formula $CrCl_3 \cdot nNH_3$, where $n = 3$ to 6. Which of the compounds has an electrical conductivity in aqueous solution similar to that of an equimolar NaCl solution?

23.78 When $MCl_4(NH_3)_2$ is dissolved in water and treated with $AgNO_3$, 2 mol of AgCl precipitates immediately for each mole of $MCl_4(NH_3)_2$. Give the coordination number of M in the complex.

23.79 Palladium, like its group neighbor platinum, forms four-coordinate Pd(II) and six-coordinate Pd(IV) complexes. Write modern formulas for the complexes with these compositions:
(a) $PdK(NH_3)Cl_3$ (b) $PdCl_2(NH_3)_2$
(c) PdK_2Cl_6 (d) $Pd(NH_3)_4Cl_4$

Theoretical Basis for the Bonding and Properties of Complexes

(Sample Problems 23.5 and 23.6)

Concept Review Questions

23.80 (a) What is a coordinate covalent bond?
(b) Is it involved when $FeCl_3$ dissolves in water? Explain.
(c) Is it involved when HCl gas dissolves in water? Explain.

23.81 According to valence bond theory, what set of orbitals is used by a Period 4 metal ion in forming (a) a square planar complex; (b) a tetrahedral complex?

23.82 A metal ion is described as using a d^2sp^3 set of orbitals when forming a complex. What is the coordination number of the metal ion and the shape of the complex?

23.83 A complex in solution absorbs green light. What is the color of the solution?

23.84 What *two* possibilities of color absorption by a solution could give rise to an observed blue color?

23.85 (a) What is the crystal field splitting energy (Δ)?
(b) How does it arise for an octahedral field of ligands?
(c) How is it different for a tetrahedral field of ligands?

23.86 What is the distinction between a weak-field ligand and a strong-field ligand? Give an example of each.

23.87 Is a complex with the same number of unpaired electrons as the free gaseous metal ion termed high spin or low spin?

23.88 How do the relative magnitudes of $E_{pairing}$ and Δ affect the paramagnetism of a complex?

23.89 Why are there both high-spin and low-spin octahedral complexes but only high-spin tetrahedral complexes?

Skill-Building Exercises *(grouped in similar pairs)*

23.90 Give the number of d electrons (n of d^n) for the central metal ion in each of these species: (a) $[TiCl_6]^{2-}$; (b) $K[AuCl_4]$; (c) $[RhCl_6]^{3-}$.

23.91 Give the number of d electrons (n of d^n) for the central metal ion in each of these species: (a) $[Cr(H_2O)_6](ClO_3)_2$; (b) $[Mn(CN)_6]^{2-}$; (c) $[Ru(NO)(en)_2Cl]Br$.

23.92 Give the number of d electrons (n of d^n) for the central metal ion in each of these species: (a) $Ca[IrF_6]$; (b) $[HgI_4]^{2-}$; (c) $[Co(EDTA)]^{2-}$.

23.93 Give the number of d electrons (n of d^n) for the central metal ion in each of these species: (a) $[Ru(NH_3)_5Cl]SO_4$; (b) $Na_2[Os(CN)_6]$; (c) $[Co(NH_3)_4CO_3I]$.

23.94 Sketch the orientation of the orbitals relative to the ligands in an octahedral complex to explain the splitting and the relative energies of the d_{xy} and the $d_{x^2-y^2}$ orbitals.

23.95 The two e_g orbitals are identical in energy in an octahedral complex but have different energies in a square planar complex, with the d_{z^2} orbital being much lower in energy than the $d_{x^2-y^2}$. Explain with orbital sketches.

23.96 Which of these ions *cannot* form both high- and low-spin octahedral complexes: (a) Ti^{3+}; (b) Co^{2+}; (c) Fe^{2+}; (d) Cu^{2+}?

23.97 Which of these ions *cannot* form both high- and low-spin octahedral complexes: (a) Mn^{3+}; (b) Nb^{3+}; (c) Ru^{3+}; (d) Ni^{2+}?

23.98 Draw orbital-energy splitting diagrams and use the spectrochemical series to show the orbital occupancy for each of the following (assuming that H_2O is a weak-field ligand):
(a) $[Cr(H_2O)_6]^{3+}$ (b) $[Cu(H_2O)_4]^{2+}$ (c) $[FeF_6]^{3-}$

23.99 Draw orbital-energy splitting diagrams and use the spectrochemical series to show the orbital occupancy for each of the following (assuming that H_2O is a weak-field ligand):
(a) $[Cr(CN)_6]^{3-}$ (b) $[Rh(CO)_6]^{3+}$ (c) $[Co(OH)_6]^{4-}$

23.100 Draw orbital-energy splitting diagrams and use the spectrochemical series to show the orbital occupancy for each of the following (assuming that H_2O is a weak-field ligand):
(a) $[MoCl_6]^{3-}$ (b) $[Ni(H_2O)_6]^{2+}$ (c) $[Ni(CN)_4]^{2-}$

23.101 Draw orbital-energy splitting diagrams and use the spectrochemical series to show the orbital occupancy for each of the following (assuming that H_2O is a weak-field ligand):
(a) $[Fe(C_2O_4)_3]^{3-}$ ($C_2O_4^{2-}$ creates a weaker field than H_2O does.)
(b) $[Co(CN)_6]^{4-}$ (c) $[MnCl_6]^{4-}$

23.102 Rank the following complex ions in order of *increasing* Δ and energy of visible light absorbed: $[Cr(NH_3)_6]^{3+}$, $[Cr(H_2O)_6]^{3+}$, $[Cr(NO_2)_6]^{3-}$.

23.103 Rank the following complex ions in order of *decreasing* Δ and energy of visible light absorbed: $[Cr(en)_3]^{3+}$, $[Cr(CN)_6]^{3-}$, $[CrCl_6]^{3-}$.

23.104 A complex, ML_6^{2+}, is violet. The same metal forms a complex with another ligand, Q, that creates a weaker field. What color might MQ_6^{2+} be expected to show? Explain.

23.105 $[Cr(H_2O)_6]^{2+}$ is violet. Another CrL_6 complex is green. Can ligand L be CN^-? Can it be Cl^-? Explain.

Problems in Context

23.106 Octahedral $[Ni(NH_3)_6]^{2+}$ is paramagnetic, whereas planar $[Pt(NH_3)_4]^{2+}$ is diamagnetic, even though both metal ions are d^8 species. Explain.

23.107 The hexaaqua complex $[Ni(H_2O)_6]^{2+}$ is green, whereas the hexaammonia complex $[Ni(NH_3)_6]^{2+}$ is violet. Explain.

23.108 Three of the complex ions that are formed by Co^{3+} are $[Co(H_2O)_6]^{3+}$, $[Co(NH_3)_6]^{3+}$, and $[CoF_6]^{3-}$. These ions have the observed colors (listed in arbitrary order) yellow-orange, green, and blue. Match each complex with its color. Explain.

Comprehensive Problems

23.109 When neptunium (Np) and plutonium (Pu) were discovered, the periodic table did not include the actinides, so these elements were placed in Group 7B(7) and 8B(8). When americium (Am) and curium (Cm) were synthesized, they were placed in Group 8B(9) and 8B(10). However, during chemical isolation procedures, Glenn Seaborg and his group, who had synthesized these elements, could not find their compounds among other compounds of these groups, which led Seaborg to suggest they were part of a new inner transition series. (a) How do the electron configurations of these elements support Seaborg's suggestion? (b) The highest fluorides of Np and Pu are hexafluorides, as is the highest fluoride of uranium. How does this chemical evidence support the placement of Np and Pu as *inner* transition elements rather than transition elements?

23.110 How many different formulas are there for octahedral complexes with a metal M and four ligands A, B, C and D? Give the number of isomers for each formula and describe the isomers.

23.111 At one time, it was common to write the formula for copper(I) chloride as Cu_2Cl_2, instead of CuCl, analogously to Hg_2Cl_2 for mercury(I) chloride. Use electron configurations to explain why Hg_2Cl_2 is correct but so is CuCl.

23.112 Correct each name that has an error:
(a) $Na[FeBr_4]$, sodium tetrabromoferrate(II)
(b) $[Ni(NH_3)_6]^{2+}$, nickel hexaammine ion
(c) $[Co(NH_3)_3I_3]$, triamminetriiodocobalt(III)
(d) $[V(CN)_6]^{3-}$, hexacyanovanadium(III) ion
(e) $K[FeCl_4]$, potassium tetrachloroiron(III)

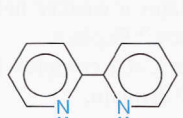
23.113 For the compound $[Co(en)_2Cl_2]Cl$, give:
(a) The coordination number of the metal ion
(b) The oxidation number of the central metal ion
(c) The number of individual ions per formula unit
(d) The moles of AgCl that precipitate immediately when 1 mol of compound is dissolved in water and treated with $AgNO_3$

23.114 Hexafluorocobaltate(III) ion is a high-spin complex. Draw the orbital-energy splitting diagram for its *d* orbitals.

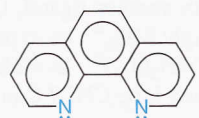
23.115 A salt of each of the ions in Table 23.3 (p. 1009) is dissolved in water. A Pt electrode is immersed in each solution and connected to a 0.38-V battery. All of the electrolytic cells are run for the same amount of time with the same current.
(a) In which cell(s) will a metal plate out? Explain.
(b) Which cell will plate out the least mass of metal? Explain.

23.116 Criticize and correct the following statement: strong-field ligands always give rise to low-spin complexes.

23.117 Two major bidentate ligands used in analytical chemistry are bipyridyl (bipy) and *ortho*-phenanthroline (*o*-phen):



bipyridyl



o-phenanthroline

Draw structures and discuss the possibility of isomers for
(a) $[Pt(bipy)Cl_2]$ (b) $[Fe(o\text{-phen})_3]^{3+}$
(c) $[Co(bipy)_2F_2]^{+}$ (d) $[Co(o\text{-phen})(NH_3)_3Cl]^{2+}$

23.118 The following reaction is a key step in black-and-white photography (see p. 1015):

$$AgBr(s) + 2S_2O_3^{2-}(aq) \longrightarrow Ag(S_2O_3)_2^{3-}(aq) + Br^-(aq)$$

During fixing, 258 mL of hypo (sodium thiosulfate) was used. The hypo concentration was 0.1052 *M* before the AgBr reacted, and 0.0378 *M* afterward. How many grams of AgBr reacted?

23.119 The metal ion in platinum(IV) complexes, like that in cobalt(III) complexes, has a coordination number of 6. Many of these complexes occur with Cl^- ions and NH_3 molecules as ligands. Consider the following traditional (before the work of Werner) formulas for two coordination compounds:
(a) $PtCl_4 \cdot 6NH_3$ (b) $PtCl_4 \cdot 4NH_3$
For each of these compounds:
(1) Give the modern formula and charge of the complex ion.
(2) Predict moles of ions formed per mole of compound dissolved and moles of AgCl formed immediately with excess $AgNO_3$.

23.120 In 1940, when the elements Np and Pu were prepared, a controversy arose about whether the elements from Ac on were analogs of the transition elements (and related to Y through Mo) or analogs of the lanthanides (and related to La through Nd). The arguments hinged primarily on comparing observed oxidation states to those of the earlier elements. (a) If the actinides were analogs of the transition elements, what would you predict about the maximum oxidation state for U? For Np? (b) If the actinides were analogs of the lanthanides, what would you predict about the maximum oxidation state for U? For Pu?

23.121 In many species, a transition metal has an unusually high or low oxidation state. Write balanced equations for the following and find the oxidation state of the transition metal in the product:
(a) Iron(III) ion reacts with hypochlorite ion in basic solution to form ferrate ion (FeO_4^{2-}), Cl^-, and water.
(b) Potassium hexacyanomanganate(II) reacts with K metal to form $K_6[Mn(CN)_6]$.
(c) Heating sodium superoxide with Co_3O_4 produces Na_4CoO_4 and O_2 gas.
(d) Vanadium(III) chloride reacts with Na metal under a CO atmosphere to produce $Na[V(CO)_6]$ and NaCl.
(e) Barium peroxide reacts with nickel(II) ions in basic solution to produce $BaNiO_3$.
(f) Bubbling CO through a basic solution of cobalt(II) ion produces $[Co(CO)_4]^-$, CO_3^{2-}, and water.
(g) Heating cesium tetrafluorocuprate(II) with F_2 gas under pressure gives Cs_2CuF_6.
(h) Heating tantalum(V) chloride with Na metal produces NaCl and Ta_6Cl_{15}, in which half of the Ta is in the +2 state.
(i) Heating cesium tetrafluoroargentate(II) with F_2 gas gives Cs_2AgF_6, in which half the silver is in the +3 state.
(j) Potassium tetracyanonickelate(II) reacts with hydrazine (N_2H_4) in basic solution to form $K_4[Ni_2(CN)_6]$ and N_2 gas.

23.122 For the permanganate ion, draw a Lewis structure that has the lowest formal charges.

23.123 The coordination compound $[Pt(NH_3)_2(SCN)_2]$ displays two types of isomerism. Name the types and give names and structures for the six possible isomers.

23.124 In the sepia "toning" of a black-and-white photograph, the image is converted to a rich brownish violet by placing the finished photograph in a solution of gold(III) ions, in which metallic gold replaces the metallic silver. Use Appendix D to explain the chemistry of this process.

23.125 An octahedral complex with three different ligands (A, B, and C) can have formulas with three different ratios of the ligands:
$[MA_4BC]^{n+}$, such as $[Co(NH_3)_4(H_2O)Cl]^{2+}$
$[MA_3B_2C]^{n+}$, such as $[Cr(H_2O)_3Br_2Cl]$
$[MA_2B_2C_2]^{n+}$, such as $[Cr(NH_3)_2(H_2O)_2Br_2]^{+}$
For each example, give the name, state the type(s) of isomerism present, and draw all isomers.

23.126 In black-and-white photography, what are the major chemical changes involved in exposing, developing, and fixing?

23.127 In $[Cr(NH_3)_6]Cl_3$, the $[Cr(NH_3)_6]^{3+}$ ion absorbs visible light in the blue-violet range, and the compound is yellow-orange. In $[Cr(H_2O)_6]Br_3$, the $[Cr(H_2O)_6]^{3+}$ ion absorbs visible light in the red range, and the compound is blue-gray. Explain these differences in light absorbed and colors of the compounds.

23.128 Dark green manganate salts contain the MnO_4^{2-} ion. The ion is stable in basic solution but disproportionates in acid to $MnO_2(s)$ and MnO_4^-. (a) What is the oxidation state of Mn in MnO_4^{2-}, MnO_4^-, and MnO_2? (b) Write a balanced equation for the reaction of MnO_4^{2-} in acidic solution.

23.129 Aqueous electrolysis of potassium manganate (K_2MnO_4) in basic solution is used for the production of tens of thousands of tons of potassium permanganate ($KMnO_4$) annually. (a) Write

a balanced equation for the electrolysis reaction. (Water is reduced also.) (b) How many moles of MnO_4^- can be formed if 12 A flow through a tank of aqueous MnO_4^{2-} for 96 h?

23.130 The actinides Pa, U, and Np form a series of complex ions, such as the anion in the compound $Na_3[UF_8]$, in which the central metal ion has an unusual geometry and oxidation state. In the crystal structure, the complex ion can be pictured as resulting from interpenetration of simple cubic arrays of uranium and fluoride ions. (a) What is the coordination number of the metal ion in the complex ion? (b) What is the oxidation state of uranium in the compound? (c) Sketch the complex ion.

23.131 Ionic liquids have many new applications in engineering and materials science. The dissolution of the metavanadate ion in chloroaluminate ionic liquids has been studied:

$$VO_3^- + AlCl_4^- \longrightarrow VO_2Cl_2^- + AlOCl_2^-$$

(a) What is the oxidation number of V and Al in each ion?

(b) In reactions with V_2O_5, acid concentration affects the product. At low acid concentration, $VO_2Cl_2^-$ and VO_3^- form:

$$V_2O_5 + HCl \longrightarrow VO_2Cl_2^- + VO_3^- + H^+$$

At high acid concentration, $VOCl_3$ forms:

$$V_2O_5 + HCl \longrightarrow VOCl_3 + H_2O$$

Balance each equation, and state which, if either, involves a redox process.

(c) What mass of $VO_2Cl_2^-$ or $VOCl_3$ can form from 10.0 g of V_2O_5 and the appropriate concentration of acid?

23.132 (a) What are the central metal ions in chlorophyll, heme, and vitamin B_{12}? (b) What similarity in structure do these compounds have?

23.133 Several coordination isomers, with both Co and Cr as 3+ ions, have the molecular formula $CoCrC_6H_{18}N_{12}$. (a) Give the name and standard formula of the isomer in which the Co complex ion has six NH_3 groups. (b) Give the name and standard formula of the isomer in which the Co complex ion has one CN and five NH_3 groups.

23.134 There are several coordination isomers with the molecular formula $Pt_2H_{12}Cl_6N_4$. (a) Give the name and standard formula of the isomer in which the Pt complex ion has six Cl groups and a charge of 2−. (b) Give the name and standard formula of the isomer in which the Pt complex ion has four Cl groups and a charge of 2−.

23.135 A shortcut to finding optical isomers is to see if the complex has a "plane of symmetry"—a plane passing through the metal atom such that every atom on one side of the plane is matched by an identical one at the same distance from the plane on the other side. Any planar complex has a plane of symmetry, since all atoms lie in one plane. Use this approach to determine whether these exist as optical isomers: (a) $[Zn(NH_3)_2Cl_2]$ (tetrahedral); (b) $[Pt(en)_2]^{2+}$; (c) *trans*-$[PtBr_4Cl_2]^{2-}$; (d) *trans*-$[Co(en)_2F_2]^+$; (e) *cis*-$[Co(en)_2F_2]^+$.

23.136 Werner prepared two compounds by heating a solution of $PtCl_2$ with triethyl phosphine, $P(C_2H_5)_3$, which is an excellent ligand for Pt. The two compounds gave the same analysis: Pt, 38.8%; Cl, 14.1%; C, 28.7%; P, 12.4%; and H, 6.02%. Write formulas, structures, and systematic names for the two isomers.

23.137 Some octahedral complexes have distorted shapes. In the Jahn-Teller distortion, two metal-ligand bonds that are 180° apart are shorter than the other four. In $[Cu(NH_3)_6]^{2+}$, for example, two Cu—N bonds are 207 pm long, and the other four are 262 pm long. (a) Calculate the longest distance between two N atoms in this complex. (b) Calculate the shortest distance between two N atoms.

23.138 Mercury has a small but significant vapor pressure, and Hg poisoning can occur in poorly ventilated rooms where Hg has been spilled. What is the partial pressure of Hg at 25°C for a maximum concentration of 20.0 mg/m^3?

23.139 Normal carbonic anhydrase has zinc at its active site (see Figure B23.2, p. 1036). Suggest a structural reason why carbonic anhydrase synthesized with Ni^{2+}, Fe^{2+}, or Mn^{2+} in place of Zn^{2+} gives an enzyme with less catalytic efficiency.

23.140 The effect of entropy on reactions is evident in the stabilities of certain complexes.

(a) Using the criterion of number of product particles, predict which of the following will be favored in terms of ΔS^0_{rxn}:

$$[Cu(NH_3)_4]^{2+}(aq) + 4H_2O(l) \longrightarrow [Cu(H_2O)_4]^{2+}(aq) + 4NH_3(aq)$$

$$[Cu(H_2NCH_2CH_2NH_2)_2]^{2+}(aq) + 4H_2O(l) \longrightarrow [Cu(H_2O)_4]^{2+}(aq) + 2en(aq)$$

(b) Given that the Cu—N bond strength is approximately the same in both complexes, which complex will be more stable with respect to ligand exchange in water? Explain.

23.141 The extent of crystal field splitting is often determined from spectra.

(a) Given the wavelength (λ) of maximum absorption, find the crystal field splitting energy (Δ), in kJ/mol, for each of the following complex ions:

Ion	λ (nm)	Ion	λ (nm)
$[Cr(H_2O)_6]^{3+}$	562	$[Fe(H_2O)_6]^{2+}$	966
$[Cr(CN)_6]^{3-}$	381	$[Fe(H_2O)_6]^{3+}$	730
$[CrCl_6]^{3-}$	735	$[Co(NH_3)_6]^{3+}$	405
$[Cr(NH_3)_6]^{3+}$	462	$[Rh(NH_3)_6]^{3+}$	295
$[Ir(NH_3)_6]^{3+}$	244		

(b) Construct a spectrochemical series for the ligands in the Cr complexes.

(c) Use the Fe data to state how oxidation state affects Δ.

(d) Use the Co, Rh, and Ir data to state how period number affects Δ.

23.142 You know the following about a coordination compound:

(1) The partial empirical formula is $KM(CrO_4)Cl_2(NH_3)_4$.

(2) It has A (red) and B (blue) crystal forms.

(3) When 1.0 mol of A or B reacts with 1.0 mol of $AgNO_3$, 0.50 mol of a red precipitate forms immediately.

(4) After the reaction in (3), 1.0 mol of A reacts very slowly with 1.0 mol of silver oxalate ($Ag_2C_2O_4$) to form 2.0 mol of a white precipitate. (Oxalate can displace other ligands.)

(5) After the reaction in (3), 1.0 mol of B does not react further with 1.0 mol of $AgNO_3$.

From this information, determine the following:

(a) The coordination number of M

(b) The group(s) bonded to M ionically and covalently

(c) The stereochemistry of the red and blue forms

Fusing nuclei The Z machine of Sandia National Laboratory, the most powerful x-ray generator on Earth, helps scientists understand phenomena from the origin of the universe to nuclear fusion. It is routinely used to fuse hydrogen nuclei at temperatures exceeding those within the Sun. In this chapter, we explore both the fundamental nature of atomic nuclei and their remarkable practical applications.

The Mass Defect
Nuclear Binding Energy

24.7 **Applications of Fission and Fusion**
Nuclear Fission
Nuclear Fusion

Far below the outer fringes of the cloud of electrons lies the atom's tiny, dense core, held together by the strongest force in the universe. For nearly the entire text so far, we have focused on an atom's electrons, treating the nucleus as little more than their electrostatic anchor, examining the effect of its positive charge on atomic properties and, ultimately, chemical behavior. But, for the scientists probing the structure and behavior of the nucleus itself, *there* is the scene of real action, one that holds enormous potential benefit and great mystery and wonder.

Society is ambivalent about the applications of nuclear research, however. The promise of abundant energy and treatments for disease comes hand-in-hand with the threat of nuclear waste contamination, reactor accidents, and unimaginable destruction from nuclear war or terrorism. Can the power of the nucleus be harnessed for our benefit, or are the risks too great? In this chapter, we discuss the principles that can help you answer this vital question.

The changes that occur in atomic nuclei are strikingly different from chemical changes. In the reactions you've studied so far, electrons are shared or transferred to form *compounds*, while nuclei sit by passively, never changing their identities. In nuclear reactions, the roles are reversed: electrons in their orbitals are usually bystanders as the nuclei undergo changes that, in nearly every case, form different *elements*. Nuclear reactions are often accompanied by energy changes a million times greater than those in chemical reactions, energy changes so great that changes in mass *are* detectable. Moreover, nuclear reaction yields and rates are typically *not* subject to the effects of pressure, temperature, and catalysis that so clearly influence chemical reactions. Table 24.1 summarizes the general differences between chemical and nuclear reactions.

Concepts & Skills to Review

before you study this chapter

- discovery of the atomic nucleus (Section 2.4)
- protons, neutrons, mass number, and the ${}^{A}_{Z}X$ notation (Section 2.5)
- half-life and first-order reaction rate (Section 16.4)

Table 24.1 Comparison of Chemical and Nuclear Reactions

Chemical Reactions	Nuclear Reactions
1. One substance is converted into another, but atoms never change identity.	1. Atoms of one element typically are converted into atoms of another element.
2. Orbital electrons are involved as bonds break and form; nuclear particles do not take part.	2. Protons, neutrons, and other particles are involved; orbital electrons rarely take part.
3. Reactions are accompanied by relatively small changes in energy and no measurable changes in mass.	3. Reactions are accompanied by relatively large changes in energy and measurable changes in mass.
4. Reaction rates are influenced by temperature, concentration, catalysts, and the compound in which an element occurs.	4. Reaction rates are affected by number of nuclei, but not by temperature, catalysts, or, normally, the compound in which an element occurs.

IN THIS CHAPTER . . . We survey the field of nuclear chemistry, beginning with an investigation of nuclear stability—why some nuclei are stable, whereas others are unstable and undergo radioactive decay. You'll see how radioactivity is detected and how the kinetics of decay is applied. We explore how nuclei synthesized in particle accelerators have extended the periodic table beyond uranium, the last naturally occurring element. Then, we consider the effects of radioactive emissions on matter, especially living matter, focusing on some major applications in science, technology, and medicine. A major focus is to calculate the energy released in nuclear fission and fusion and discuss current and future attempts to harness this energy. Finally, we end with a look at the nuclear processes that create the chemical elements in the stars.

24.1 RADIOACTIVE DECAY AND NUCLEAR STABILITY

A stable nucleus remains intact indefinitely, but *the great majority of nuclei are unstable*. An unstable nucleus exhibits **radioactivity:** it spontaneously disintegrates, or *decays,* by emitting radiation. In the next section, you'll see that each type of unstable nucleus has its own characteristic *rate* of radioactive decay, which can range from a fraction of a second to billions of years. In this section, we consider important terms and notation for nuclei, discuss some of the key events in the discovery of radioactivity, and describe the various types of radioactive decay and how to predict which type occurs for a given nucleus.

The Components of the Nucleus: Terms and Notation

The Tiny, Massive Nucleus If you could strip the electrons from the atoms in an object and compress the nuclei together, the object would lose only a fraction of a percent of its mass, but it would shrink to 0.0000000001% (10^{-10}%) of its volume. An atom the size of the Houston Astrodome would have a nucleus the size of a grapefruit, which would contain virtually all the atom's mass.

Recall from Chapter 2 that the nucleus contains essentially all the atom's mass but is only about 10^{-4} times its diameter (or 10^{-12} times its volume). Obviously, the nucleus is incredibly dense: about 10^{14} g/mL. *Protons* and *neutrons,* the elementary particles that make up the nucleus, are collectively called **nucleons.** The term **nuclide** refers to a nucleus with a particular composition, that is, with specific numbers of the two types of nucleons. Most elements occur in nature as a mixture of **isotopes,** atoms with the characteristic number of protons of the element but different numbers of neutrons. Therefore, each isotope of an element has a particular nuclide that we identify by the numbers of protons and neutrons it contains. The nuclide of the most abundant isotope of oxygen, for example, contains eight protons and eight neutrons, whereas the nuclide of the least abundant isotope contains eight protons and ten neutrons.

The relative mass and charge of a particle—a nucleon, another elementary particle, or a nuclide—is described by the notation ${}^{A}_{Z}\mathrm{X}$, where X is the *symbol* for the particle, A is the *mass number,* or the total number of nucleons, and Z is the *charge* of the particle; for nuclides, A is the *sum of protons and neutrons* and Z is the *number of protons* (atomic number). Using this notation, we write the three subatomic elementary particles as follows:

$${}^{0}_{-1}\mathrm{e}\ \text{(electron)},\ {}^{1}_{1}\mathrm{p}\ \text{(proton)},\ \text{and}\ {}^{1}_{0}\mathrm{n}\ \text{(neutron)}$$

(In nuclear notation, the element symbol refers to the nucleus only, so a proton is also sometimes represented as ${}^{1}_{1}\mathrm{H}$.) The number of neutrons (N) in a nucleus is the mass number (A) minus the atomic number (Z): $N = A - Z$. The two naturally occurring isotopes of chlorine, for example, have 17 protons ($Z = 17$), but one has 18 neutrons (${}^{35}_{17}\mathrm{Cl}$, also written ${}^{35}\mathrm{Cl}$) and the other has 20 (${}^{37}_{17}\mathrm{Cl}$, or ${}^{37}\mathrm{Cl}$). Nuclides can also be designated with the element name followed by the mass number, for example, chlorine-35 and chlorine-37. Despite some small variations, in *naturally occurring* samples of an element or its compounds, the isotopes of the element are present in particular, fixed proportions. Thus, in a sample of sodium chloride (or any Cl-containing substance), 75.77% of the Cl atoms are chlorine-35 and the remaining 24.23% are chlorine-37.

To understand this chapter, it's very important for you to be comfortable with nuclear notations, so please take a moment to review Sample Problem 2.2 on p. 51 and Problems 2.37 to 2.44 at the end of Chapter 2.

The Discovery of Radioactivity and the Types of Emissions

In 1896, the French physicist Antoine-Henri Becquerel discovered, quite by accident, that uranium minerals, even when wrapped in paper and stored in the dark, emit a penetrating radiation that can produce bright images on a photographic plate. Becquerel also found that the radiation creates an electric discharge in air,

thus providing a means for measuring its intensity. Two years later, a young doctoral student named Marie Sklodowska Curie began a search for other minerals that behaved like uranium in this way. She found that thorium minerals also emit radiation and discovered that *the intensity of the radiation is directly proportional to the concentration of the element in the mineral, not to the nature of the mineral or compound* in which the element occurs. Curie named the emissions *radioactivity* and showed that they are *unaffected by temperature, pressure, or other physical and chemical conditions.*

To her surprise, Curie found that certain uranium minerals were even more radioactive than pure uranium, which implied that they contained traces of one or more as yet unknown, highly radioactive elements. She and her husband, the physicist Pierre Curie, set out to isolate all the radioactive components in pitchblende, the principal ore of uranium. After months of painstaking chemical work, they isolated two extremely small, highly radioactive fractions, one that precipitated with bismuth compounds and another that precipitated with alkaline earth compounds. Through chemical and spectroscopic analysis, Marie Curie was able to show that these fractions contained two new elements, which she named polonium (after her native Poland) and radium. Polonium (Po; $Z = 84$), the most metallic member of Group 6A(16), lies to the right of bismuth in Period 6. Radium (Ra; $Z = 88$), which is the heaviest alkaline earth metal, lies under barium in Group 2A(2).

Purifying radium proved to be another arduous task. Starting with several tons of pitchblende residues from which the uranium had been extracted, Curie prepared compounds of the larger Group 2A(2) elements, continually separating minuscule amounts of radium compounds from enormously larger amounts of chemically similar barium compounds. It took her four years to isolate 0.1 g of radium chloride, which she melted and electrolyzed to obtain pure metallic radium.

During the next few years, Henri Becquerel, the Curies, and P. Villard in France and Ernest Rutherford and his coworkers in England studied the nature of radioactive emissions. Rutherford and his colleague Frederick Soddy observed that elements other than radium were formed when radium decayed. In 1902, they proposed that radioactive emission results in the change of one element into another. To their contemporaries, this idea sounded like a resurrection of alchemy and was met with disbelief and ridicule. We now know it to be true: under most circumstances, *when a nuclide of one element decays, it changes into a nuclide of a different element.*

These studies led to an understanding of the three most common types of radioactive emission:

- **Alpha particles** (symbolized α or ^4_2He) are dense, positively charged particles identical to helium nuclei.
- **Beta particles** (symbolized β, β^-, or more usually $^0_{-1}\beta$) are negatively charged particles identified as high-speed electrons. (The emission of electrons from the nucleus may seem strange, but as you'll see shortly, β particles arise as a result of a nuclear reaction.)
- **Gamma rays** (symbolized as γ, or sometimes $^0_0\gamma$) are very high-energy photons, about 10^5 times as energetic as visible light.

The behavior of these three emissions in an electric field is shown in Figure 24.1. Note that α particles bend to a small extent toward the negative plate, β particles bend to a great extent toward the positive plate, and γ rays are not affected by the electric field. We'll discuss the effects of these emissions on matter later.

Her Brilliant Career Marie Curie (1867–1934) is the only person to be awarded Nobel Prizes in two *different* sciences, one in physics in 1903 for her research into radioactivity and the other in chemistry in 1911 for the discovery of polonium and the discovery, isolation, and study of radium and its compounds.

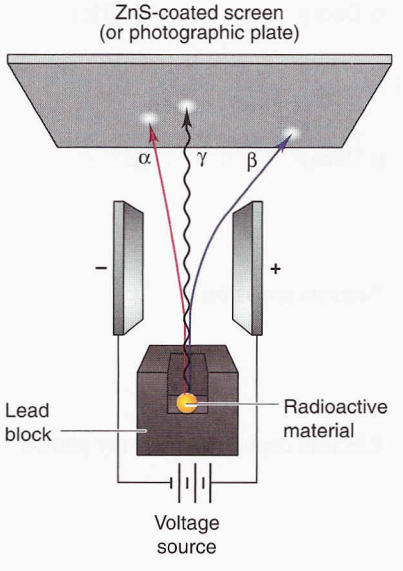

Figure 24.1 Three types of radioactive emissions in an electric field. Positively charged α particles bend toward the negative plate; negatively charged β particles bend toward the positive plate. The curvature is greater for β particles because they have much lower mass. The γ rays, uncharged high-energy photons, are unaffected by the field.

Types of Radioactive Decay; Balancing Nuclear Equations

When a nuclide decays, it forms a nuclide of lower energy, and the excess energy is carried off by the emitted radiation. The decaying, or reactant, nuclide is called the *parent;* the product nuclide is called the *daughter.* Nuclides can decay in several ways. As we discuss the major types of decay, which are summarized in Table 24.2, note the principle used to balance nuclear reactions: *the total Z (charge, number of protons) and the total A (sum of protons and neutrons) of the reactants equal those of the products:*

$$\text{Total } {}^{A}_{Z} \text{ Reactants} = \text{Total } {}^{A}_{Z} \text{ Products} \qquad (24.1)$$

1. **Alpha decay** involves the loss of an α particle ($^4_2$He) from a nucleus. For each α particle emitted by the parent nucleus, *A decreases by 4 and Z decreases by 2.* Every element that is heavier than lead (Pb; $Z = 82$), as well as a few lighter ones, exhibits α decay. In Rutherford's classic experiment that established the existence of the atomic nucleus (Section 2.4, pp. 47–48), radium was the source of the α particles that were used as projectiles. Radium undergoes α decay to yield radon (Rn; $Z = 86$):

$$^{226}_{88}\text{Ra} \longrightarrow {}^{222}_{86}\text{Rn} + {}^{4}_{2}\text{He}$$

Table 24.2 Modes of Radioactive Decay*

Mode	Emission	Decay Process	Change in A	Change in Z	Change in N
α Decay	α ($^4_2$He)	Reactant (parent) → Product (daughter) + α expelled	−4	−2	−2
β Decay†	$^0_{-1}\beta$	$^1_0$n in nucleus → $^1_1$p in nucleus + $^0_{-1}\beta$ β expelled	0	+1	−1
Positron emission†	$^0_1\beta$	$h\nu$ high-energy photon + nucleus with xp^+ and yn^0 → nucleus with $(x-1)p^+$ and $(y+1)n^0$ + $^0_1\beta$ positron expelled	0	−1	+1
Electron capture†	x-ray photon	$^0_{-1}$e absorbed from low-energy orbital + $^1_1$p in nucleus → $^1_0$n in nucleus	0	−1	+1
γ Emission	$^0_0\gamma$	excited nucleus → stable nucleus + $^0_0\gamma$ γ photon radiated	0	0	0

*Neutrinos (ν) are involved in several of these processes but are not shown.
†Nuclear chemists consider β decay to be a more general process that includes three decay modes: negatron emission (which the text calls "β decay"), positron emission, and electron capture.

Note that the A value for Ra equals the sum of the A values for Rn and He (226 = 222 + 4), and that the Z value for Ra equals the sum of the Z values for Rn and He (88 = 86 + 2).

2. **Beta decay** involves the ejection of a β particle ($_{-1}^{0}\beta$) from the nucleus.* This change does not involve the expulsion of a β particle that was actually in the nucleus, but rather the *conversion of a neutron into a proton, which remains in the nucleus, and a β particle, which is expelled immediately:*

$$_{0}^{1}n \longrightarrow {}_{1}^{1}p + {}_{-1}^{0}\beta$$

As always, the totals of the A and the Z values for reactant and products are equal. Radioactive nickel-63 becomes stable copper-63 through β decay:

$$_{28}^{63}Ni \longrightarrow {}_{29}^{63}Cu + {}_{-1}^{0}\beta$$

Another example is the β decay of carbon-14, applied in radiocarbon dating:

$$_{6}^{14}C \longrightarrow {}_{7}^{14}N + {}_{-1}^{0}\beta$$

Note that *β decay results in a product nuclide with the same A but with Z one higher (one more proton) than in the reactant nuclide.* In other words, an atom of the element with the next *higher* atomic number is formed.

3. **Positron decay** involves the emission of a positron from the nucleus. A key idea of modern physics is that every fundamental particle has a corresponding *antiparticle,* another particle with the same mass but opposite charge. The **positron** (symbolized $_{1}^{0}\beta$; note the positive Z) is the antiparticle of the electron. Positron decay occurs through a process in which *a proton in the nucleus is converted into a neutron, and a positron is expelled.*† *Positron decay has the opposite effect of β decay, resulting in a daughter nuclide with the same A but with Z one lower (one fewer proton) than the parent;* thus, an atom of the element with the next *lower* atomic number forms. Carbon-11, a synthetic radioisotope, decays to a stable boron isotope through emission of a positron:

$$_{6}^{11}C \longrightarrow {}_{5}^{11}B + {}_{1}^{0}\beta$$

4. **Electron capture** occurs when the nucleus of an atom draws in an electron from an orbital of the lowest energy level. The net effect is that *a nuclear proton is transformed into a neutron:*

$$_{1}^{1}p + {}_{-1}^{0}e \longrightarrow {}_{0}^{1}n$$

(We use the symbol $_{-1}^{0}e$ to distinguish an orbital electron from a beta particle, symbol $_{-1}^{0}\beta$.) The orbital vacancy is quickly filled by an electron that moves down from a higher energy level, and that energy difference appears as an *x-ray photon.* Radioactive iron forms stable manganese through electron capture:

$$_{26}^{55}Fe + {}_{-1}^{0}e \longrightarrow {}_{25}^{55}Mn + h\nu \text{ (x-ray)}$$

Electron capture has the same net effect as positron decay (Z lower by 1, A unchanged), even though the processes are entirely different.

5. **Gamma emission** involves the radiation of high-energy γ photons from an excited nucleus. Recall that an atom in an excited *electronic* state reduces its energy by emitting photons, usually in the UV and visible ranges. Similarly, a nucleus in an excited state lowers its energy by emitting γ photons, which are of much higher energy (much shorter wavelength) than UV photons. Many nuclear processes leave the nucleus in an excited state, so *γ emission accompanies most other types of decay.* Several γ photons (γ rays) of different frequencies can be

The Little Neutral One A neutral particle called a *neutrino* (ν) is also emitted in many nuclear reactions, including the change of a neutron to a proton:

$$_{0}^{1}n \longrightarrow {}_{1}^{1}p + {}_{-1}^{0}\beta + \nu$$

Theory suggests that neutrinos have a mass much less than 10^{-4} times that of an electron, and that at least 10^{9} neutrinos exist in the universe for every proton. Neutrinos interact with matter so slightly that it would take a piece of lead 1 light-year thick to absorb them. We will not discuss them further, except to mention that experiments in Japan in the 1990s detected neutrinos and obtained evidence that they have mass. Using a cathedral-sized pool containing 50,000 tons of ultrapure water buried 1 mile underground in a zinc mine, an international team of scientists obtained results that suggest that neutrinos may account for a significant portion of the "missing" matter in the universe and may provide enough mass (and, thus, gravitational attraction) to prevent the universe from expanding forever.

*In formal nuclear chemistry terminology, *β decay* indicates a more general phenomenon that also includes positron emission and electron capture (see footnote to Table 24.2).

†The process, called *pair production,* involves a transformation of energy into matter. A high-energy ($>1.63\times10^{-13}$ J) photon becomes an electron and a positron simultaneously. The electron and a proton in the nucleus form a neutron, while the positron is expelled.

emitted from an excited nucleus as it returns to the ground state. Many of Marie Curie's experiments involved the release of γ rays, such as

$$^{238}_{92}\text{U} \longrightarrow {}^{234}_{90}\text{Th} + {}^{4}_{2}\text{He} + 2{}^{0}_{0}\gamma$$

Because γ rays have no mass or charge, *γ emission does not change A or Z.* Gamma rays also result when a particle and an antiparticle annihilate each other, as when an emitted positron meets an orbital electron:

$${}^{0}_{1}\beta \text{ (from nucleus)} + {}_{-1}^{0}\text{e (outside nucleus)} \longrightarrow 2{}^{0}_{0}\gamma$$

SAMPLE PROBLEM 24.1 Writing Equations for Nuclear Reactions

Problem Write balanced equations for the following nuclear reactions:
(a) Naturally occurring thorium-232 undergoes α decay.
(b) Chlorine-36 undergoes electron capture.

Plan We first write a skeleton equation that includes the mass numbers, atomic numbers, and symbols of all the particles, showing the unknown particles as ${}^{A}_{Z}\text{X}$. Then, because the total of mass numbers and the total of charges on the left side and the right side must be equal, we solve for *A* and *Z*, and use *Z* to determine X from the periodic table.

Solution **(a)** Writing the skeleton equation:

$$^{232}_{90}\text{Th} \longrightarrow {}^{A}_{Z}\text{X} + {}^{4}_{2}\text{He}$$

Solving for *A* and *Z* and balancing the equation: For *A*, $232 = A + 4$, so $A = 228$. For *Z*, $90 = Z + 2$, so $Z = 88$. From the periodic table, we see that the element with $Z = 88$ is radium (Ra). Thus, the balanced equation is

$$^{232}_{90}\text{Th} \longrightarrow {}^{228}_{88}\text{Ra} + {}^{4}_{2}\text{He}$$

(b) Writing the skeleton equation:

$$^{36}_{17}\text{Cl} + {}_{-1}^{0}\text{e} \longrightarrow {}^{A}_{Z}\text{X}$$

Solving for *A* and *Z* and balancing the equation: For *A*, $36 + 0 = A$, so $A = 36$. For *Z*, $17 + (-1) = Z$, so $Z = 16$. The element with $Z = 16$ is sulfur (S), so we have

$$^{36}_{17}\text{Cl} + {}_{-1}^{0}\text{e} \longrightarrow {}^{36}_{16}\text{S}$$

Check Always read across superscripts and then across subscripts, with the yield arrow as an equal sign, to check your arithmetic. In part (a), for example, $232 = 228 + 4$, and $90 = 88 + 2$.

FOLLOW-UP PROBLEM 24.1 Write a balanced equation for the reaction in which a nuclide undergoes β decay and produces cesium-133.

Nuclear Stability and the Mode of Decay

There are several ways that an unstable nuclide *might* decay, but can we predict how it *will* decay? Indeed, can we predict *if* a given nuclide will decay at all? Our knowledge of the nucleus is much less than that of the atom as a whole, but some patterns emerge from observation of the naturally occurring nuclides.

The Band of Stability and the Neutron-to-Proton (*N*/*Z*) Ratio A key factor that determines the stability of a nuclide is the ratio of the number of neutrons to the number of protons, the ***N*/*Z* ratio,** which we calculate from $(A - Z)/Z$. For lighter nuclides, one neutron for each proton ($N/Z \approx 1$) is enough to provide stability. However, for heavier nuclides to be stable, the number of neutrons must exceed the number of protons, and often by quite a lot. But, if the *N*/*Z* ratio is either too high or not high enough, the nuclide is unstable and decays.

Figure 24.2A is a plot of number of neutrons vs. number of protons for the *stable* nuclides. The nuclides form a narrow **band of stability** that gradually increases from an *N*/*Z* ratio of 1, near $Z = 10$, to an *N*/*Z* ratio slightly greater than 1.5, near $Z = 83$ for ^{209}Bi. Several key points are as follows:

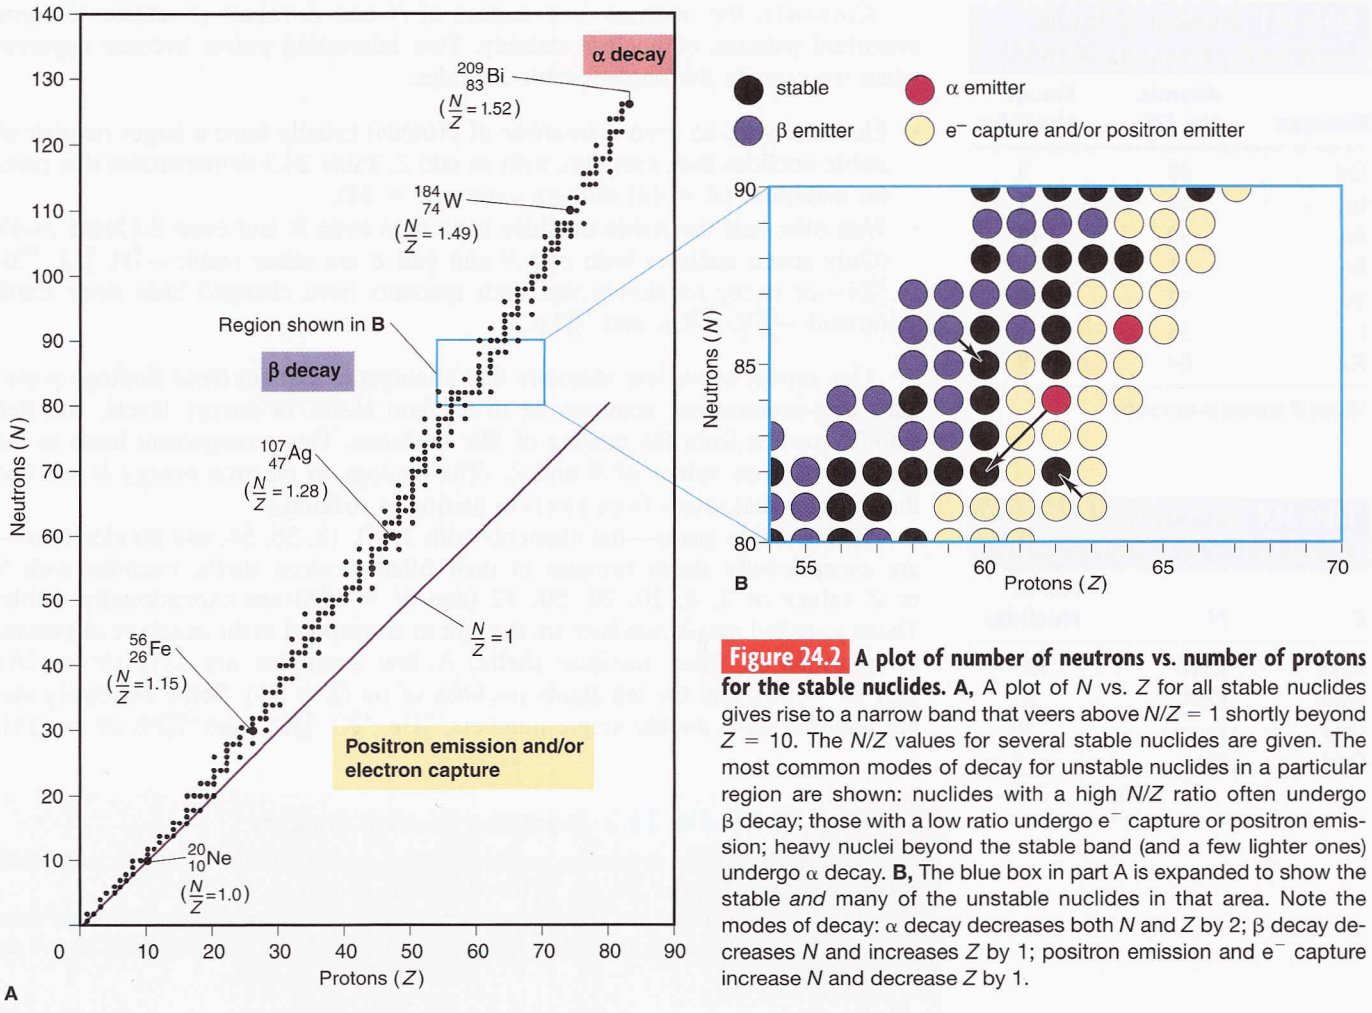

Figure 24.2 A plot of number of neutrons vs. number of protons for the stable nuclides. A, A plot of *N* vs. *Z* for all stable nuclides gives rise to a narrow band that veers above $N/Z = 1$ shortly beyond $Z = 10$. The N/Z values for several stable nuclides are given. The most common modes of decay for unstable nuclides in a particular region are shown: nuclides with a high N/Z ratio often undergo β decay; those with a low ratio undergo e^- capture or positron emission; heavy nuclei beyond the stable band (and a few lighter ones) undergo α decay. **B,** The blue box in part A is expanded to show the stable *and* many of the unstable nuclides in that area. Note the modes of decay: α decay decreases both *N* and *Z* by 2; β decay decreases *N* and increases *Z* by 1; positron emission and e^- capture increase *N* and decrease *Z* by 1.

- Very few stable nuclides exist with $N/Z < 1$; the only two are $^{1}_{1}H$ and $^{3}_{2}He$. For lighter nuclides, $N/Z \approx 1$: for example, $^{4}_{2}He$, $^{12}_{6}C$, $^{16}_{8}O$, and $^{20}_{10}Ne$ are particularly stable.
- The N/Z ratio of stable nuclides gradually increases as Z increases. No stable nuclide exists with $N/Z = 1$ for $Z > 20$. Thus, for $^{56}_{26}Fe$, $N/Z = 1.15$; for $^{107}_{47}Ag$, $N/Z = 1.28$; and for $^{184}_{74}W$, $N/Z = 1.49$.
- All nuclides with $Z > 83$ are unstable. Bismuth-209 is the heaviest stable nuclide. Therefore, the largest members of Groups 1A(1), 2A(2), 4A(14), 6A(16), 7A(17), and 8A(18) are radioactive, as are all the actinides and the elements of the fourth transition series (Period 7).

Stability and Nuclear Structure Given that protons are positively charged and neutrons uncharged, what holds the nucleus together? Nuclear scientists answer this question and explain the importance of the N/Z ratio in terms of two opposing forces. Electrostatic repulsive forces between protons would break the nucleus apart if not for the presence of an attractive force that exists between all nucleons (protons and neutrons) called the **strong force.** This force is about 1000 times stronger than the repulsive force but *operates only over the short distances within the nucleus*. Competition between the *attractive* strong force and the *repulsive* electrostatic force determines nuclear stability.

Table 24.3 Number of Stable Nuclides for Elements 48 to 54*

Element	Atomic No. (Z)	No. of Nuclides
Cd	**48**	**8**
In	49	2
Sn	**50**	**10**
Sb	51	2
Te	**52**	**8**
I	53	1
Xe	**54**	**9**

*Even Z shown in boldface.

Table 24.4 An Even-Odd Breakdown of the Stable Nuclides

Z	N	No. of Nuclides
Even	Even	157
Even	Odd	53
Odd	Even	50
Odd	Odd	7
	TOTAL	267

Curiously, the oddness or evenness of N and Z values is related to some important patterns of nuclear stability. Two interesting points become apparent when we classify the known stable nuclides:

- Elements with an even Z (number of protons) usually have a larger number of stable nuclides than elements with an odd Z. Table 24.3 demonstrates this point for cadmium ($Z = 48$) through xenon ($Z = 54$).
- Well over half the stable nuclides have *both* even N and even Z (Table 24.4). (Only seven nuclides with odd N and odd Z are either stable—$^{2}_{1}H$, $^{6}_{3}Li$, $^{10}_{5}B$, $^{14}_{7}N$—or decay so slowly that their amounts have changed little since Earth formed—$^{50}_{23}V$, $^{138}_{57}La$, and $^{176}_{71}Lu$.)

One model of nuclear structure that attempts to explain these findings postulates that protons and neutrons lie in *nucleon shells,* or energy levels, and that stability results from the *pairing* of like nucleons. This arrangement leads to the stability of even values of N and Z. (The analogy to electron energy levels and the stability that arises from electron pairing is striking.)

Just as noble gases—the elements with 2, 10, 18, 36, 54, and 86 electrons—are exceptionally stable because of their filled *electron* shells, nuclides with N or Z values of 2, 8, 20, 28, 50, 82 (and $N = 126$) are exceptionally stable. These so-called *magic numbers* are thought to correspond to the numbers of protons or neutrons in filled *nucleon* shells. A few examples are $^{50}_{22}Ti$ ($N = 28$), $^{88}_{38}Sr$ ($N = 50$), and the ten stable nuclides of tin ($Z = 50$). Some extremely stable nuclides have double magic numbers: $^{4}_{2}He$, $^{16}_{8}O$, $^{40}_{20}Ca$, and $^{208}_{82}Pb$ ($N = 126$).

SAMPLE PROBLEM 24.2 Predicting Nuclear Stability

Problem Which of the following nuclides would you predict to be stable and which radioactive: **(a)** $^{18}_{10}Ne$; **(b)** $^{32}_{16}S$; **(c)** $^{236}_{90}Th$; **(d)** $^{123}_{56}Ba$? Explain.

Plan In order to evaluate the stability of each nuclide, we determine the N/Z ratio from $(A - Z)/Z$, the value of Z, stable N/Z ratios (from Figure 24.2), and whether Z and N are even or odd.

Solution **(a)** Radioactive. The ratio $N/Z = \dfrac{18 - 10}{10} = 0.8$. The minimum ratio for stability is 1.0; so, despite even N and Z, this nuclide has too few neutrons to be stable.

(b) Stable. This nuclide has $N/Z = 1.0$ and $Z < 20$, with even N and Z. Thus, it is most likely stable.

(c) Radioactive. Every nuclide with $Z > 83$ is radioactive.

(d) Radioactive. The ratio $N/Z = 1.20$. For Z from 55 to 60, Figure 24.2A shows $N/Z \geq 1.3$, so this nuclide probably has too few neutrons to be stable.

Check By consulting a table of isotopes, such as the one in the *CRC Handbook of Chemistry and Physics,* we find that our predictions are correct.

FOLLOW-UP PROBLEM 24.2 Why is $^{31}_{15}P$ stable but $^{30}_{15}P$ unstable?

Predicting the Mode of Decay An unstable nuclide generally decays in a mode that shifts its N/Z ratio toward the band of stability. This fact is illustrated in Figure 24.2B on the preceding page, which expands a small region of Figure 24.2A to show all of the stable *and* many of the radioactive nuclides in that region, as well as their modes of decay. Note the following points, and then we'll apply them in a sample problem:

1. *Neutron-rich nuclides.* Nuclides with too many neutrons for stability (a high N/Z) lie above the band of stability. They undergo β *decay,* which converts a neutron into a proton, thus reducing the value of N/Z.

2. *Neutron-poor nuclides.* Nuclides with too few neutrons for stability (a low *N*/*Z*) lie below the band. They undergo *positron decay* or *electron capture,* both of which convert a proton into a neutron, thus increasing the value of *N*/*Z*.
3. *Heavy nuclides.* Nuclides with $Z > 83$ are too heavy to lie within the band and undergo *α decay,* which reduces their *Z* and *N* values by two units per emission. (Several lighter nuclides also exhibit α decay.)

SAMPLE PROBLEM 24.3 Predicting the Mode of Nuclear Decay

Problem Predict the nature of the nuclear change(s) each of the following radioactive nuclides is likely to undergo: **(a)** $^{12}_{5}B$; **(b)** $^{234}_{92}U$; **(c)** $^{74}_{33}As$; **(d)** $^{127}_{57}La$.

Plan We use the *N*/*Z* ratio to decide where the nuclide lies relative to the band of stability and how its ratio compares with others in the nearby region of the band. Then, we predict which of the decay modes just discussed will yield a product nuclide that is closer to the band.

Solution **(a)** This nuclide has an *N*/*Z* ratio of 1.4, which is too high for this region of the band. It will probably undergo β decay, increasing *Z* to 6 and lowering the *N*/*Z* ratio to 1.

(b) This nuclide is heavier than those close to it in the band of stability. It will probably undergo α decay and decrease its total mass.

(c) This nuclide, with an *N*/*Z* ratio of 1.24, lies in the band of stability, so it will probably undergo either β decay or positron emission.

(d) This nuclide has an *N*/*Z* ratio of 1.23, which is too low for this region of the band, so it will decrease *Z* by either positron emission or electron capture.

Comment Both possible modes of decay are observed for the nuclides in parts (c) and (d).

FOLLOW-UP PROBLEM 24.3 What mode of decay would you expect for **(a)** $^{61}_{26}Fe$; **(b)** $^{241}_{95}Am$?

Decay Series A parent nuclide may undergo a series of decay steps before a stable daughter nuclide forms. The succession of steps is called a **decay series,** or **disintegration series,** and is typically depicted on a gridlike display. Figure 24.3 shows the decay series from uranium-238 to lead-206. Numbers of neutrons (*N*) are plotted against numbers of protons (*Z*) to form the grid, which displays a series of α and β decays. The zigzag pattern is typical and occurs because α decay decreases both *N* and *Z*, whereas β decay decreases *N* but increases *Z*. Note that it is quite common for a given nuclide to undergo both types of decay. (Gamma decay accompanies many of these steps, but it does not affect the mass or type of the nuclide.) This decay series is one of three that occur in nature. All end with isotopes of lead whose nuclides all have one ($Z = 82$) or two ($N = 126$, $Z = 82$) magic numbers. A second series begins with uranium-235 and ends with lead-207, and a third begins with thorium-232 and ends with lead-208. (Neptunium-237 began a fourth series, but its half-life is so much less than the age of Earth that only traces of it remain today.)

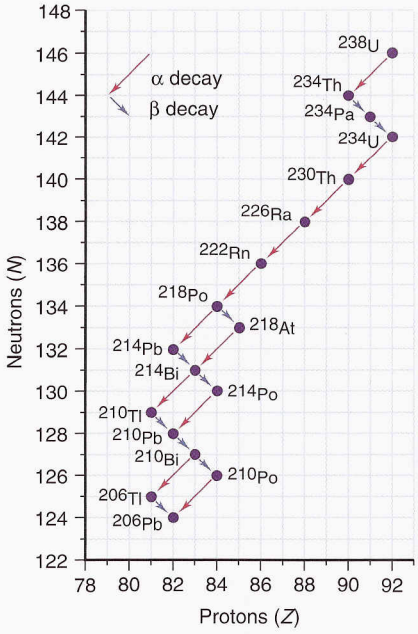

Figure 24.3 The ^{238}U decay series. Uranium-238 (*top right*) decays through a series of emissions of α or β particles to lead-206 (*bottom left*) in 14 steps.

SECTION SUMMARY

Nuclear reactions are not affected by reaction conditions or chemical composition and release much more energy than chemical reactions. A radioactive nuclide is unstable and may emit α particles ($^{4}_{2}He$ nuclei), β particles ($^{0}_{-1}\beta$; high-speed electrons), positrons ($^{0}_{1}\beta$), or γ rays ($^{0}_{0}\gamma$; high-energy photons) or may capture an orbital electron ($^{0}_{-1}e$). A narrow band of neutron-to-proton ratios (*N*/*Z*) includes those of all the stable nuclides. Radioactive decay allows an unstable nuclide to achieve a more stable *N*/*Z* ratio. Certain "magic numbers" of neutrons and protons are associated with very stable nuclides. By comparing a nuclide's *N*/*Z* ratio with those in the band of stability, we can predict that, in general, heavy nuclides undergo α decay, neutron-rich nuclides undergo β decay, and proton-rich nuclides undergo positron emission or electron capture. Three naturally occurring decay series all end in isotopes of lead.

24.2 THE KINETICS OF RADIOACTIVE DECAY

Chemical and nuclear systems both tend toward maximum stability. Just as the concentrations in a chemical system change in a predictable direction to give a stable equilibrium ratio, the type and number of nucleons in an unstable nucleus change in a predictable direction to give a stable *N*/*Z* ratio. As you know, however, the tendency of a chemical system to become more stable tells nothing about how long that process will take, and the same holds true for nuclear systems. In this section, we examine the kinetics of nuclear change; later, we'll examine the energetics of such change. To begin, a Tools of the Laboratory essay on the opposite page describes how radioactivity is detected and measured.

The Rate of Radioactive Decay

Animation: Radioactive Decay
Online Learning Center

Radioactive nuclei decay at a characteristic rate, regardless of the chemical substance in which they occur. The *decay rate,* or **activity ($\mathcal{A}$),** of a radioactive sample is the change in number of nuclei ($\mathcal{N}$) divided by the change in time (t). As we saw with chemical reaction rates, because the number of nuclei is *decreasing,* a minus sign precedes the expression for the decay rate:

$$\text{Decay rate } (\mathcal{A}) = -\frac{\Delta \mathcal{N}}{\Delta t}$$

The SI unit of radioactivity is the **becquerel (Bq);** it is defined as one disintegration per second (d/s): 1 Bq = 1 d/s. A much larger and more common unit of radioactivity is the **curie (Ci):** 1 curie equals the number of nuclei disintegrating each second in 1 g of radium-226:

$$1 \text{ Ci} = 3.70 \times 10^{10} \text{ d/s} \tag{24.2}$$

Because the curie is so large, the millicurie (mCi) and microcurie (μCi) are commonly used. We often express the radioactivity of a sample in terms of *specific activity,* the decay rate per gram.

An activity is meaningful only when we consider the large number of nuclei in a macroscopic sample. Suppose there are 1×10^{15} radioactive nuclei of a particular type in a sample and they decay at a rate of 10% per hour. Although any particular nucleus in the sample might decay in a microsecond or in a million hours, the *average* of all decays results in 10% of the entire collection of nuclei disintegrating each hour. During the first hour, 10% of the *original* number, or 1×10^{14} nuclei, will decay. During the next hour, 10% of the remaining 9×10^{14} nuclei, or 9×10^{13} nuclei, will decay. During the next hour, 10% of those remaining will decay, and so forth. Thus, for a large collection of radioactive nuclei, *the number decaying per unit time is proportional to the number present:*

$$\text{Decay rate } (\mathcal{A}) \propto \mathcal{N} \qquad \text{or} \qquad \mathcal{A} = k\mathcal{N}$$

where k is called the **decay constant** and is characteristic of each type of nuclide. The larger the value of k, the higher is the decay rate.

Combining the two rate expressions just given, we obtain

$$\mathcal{A} = -\frac{\Delta \mathcal{N}}{\Delta t} = k\mathcal{N} \tag{24.3}$$

Note that the activity depends only on $\mathcal{N}$ raised to the first power (and on the constant value of k). Therefore, *radioactive decay is a first-order process* (see Section 16.4). The only difference in the case of nuclear decay is that we consider the *number* of nuclei rather than their concentration.

Animation: Half-Life
Online Learning Center

Half-Life of Radioactive Decay Decay rates are also commonly expressed in terms of the fraction of nuclei that decay over a given time interval. The **half-life ($t_{1/2}$)** of a nuclide is the time it takes for half the nuclei present in a sample to decay. *The number of nuclei remaining is halved after each half-life.* Thus, half-life has the same meaning for a nuclear change as for a chemical change (Section 16.4).

Counters for the Detection of Radioactive Emissions

Radioactive emissions interact with atoms in surrounding materials. To determine the rate of nuclear decay, we measure the radioactivity of a sample by observing the effects of these interactions over time. Because these effects can be electrically amplified billions of times, it is even possible to detect the decay of a single nucleus. Ionization counters and scintillation counters are two devices used to measure radioactive emissions.

An *ionization counter* detects radioactive emissions as they ionize a gas. Ionization produces free electrons and gaseous cations, which are attracted to electrodes that conduct a current to a recording device. The most common type of ionization counter is a **Geiger-Müller counter** (Figure B24.1). It consists of a tube filled with argon gas; the tube housing acts as the cathode, and a thin wire in the center of the tube acts as the anode. Emissions from the sample enter the tube through a thin window and strike argon atoms, producing free electrons that are accelerated toward the anode. These electrons collide with other argon atoms and free more electrons in an *avalanche effect*. The current created is amplified and appears as a meter reading and/or an audible click. The initial release of 1 electron can release 10^{10} electrons in a microsecond, giving the Geiger-Müller counter great sensitivity.

In a **scintillation counter,** radioactive emissions too weak to ionize surrounding atoms are detected by their ability to excite atoms and cause them to emit light. The light-emitting substance in the counter, called a *phosphor,* is coated onto part of a *photomultiplier tube,* a device that increases the original electrical signal. Incoming radioactive particles strike the phosphor, which emits photons. Each photon, in turn, strikes a cathode, releasing an electron through the photoelectric effect (Section 7.1). This electron hits other portions of the tube that release increasing numbers of electrons, and the resulting current is recorded. Liquid scintillation counters employ an organic mixture that contains a phosphor and a solvent (Figure B24.2). This "cocktail" dissolves the sample *and* emits light when excited by the emission. These counters are often used to measure emissions from dissolved radioactive biological samples.

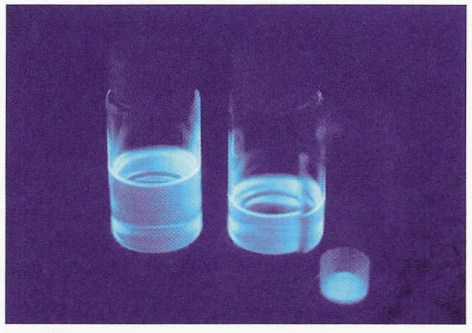

Figure B24.2 Vials of a scintillation "cocktail" emitting light. A radioactive substance dissolved in an organic mixture (cocktail) emits particles that excite the phosphor component to emit light. Light intensity is proportional to the concentration of the substance.

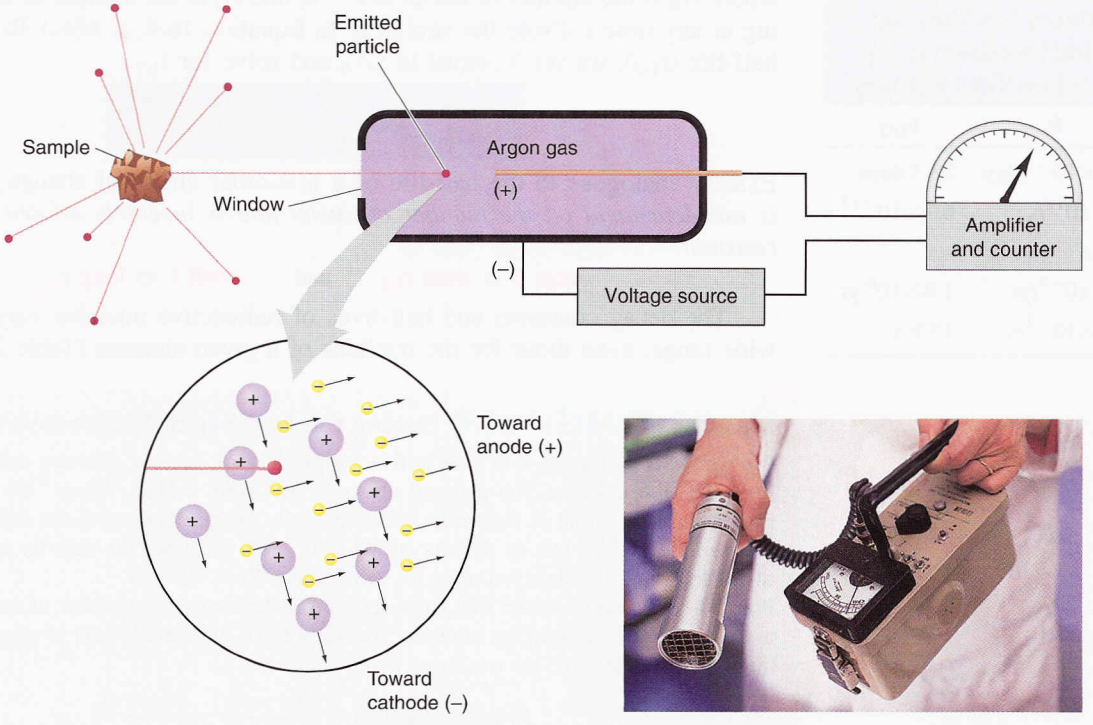

Figure B24.1 Detection of radioactivity by an ionization counter. When an Ar atom absorbs the energy of a radioactive particle *(red),* it is ionized to an Ar^+ ion *(purple)* and an electron *(yellow).* The free electron collides with and ionizes another Ar atom. As the process continues, the Ar^+ ions migrate to the negative electrode, and the electrons migrate to the positive electrode, resulting in a current.

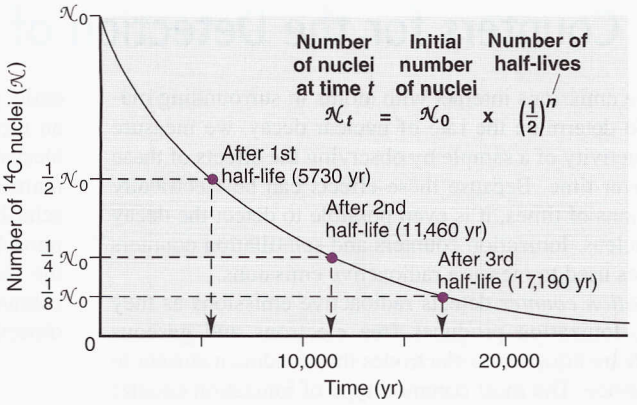

Figure 24.4 Decrease in number of ^{14}C nuclei over time. A plot of number of ^{14}C nuclei vs. time gives a decreasing curve. In each half-life (5730 years), half the ^{14}C nuclei present undergo decay. A plot of mass of ^{14}C vs. time is identical.

Figure 24.4 shows the decay of carbon-14, which has a half-life of 5730 years, in terms of number of ^{14}C nuclei remaining:

$$^{14}_{6}\text{C} \longrightarrow {}^{14}_{7}\text{N} + {}^{0}_{-1}\beta$$

We can also consider the half-life in terms of mass of substance. As ^{14}C decays to the product ^{14}N, its mass decreases. If we start with 1.0 g of carbon-14, half that mass of ^{14}C (0.50 g) will be left after 5730 years, half of that mass (0.25 g) after another 5730 years, and so on. The activity depends on the number of nuclei present, so the activity is halved after each succeeding half-life as well.

We determine the half-life of a nuclear reaction from its rate constant. Rearranging Equation 24.3 and integrating over time gives

$$\ln \frac{\mathcal{N}_t}{\mathcal{N}_0} = -kt \quad \text{or} \quad \ln \frac{\mathcal{N}_0}{\mathcal{N}_t} = kt \tag{24.4}$$

where $\mathcal{N}_0$ is the number of nuclei at $t = 0$, and $\mathcal{N}_t$ is the number of nuclei remaining at any time t. (Note the similarity to Equation 16.4, p. 686.) To calculate the half-life ($t_{1/2}$), we set $\mathcal{N}_t$ equal to $\frac{1}{2}\mathcal{N}_0$ and solve for $t_{1/2}$:

$$\ln \frac{\mathcal{N}_0}{\frac{1}{2}\mathcal{N}_0} = kt_{1/2} \quad \text{so} \quad t_{1/2} = \frac{\ln 2}{k} \tag{24.5}$$

Exactly analogous to the half-life of a first-order chemical change, *this half-life is **not** dependent on the number of nuclei and is inversely related to the decay constant:*

large $k \Rightarrow$ short $t_{1/2}$ and small $k \Rightarrow$ long $t_{1/2}$

The decay constants and half-lives of radioactive nuclides vary over a very wide range, even those for the nuclides of a given element (Table 24.5).

Table 24.5 Decay Constants (k) and Half-Lives ($t_{1/2}$) of Beryllium Isotopes

Nuclide	k	$t_{1/2}$
$^{7}_{4}$Be	1.30×10^{-2}/day	53.3 days
$^{8}_{4}$Be	1.0×10^{16}/s	6.7×10^{-17} s
$^{9}_{4}$Be	Stable	
$^{10}_{4}$Be	4.3×10^{-7}/yr	1.6×10^{6} yr
$^{11}_{4}$Be	5.02×10^{-2}/s	13.8 s

SAMPLE PROBLEM 24.4 Finding the Number of Radioactive Nuclei

Problem Strontium-90 is a radioactive by-product of nuclear reactors that behaves biologically like calcium, the element above it in Group 2A(2). When ^{90}Sr is ingested by mammals, it is found in their milk and eventually in the bones of those drinking the milk. If a sample of ^{90}Sr has an activity of 1.2×10^{12} d/s, what are the activity and the fraction of nuclei that have decayed after 59 yr ($t_{1/2}$ of ^{90}Sr = 29 yr)?

Plan The fraction of nuclei that have decayed is the change in number of nuclei, expressed as a fraction of the starting number. The activity of the sample ($\mathcal{A}$) is proportional to the number of nuclei ($\mathcal{N}$), so we know that

$$\text{Fraction decayed} = \frac{\mathcal{N}_0 - \mathcal{N}_t}{\mathcal{N}_0} = \frac{\mathcal{A}_0 - \mathcal{A}_t}{\mathcal{A}_0}$$

We are given $\mathcal{A}_0$ (1.2×10^{12} d/s), so we find $\mathcal{A}_t$ from the integrated form of the first-order rate equation (Equation 24.4), in which t is 59 yr. To solve that equation, we first need k, which we can calculate from the given $t_{1/2}$ (29 yr).

Solution Calculating the decay constant k:

$$t_{1/2} = \frac{\ln 2}{k} \qquad \text{so} \qquad k = \frac{\ln 2}{t_{1/2}} = \frac{0.693}{29\ \text{yr}} = 0.024\ \text{yr}^{-1}$$

Applying Equation 24.4 to calculate $\mathcal{A}_t$, the activity remaining at time t:

$$\ln \frac{\mathcal{N}_0}{\mathcal{N}_t} = \ln \frac{\mathcal{A}_0}{\mathcal{A}_t} = kt \qquad \text{or} \qquad \ln \mathcal{A}_0 - \ln \mathcal{A}_t = kt$$

So, $\ln \mathcal{A}_t = -kt + \ln \mathcal{A}_0 = -(0.024\ \text{yr}^{-1} \times 59\ \text{yr}) + \ln (1.2\times10^{12}\ \text{d/s})$

$\ln \mathcal{A}_t = -1.4 + 27.81 = 26.4$

$\mathcal{A}_t = 2.9\times10^{11}\ \text{d/s}$

(All the data contain two significant figures, so we retained two in the answer.) Calculating the fraction decayed:

$$\text{Fraction decayed} = \frac{\mathcal{A}_0 - \mathcal{A}_t}{\mathcal{A}_0} = \frac{1.2\times10^{12}\ \text{d/s} - 2.9\times10^{11}\ \text{d/s}}{1.2\times10^{12}\ \text{d/s}} = 0.76$$

Check The answer is reasonable: t is about 2 half-lives, so $\mathcal{A}_t$ should be about $\frac{1}{4}\mathcal{A}_0$, or about 0.3×10^{12}; therefore, the activity should have decreased by about $\frac{3}{4}$.

Comment An *alternative approach* is to use the number of half-lives ($t/t_{1/2}$) to find the fraction of activity (or nuclei) remaining. By combining Equations 24.4 and 24.5 and substituting $(\ln 2)/t_{1/2}$ for k, we obtain

$$\ln \frac{\mathcal{N}_0}{\mathcal{N}_t} = \left(\frac{\ln 2}{t_{1/2}}\right)t = \frac{t}{t_{1/2}} \ln 2 = \ln 2^{t/t_{1/2}}$$

Thus,

$$\ln \frac{\mathcal{N}_t}{\mathcal{N}_0} = \ln \left(\frac{1}{2}\right)^{t/t_{1/2}}$$

Taking the antilog gives

$$\text{Fraction remaining} = \frac{\mathcal{N}_t}{\mathcal{N}_0} = \left(\frac{1}{2}\right)^{t/t_{1/2}} = \left(\frac{1}{2}\right)^{59/29} = 0.24$$

So,

$$\text{Fraction decayed} = 1.00 - 0.24 = 0.76$$

FOLLOW-UP PROBLEM 24.4 Sodium-24 ($t_{1/2}$ = 15 h) is used to study blood circulation. If a patient is injected with a ^{24}NaCl solution whose activity is 2.5×10^9 d/s, how much of the activity is present in the patient's body and excreted fluids after 4.0 days?

Radioisotopic Dating

The historical record fades rapidly with time and virtually disappears for events of more than a few thousand years ago. Much of our understanding of prehistory comes from a technique called **radioisotopic dating,** which uses **radioisotopes** to determine the age of an object. The method supplies data about the ages of objects in fields as diverse as art history, archeology, geology, and paleontology.

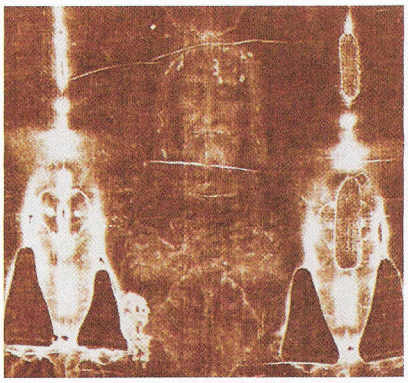
The technique of *radiocarbon dating,* for which the American chemist Willard F. Libby won the Nobel Prize in chemistry in 1960, is based on measuring the amounts of ^{14}C and ^{12}C in materials of biological origin. The accuracy of the method falls off after about six half-lives of ^{14}C ($t_{1/2}$ = 5730 yr), so it is used to date objects up to about 36,000 years old.

Here is how the method works. High-energy neutrons resulting from cosmic ray collisions reach Earth continually from outer space. They enter the atmosphere and cause the slow formation of ^{14}C by bombarding ordinary ^{14}N atoms:

$$^{14}_{7}\text{N} + {}^{1}_{0}\text{n} \longrightarrow {}^{14}_{6}\text{C} + {}^{1}_{1}\text{p}$$

Through the processes of formation and radioactive decay, the amount of ^{14}C in the atmosphere has remained nearly constant.*

*Cosmic ray intensity does vary slightly with time, which affects the amount of atmospheric ^{14}C. From ^{14}C activity in ancient trees, we know the amount fell slightly about 3000 years ago to current levels. Recently, nuclear testing and fossil fuel combustion have also altered the fraction of ^{14}C slightly. Taking these factors into account improves the accuracy of the dating method.



The Case of the Shroud of Turin One of the holiest Christian relics is the famed Shroud of Turin. It is a piece of linen that bears a faint image of a man's body and was thought to be the burial cloth used to wrap the body of Jesus Christ. In 1988, the Vatican allowed scientific testing of the cloth by radiocarbon dating. Three labs in Europe and the United States independently measured the ^{12}C:^{14}C ratio of a 50-mg piece of the linen and determined that the flax from which the cloth was made was grown between 1260 AD and 1390 AD. Despite this evidence, the shroud lost none of its fascination: 10 years later, in 1998, when the shroud was again put on display, about 2 million people lined up to view it.

The ^{14}C atoms combine with O_2, diffuse throughout the lower atmosphere, and enter the total carbon pool as gaseous $^{14}CO_2$ and aqueous $H^{14}CO_3^-$. They mix with ordinary $^{12}CO_2$ and $H^{12}CO_3^-$, reaching a constant ^{12}C:^{14}C ratio of about 10^{12}:1. The CO_2 is taken up by plants during photosynthesis, and then taken up and excreted by animals that eat the plants. Thus, the ^{12}C:^{14}C ratio of a living organism has the same constant value as the environment. When an organism dies, however, it no longer takes in ^{14}C, so the ^{12}C:^{14}C ratio steadily increases because the amount of *^{14}C decreases as it decays*:

$$^{14}_{6}C \longrightarrow {}^{14}_{7}N + {}^{0}_{-1}\beta$$

The difference between the ^{12}C:^{14}C ratio in a dead organism and the ratio in living organisms reflects the time elapsed since the organism died.

As you saw in Sample Problem 24.4, the first-order rate equation can be expressed in terms of a ratio of activities:

$$\ln \frac{\mathcal{N}_0}{\mathcal{N}_t} = \ln \frac{\mathcal{A}_0}{\mathcal{A}_t} = kt$$

We use this expression in radiocarbon dating, where $\mathcal{A}_0$ is the activity in a living organism and $\mathcal{A}_t$ is the activity in the object whose age is unknown. Solving for t gives the age of the object:

$$t = \frac{1}{k} \ln \frac{\mathcal{A}_0}{\mathcal{A}_t} \tag{24.6}$$

A useful graphical method in radioisotopic dating shows a plot of the natural logarithm of the specific activity vs. time, which gives a straight line with a slope of $-k$, the negative of the decay constant. Using such a plot and measuring the ^{14}C specific activity of an object, we can determine its age; several examples appear in Figure 24.5. To determine the ages of more ancient objects or of objects that do not contain carbon, different radioisotopes are measured. (See the margin note on the opposite page.)

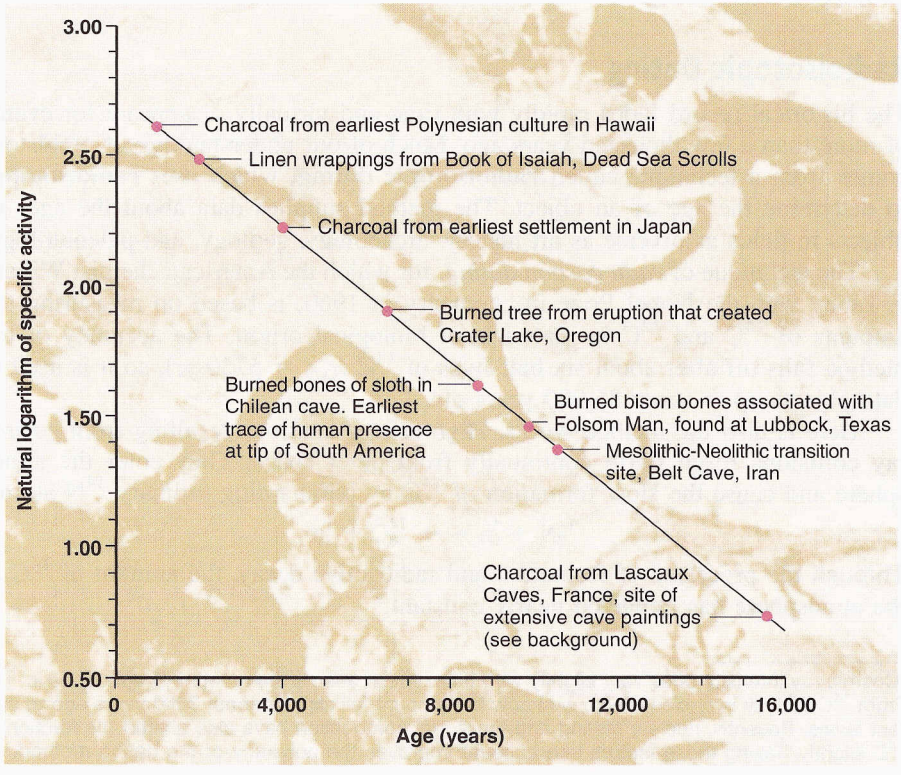


Figure 24.5 Radiocarbon dating for determining the age of artifacts. The natural logarithms of the specific activities of ^{14}C (activity/g ^{14}C) for various artifacts are projected onto a line whose slope equals $-k$, the negative of the ^{14}C decay constant. The age (in years) of an artifact is determined from the horizontal axis.

SAMPLE PROBLEM 24.5 Applying Radiocarbon Dating

Problem The charred bones of a sloth in a cave in Chile represent the earliest evidence of human presence at the southern tip of South America. A sample of the bone has a specific activity of 5.22 disintegrations per minute per gram of carbon (d/min·g). If the ratio of ^{12}C:^{14}C in living organisms results in a specific activity of 15.3 d/min·g, how old are the bones ($t_{1/2}$ of ^{14}C = 5730 yr)?

Plan We first calculate k from the given $t_{1/2}$ (5730 yr). Then we apply Equation 24.6 to find the age (t) of the bones, using the given activities of the bones ($\mathcal{A}_t$ = 5.22 d/min·g) and of a living organism ($\mathcal{A}_0$ = 15.3 d/min·g).

Solution Calculating k for ^{14}C decay:

$$k = \frac{\ln 2}{t_{1/2}} = \frac{0.693}{5730\ \text{yr}} = 1.21\times10^{-4}\ \text{yr}^{-1}$$

Calculating the age (t) of the bones:

$$t = \frac{1}{k}\ln\frac{\mathcal{A}_0}{\mathcal{A}_t} = \frac{1}{1.21\times10^{-4}\ \text{yr}^{-1}}\ln\left(\frac{15.3\ \text{d/min·g}}{5.22\ \text{d/min·g}}\right) = 8.89\times10^{3}\ \text{yr}$$

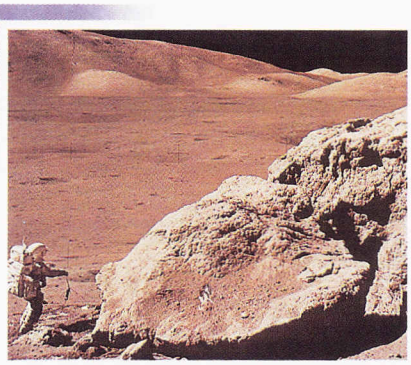
The bones are about 8900 years old.

Check The activity of the bones is between $\frac{1}{2}$ and $\frac{1}{4}$ the activity of a living organism, so the age should be between one and two half-lives (5730 to 11,460 yr).

FOLLOW-UP PROBLEM 24.5 A sample of wood from an Egyptian mummy case has a specific activity of 9.41 d/min·g. How old is the case?

SECTION SUMMARY

Ionization and scintillation counters measure the number of emissions from a radioactive sample. The decay rate (activity) of a sample is proportional to the number of radioactive nuclei. Nuclear decay is a first-order process, so the half-life does not depend on the number of nuclei. Radioisotopic methods, such as ^{14}C dating, determine the ages of objects by measuring the ratio of specific isotopes in the sample.



How Old Is the Solar System? By comparing the ratio of ^{238}U to its final decay product, ^{206}Pb, geochemists found that the oldest known surface rocks on Earth—granite in western Greenland—are about 3.7 billion years old. The ratio of ^{238}U:^{206}Pb in meteorites gives 4.65 billion years for the age of the Solar System, and therefore Earth. From this and other isotope ratios, such as ^{40}K:^{40}Ar ($t_{1/2}$ of ^{40}K = 1.3×10^{9} yr) as well as ^{87}Rb:^{87}Sr ($t_{1/2}$ of ^{87}Rb = 4.9×10^{10} yr), Moon rocks collected by Apollo astronauts have been shown to be 4.2 billion years old, and they provide evidence for volcanic activity on the Moon's surface about 3.3 billion years ago. That was about the time that, according to these methods, the first organisms were evolving on Earth.

24.3 NUCLEAR TRANSMUTATION: INDUCED CHANGES IN NUCLEI

The alchemists' dream of changing base metals into gold was never realized, but in the early 20th century, atomic physicists found that they *could* change one element into another. Research into **nuclear transmutation,** the *induced* conversion of one nucleus into another, was closely linked with research into atomic structure and led to the discovery of the neutron and to the production of artificial radioisotopes. Later, high-energy bombardment of nuclei in particle accelerators began a scientific endeavor, which continues to this day, of creating many new nuclides and a growing number of new elements.

Early Transmutation Experiments; Discovery of the Neutron

The first recognized transmutation occurred in 1919, when Ernest Rutherford showed that α particles emitted from radium bombarded atmospheric nitrogen to form a proton and oxygen-17:

$$^{14}_{7}N + {}^{4}_{2}He \longrightarrow {}^{1}_{1}H + {}^{17}_{8}O$$

By 1926, experimenters had found that α bombardment transmuted most elements with low atomic numbers to the next higher element, with ejection of a proton.

A notation for nuclear bombardment reactions shows the reactant (target) nucleus to the left and the product nucleus to the right of a set of parentheses, within which a comma separates the projectile particle from the ejected particle(s):

reactant nucleus (particle in, particle(s) out) product nucleus

Using this notation, the previous reaction is ^{14}N (α,p) ^{17}O.

The Joliot-Curies in their laboratory.

An unexpected finding in a transmutation experiment led to the discovery of the neutron. When lithium, beryllium, and boron were bombarded with α particles, they emitted highly penetrating radiation that could not be deflected by a magnetic or electric field. Unlike γ radiation, these emissions were massive enough to eject protons from the substances they penetrated. In 1932, James Chadwick, a student of Rutherford, proposed that these emissions consisted of neutral particles with a mass similar to that of a proton, and he named them *neutrons*. Chadwick received the Nobel Prize in physics in 1935 for his discovery.

In 1933, Irene and Frederic Joliot-Curie (see photo), daughter and son-in-law of Marie and Pierre Curie, created the first artificial radioisotope, phosphorus-30. When they bombarded aluminum foil with α particles, phosphorus-30 and neutrons were formed:

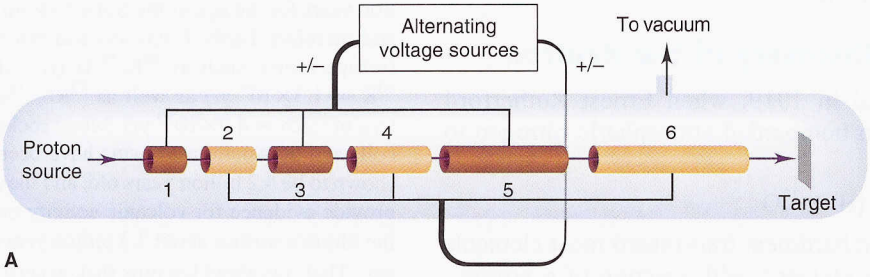
$$^{27}_{13}\text{Al} + {}^{4}_{2}\text{He} \longrightarrow {}^{1}_{0}\text{n} + {}^{30}_{15}\text{P} \qquad \text{or} \qquad {}^{27}\text{Al}\ (\alpha,\text{n})\ {}^{30}\text{P}$$

Since then, other techniques for producing artificial radioisotopes have been developed. In fact, the majority of the nearly 1000 known radionuclides have been produced artificially.

Particle Accelerators and the Transuranium Elements

During the 1930s and 1940s, researchers probing the nucleus bombarded elements with neutrons, α particles, protons, and **deuterons** (nuclei of the stable hydrogen isotope deuterium, ^{2}H). Neutrons are especially useful as projectiles because they have no charge and thus are not repelled as they approach a target nucleus. The other particles are all positive, so early researchers found it difficult to give them enough energy to overcome their repulsion by the target nuclei. Beginning in the 1930s, however, **particle accelerators** were invented to impart high kinetic energies to particles by placing them in an electric field, usually in combination with a magnetic field. In the simplest and earliest design, protons are introduced at one end of a tube and attracted to the other end by a potential difference.

A major advance was the *linear accelerator*, a series of separated tubes of increasing length that, through a source of alternating voltage, change their charge from positive to negative in synchrony with the movement of the particle through them (Figure 24.6A). A proton, for example, exits the first tube just when that tube becomes positive and the next tube negative. Repelled by the first tube and attracted by the second, the proton accelerates across the gap between them. A 40-ft linear accelerator with 46 tubes, built in California after World War II, accelerated protons to speeds several million times faster than the early accelerators. Later designs, such as the Stanford Linear Accelerator (Figure 24.6B), accelerate



A

B

Figure 24.6 A linear accelerator. A, The voltage of each tubular section is alternated, so that the positively charged particle (a proton here) is repelled from the section it is leaving and attracted to the section it is entering. As a result, the particle's speed is continually increased. **B,** The linear accelerator operated by Stanford University in California.

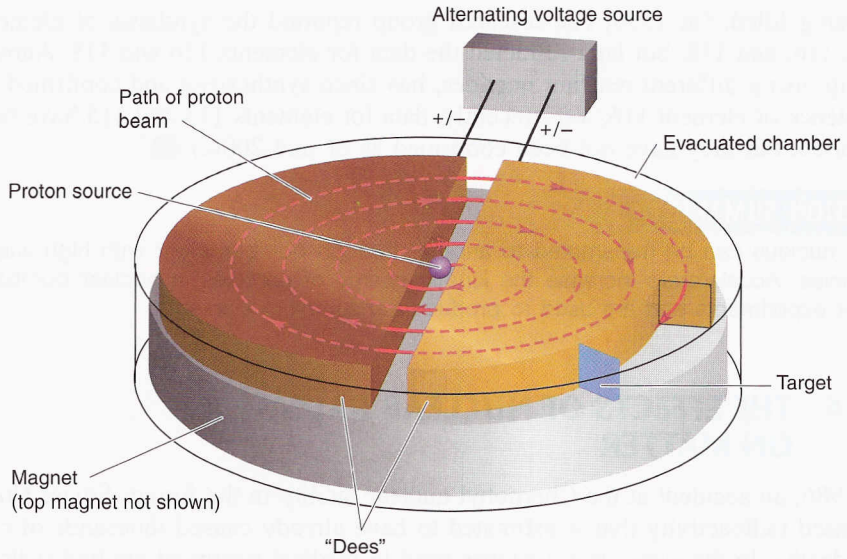


Figure 24.7 The cyclotron accelerator. When the positively charged particle reaches the gap between the two D-shaped electrodes ("dees"), it is repelled by one dee and attracted by the other. The particles move in a spiral path, so the cyclotron can be much smaller than a linear accelerator.

heavier particles, such as B, C, O, and Ne nuclei, several hundred million times faster, with correspondingly greater kinetic energies.

The *cyclotron* (Figure 24.7), invented by E. O. Lawrence in 1930, applies the principle of the linear accelerator but uses electromagnets to give the particle a spiral path, thus saving space. The magnets lie within an evacuated chamber above and below two "dees," open, D-shaped electrodes that function like the tubes in the linear design. The particle is accelerated as it passes from one dee, which is momentarily positive, to the other, which is momentarily negative. Its speed and radius increase until it is deflected toward the target nucleus. The *synchrotron* uses a synchronously increasing magnetic field to make the particle's path circular rather than spiral.

Accelerators have many applications, from producing radioisotopes used in medical applications to studying the fundamental nature of matter. Perhaps their most specific application for chemists is the synthesis of **transuranium elements,** those with atomic numbers higher than uranium, which is the heaviest naturally occurring element. Some reactions that were used to form several of these elements appear in Table 24.6. The transuranium elements include the remaining actinides (Z = 93 to 103), in which the 5*f* sublevel is being filled, and the elements in the fourth transition series (Z = 104 to 112), in which the 6*d* sublevel

The Powerful Bevatron The *bevatron,* used to study the physics of high-energy particle collisions, includes a linear section and a synchrotron section. The instrument at the Lawrence Berkeley Laboratory in California increases the kinetic energy of the particles by a factor of more than 6 billion. A beam of 10^{10} protons makes more than 4 million revolutions, a distance of 300,000 miles, in 1.8 s, attaining a final speed about 90% of the speed of light! Even more powerful bevatrons are in use at the Brookhaven National Laboratory in New York and at CERN, outside Geneva, Switzerland.

Table 24.6 Formation of Some Transuranium Nuclides

Reaction	Half-life of Product
$^{239}_{94}\text{Pu} + {}^{4}_{2}\text{He} \longrightarrow {}^{240}_{95}\text{Am} + {}^{1}_{1}\text{H} + 2{}^{1}_{0}\text{n}$	50.9 h
$^{239}_{94}\text{Pu} + {}^{4}_{2}\text{He} \longrightarrow {}^{242}_{96}\text{Cm} + {}^{1}_{0}\text{n}$	163 days
$^{244}_{96}\text{Cm} + {}^{4}_{2}\text{He} \longrightarrow {}^{245}_{97}\text{Bk} + {}^{1}_{1}\text{H} + 2{}^{1}_{0}\text{n}$	4.94 days
$^{238}_{92}\text{U} + {}^{12}_{6}\text{C} \longrightarrow {}^{246}_{98}\text{Cf} + 4{}^{1}_{0}\text{n}$	36 h
$^{253}_{99}\text{Es} + {}^{4}_{2}\text{He} \longrightarrow {}^{256}_{101}\text{Md} + {}^{1}_{0}\text{n}$	76 min
$^{252}_{98}\text{Cf} + {}^{10}_{5}\text{B} \longrightarrow {}^{256}_{103}\text{Lr} + 6{}^{1}_{0}\text{n}$	28 s

is being filled. (In 1999, one research group reported the synthesis of elements 114, 116, and 118, but later retracted the data for elements 116 and 118. Another group, using different reactant nuclides, has since synthesized and confirmed the existence of element 116. Very recently, data for elements 113 and 115 have been reported, but they have not been confirmed as of mid-2004.)

Naming the Transuranium Elements
The last naturally occurring element was named after Uranus, thought at the time to be the outermost planet; then, the first two artificial elements were named after the more recently discovered Neptune and Pluto. The next few elements were named after famous scientists, as in curium, and places, as in americium. But conflicting claims of discovery by scientists in different countries led to controversies about names for elements 104 and higher. To provide interim names until the disputes could be settled, the International Union of Pure and Applied Chemistry (IUPAC) adopted a system that uses the atomic number as the basis for a Latin name. Thus, for example, element 104 was named unnilquadium (un = 1, nil = 0, quad = 4, ium = element suffix), with the symbol Unq. After much compromise, the IUPAC has finalized these names: 104, rutherfordium (Rf); 105, dubnium (Db); 106, seaborgium (Sg); 107, bohrium (Bh); 108, hassium (Hs); 109, meitnerium (Mt); and 110, darmstadtium (Ds). Elements with atomic numbers 111 and higher have not yet been named.

SECTION SUMMARY

One nucleus can be transmuted to another through bombardment with high-energy particles. Accelerators increase the kinetic energy of particles in nuclear bombardment experiments and are used to produce transuranium elements.

24.4 THE EFFECTS OF NUCLEAR RADIATION ON MATTER

In 1986, an accident at the Chernobyl nuclear facility in the former Soviet Union released radioactivity that is estimated to have already caused thousands of cancer deaths. In the same year, isotopes used in medical treatment emitted radioactivity that prevented thousands of cancer deaths. In this section and the next, we examine the harmful and beneficial effects of radioactivity.

The key to both of these outcomes is that *nuclear changes cause chemical changes in surrounding matter.* In other words, even though the nucleus of an atom undergoes a reaction with little or no involvement of the atom's electrons, the emissions *do* affect the electrons of nearby atoms.

The Effects of Radioactive Emissions: Excitation and Ionization

Radioactive emissions interact with matter in two ways, depending on their energies:

- *Excitation.* In the process of **excitation,** radiation of relatively low energy interacts with an atom of a substance, which absorbs some of the energy and then re-emits it. Because electrons are not lost from the atom, the radiation that causes excitation is called **nonionizing radiation.** If the absorbed energy causes the atoms to move, vibrate, or rotate more rapidly, the material becomes hotter. Concentrated aqueous solutions of plutonium salts boil because the emissions excite the surrounding water molecules. (Polonium has therefore been suggested as a lightweight heat source, with no moving parts, for use on space stations.) Particles of somewhat higher energy excite electrons in other atoms to higher energy levels. As the atoms return to their ground state, they emit photons, often in the blue or UV region (see the description of scintillation counters in the Tools of the Laboratory essay, p. 1055).
- *Ionization.* In the process of **ionization,** radiation collides with an atom energetically enough to dislodge an electron:

$$\text{Atom} \xrightarrow{\text{ionizing radiation}} \text{ion}^+ + \text{e}^-$$

A cation and a free electron result, and the number of such *cation-electron pairs* that are produced is directly related to the energy of the incoming radiation. The high-energy radiation that gives rise to this effect is called **ionizing radiation.** The free electron of the pair often collides with another atom and ejects a second electron (see the description of Geiger-Müller counters in the Tools of the Laboratory essay, p. 1055).

Effects of Ionizing Radiation on Living Matter

Whereas nonionizing radiation is relatively harmless, ionizing radiation has a destructive effect on living tissue. When the atom that was ionized is part of a biological macromolecule or membrane component, the results can be devastating.

Units of Radiation Dose and Its Effects To measure the effects of ionizing radiation, we need a unit for radiation dose. Units of radioactive decay, such as the becquerel and curie, measure the number of decay events in a given time but not their energy or absorption by matter. The number of cation-electron pairs produced in a given amount of living tissue is a measure of the energy absorbed by the tissue. The SI unit for such energy absorption is the **gray (Gy);** it is equal to 1 joule of energy absorbed per kilogram of body tissue: 1 Gy = 1 J/kg. A more widely used unit is the **rad (*r*adiation-*a*bsorbed *d*ose),** which is equal to 0.01 Gy:

$$1 \text{ rad} = 0.01 \text{ J/kg} = 0.01 \text{ Gy}$$

To measure actual tissue damage, we must account for differences in the strength of the radiation, the exposure time, and the type of tissue. To do this, we multiply the number of rads by a *r*elative *b*iological *e*ffectiveness (RBE) factor, which depends on the effect of a given type of radiation on a given tissue or body part. The product is the **rem (*r*oentgen *e*quivalent for *m*an),** the unit of radiation dosage equivalent to a given amount of tissue damage in a human:

$$\text{no. of rems} = \text{no. of rads} \times \text{RBE}$$

Doses are often expressed in millirems (10^{-3} rem). The SI unit for dosage equivalent is the **sievert (Sv).** It is defined in the same way as the rem but with absorbed dose in grays; thus, 1 rem = 0.01 Sv.

Penetrating Power of Emissions The effect on living tissue of a radiation dose depends on the penetrating power *and* ionizing ability of the radiation. Figure 24.8 depicts the differences in penetrating power of the three common emissions. Note, in general, that *penetrating power is inversely related to the mass and charge of the emission.* In other words, if a particle interacts strongly with matter, it penetrates only slightly, and vice versa:

- *α Particles.* Alpha particles are massive and highly charged, which means that they interact with matter most strongly of the three common types of emissions. As a result, they penetrate so little that a piece of paper, light clothing, or the outer layer of skin can stop α radiation from an external source. However, if ingested, an α emitter such as plutonium-239 causes grave localized damage through extensive ionization.
- *β Particles and positrons.* Beta particles and positrons have less charge and much less mass than α particles, so they interact less strongly with matter. Even though a given particle has less chance of causing ionization, a β (or positron) emitter is a more destructive external source because the particles penetrate deeper. Specialized heavy clothing or a thick (0.5 cm) piece of metal is required to stop these particles.
- *γ Rays.* Neutral, massless γ rays interact least with matter and, thus, penetrate most. A block of lead several inches thick is needed to stop them. Therefore, an external γ ray source is the most dangerous because the energy can ionize many layers of living tissue.

Molecular Interactions How does the damage take place on the molecular level? When ionizing radiation interacts with a molecule, it causes the *loss of an electron from a bond or a lone pair.* The resulting charged species go on to form **free radicals,** molecular or atomic species with one or more unpaired electrons. As we've seen several times already, species with lone electrons are very reactive and tend to form electron pairs by bonding to other species. To do this, they attack bonds in other molecules, sometimes forming more free radicals.

When γ radiation strikes biological tissue, for instance, the most likely molecule to absorb it is water, which forms an electron and a water ion-radical:

$$H_2O + \gamma \longrightarrow H_2O^{\cdot +} + e^-$$

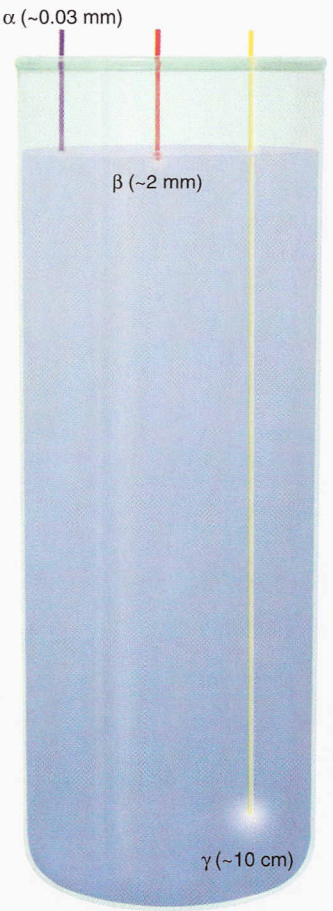

Figure 24.8 Penetrating power of radioactive emissions. Penetrating power is often measured in terms of the depth of water that stops 50% of the incoming radiation. (Water is the main component of living tissue.) Alpha particles, with the highest mass and charge, have the lowest penetrating power, and γ rays have the highest. (Average values of actual penetrating distances are shown.)

A Tragic Way to Tell Time in the Dark
In the early 20th century, wristwatch and clock dials were painted by hand with paint containing radium so they would glow in the dark. To write numbers clearly, the young women hired to apply the paint "tipped" fine brushes repeatedly between their lips. Small amounts of ingested $^{226}Ra^{2+}$ were incorporated into the bones of the women, along with normal Ca^{2+}, which led to numerous cases of bone fracture and jaw cancer.

The $H_2O\cdot^+$ and e^- collide with other water molecules to form free radicals:

$$H_2O\cdot^+ + H_2O \longrightarrow H_3O^+ + \cdot OH \quad \text{and} \quad e^- + H_2O \longrightarrow H\cdot + OH^-$$

These free radicals go on to attack more water molecules and surrounding biomolecules, whose bonding and structure, as you know (Section 15.6), are intimately connected with their function.

The double bonds in membrane lipids are particularly susceptible to free-radical attack:

$$H\cdot + RCH{=}CHR' \longrightarrow RCH_2{-}\dot{C}HR'$$

In this reaction, one electron of the π bond forms a C—H bond between one of the double-bonded carbons and the H·, and the other electron resides on the other carbon to form a free radical. Changes to lipid structure cause changes in membrane fluidity and other damage that, in turn, cause leakage of the cell and destruction of the protective fatty tissue around organs. Changes to critical bonds in enzymes lead to their malfunction as catalysts of metabolic reactions. Changes in the nucleic acids and proteins that govern the rate of cell division cause cancer. Genetic damage and mutations may occur when bonds in the DNA of sperm and egg cells are altered by free radicals.

Sources of Ionizing Radiation It is essential to keep the molecular effects of ionizing radiation in perspective. After all, we are continuously exposed to ionizing radiation from natural and artificial sources (Table 24.7). Indeed, life evolved in the presence of natural ionizing radiation, called **background radiation.** The

Table 24.7 Typical Radiation Doses from Natural and Artificial Sources

Source of Radiation	Average Adult Exposure
Natural	
Cosmic radiation	30–50 mrem/yr
Radiation from the ground	
From clay soil and rocks	~25–170 mrem/yr
In wooden houses	10–20 mrem/yr
In brick houses	60–70 mrem/yr
In concrete (cinder block) houses	60–160 mrem/yr
Radiation from the air (mainly radon)	
Outdoors, average value	20 mrem/yr
In wooden houses	70 mrem/yr
In brick houses	130 mrem/yr
In concrete (cinder block) houses	260 mrem/yr
Internal radiation from minerals in tap water and daily intake of food (^{40}K, ^{14}C, Ra)	~40 mrem/yr
Artificial	
Diagnostic x-ray methods	
Lung (local)	0.04–0.2 rad/film
Kidney (local)	1.5–3 rad/film
Dental (dose to the skin)	≤1 rad/film
Therapeutic radiation treatment	Locally ≤ 10,000 rad
Other sources	
Jet flight (4 h)	~1 mrem
Nuclear testing	<4 mrem/yr
Nuclear power industry	<1 mrem/yr
TOTAL AVERAGE VALUE	100–200 mrem/yr

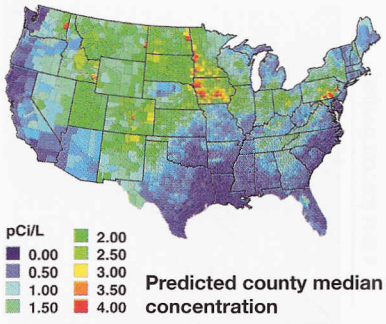
same radiation that causes harmful mutations also causes beneficial mutations that, over time, allow organisms to adapt and species to change.

Background radiation has several sources. One source is *cosmic radiation,* which increases with altitude because of decreased absorption by the atmosphere. Thus, people in Denver absorb twice as much cosmic radiation as people in Los Angeles; even a jet flight involves measurable absorption. The sources of most background radiation are thorium and uranium minerals present in rocks and soil. Radon, the heaviest noble gas [Group 8A(18)], is a radioactive product of uranium and thorium decay, and its concentration in the air we breathe varies with type of local soil and rocks. About 150 g of K^+ ions is dissolved in the water in the tissues of an average adult, and 0.0118% of that amount is radioactive ^{40}K. The presence of these substances and of atmospheric $^{14}CO_2$ means that all food, water, clothing, and building materials are slightly radioactive.

The largest artificial source of radiation, and the easiest to control, is associated with medical diagnostic techniques, especially x-rays. The radiation dosage from nuclear testing and radioactive waste disposal is miniscule for most people, but exposures for those living near test sites, nuclear energy facilities, or disposal areas may be many times higher.

Assessing the Risk from Ionizing Radiation How much radiation is too much? To approach this question, we must ask several others: How strong is the exposure? How long is the exposure? Which tissue is exposed? Are offspring affected? One reason we lack clear data to answer these questions is that scientific ethical standards forbid the intentional exposure of humans in an experimental setting. However, accidentally exposed radiation workers and Japanese atomic bomb survivors have been studied extensively. Table 24.8 summarizes the immediate tissue effects on humans of an acute single dose of ionizing radiation to the whole body. The severity of the effects increases with dose; a dose of 500 rem will kill about 50% of the exposed population within a month.

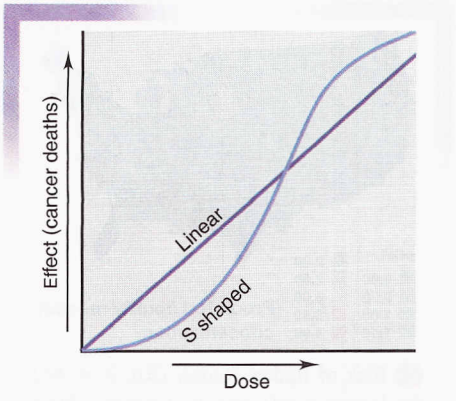
Most data come from laboratory animals, whose biological systems may differ greatly from ours. Nevertheless, studies with mice and dogs show that lesions



Risk of Radon Radon (Rn; $Z = 86$), the largest noble gas, is a natural decay product of uranium. Therefore, the uranium content of the local soil and rocks is a critical factor in the extent of the threat, but radon occurs everywhere in varying concentrations. Radon itself decays to radioactive nuclides of Po, Pb, and Bi, through α, β, and γ emission. These processes occur inside the body when radon is inhaled and pose a serious potential hazard. The emissions damage lung tissue, and the heavy-metal atoms formed aggravate the problem. The latest EPA estimates indicate that radon contributes to 15% of annual lung cancer deaths.

Table 24.8 Acute Effects of a Single Dose of Whole-Body Irradiation

Dose (rem)	Effect	Lethal Dose	
		Population (%)	No. of Days
5–20	Possible late effect; possible chromosomal aberrations	—	—
20–100	Temporary reduction in white blood cells	—	—
50+	Temporary sterility in men (100+ rem = 1 yr duration)	—	—
100–200	"Mild radiation sickness": vomiting, diarrhea, tiredness in a few hours Reduction in infection resistance Possible bone growth retardation in children	—	—
300+	Permanent sterility in women	—	—
500	"Serious radiation sickness": marrow/intestine destruction	50–70	30
400–1000	Acute illness, early deaths	60–95	30
3000+	Acute illness, death in hours to days	100	2



Modeling Radiation Risk There are two current models of effect vs. dose. The *linear response* model proposes that radiation effects, such as cancer risks, accumulate over time regardless of dose and that populations should not be exposed to any radiation above background levels. The *S-shaped response* model assumes an extremely low risk at low doses and advocates concern only at higher doses. If the linear model is more accurate, we should limit all excess exposure, but this would severely restrict medical diagnosis and research, military testing, and nuclear energy production.

and cancers appear after massive whole-body exposure, with rapidly dividing cells affected first. In an adult animal, these are cells of the bone marrow, organ linings, and reproductive organs, but many other tissues are affected in an immature animal or fetus. Studies in both animals and humans show an increase in the incidence of cancer from either a high, single exposure or a low, chronic exposure.

Reliable data on genetic effects are few. Pioneering studies on fruit flies show a linear increase in genetic defects with both dose and exposure time. However, in the mouse, whose genetic system is obviously much more similar to ours than is the fruit fly's, a total dose given over a long period created one-third as many genetic defects as the same dose given over a short period. Therefore, rate of exposure is a key factor. The children of atomic bomb survivors show higher-than-normal childhood cancer rates, implying that their parents' reproductive systems were affected.

SECTION SUMMARY

Relatively low-energy emissions cause excitation of atoms in surrounding matter, whereas high-energy emissions cause ionization. The effect of ionizing radiation on living matter depends on the quantity of energy absorbed and the extent of ionization in a given type of tissue. Radiation dose for the human body is measured in rem. Ionization forms free radicals, some of which proliferate and destroy biomolecular function. All organisms are exposed to varying quantities of natural ionizing radiation. Studies show that a large acute dose and a chronic small dose are both harmful.

24.5 APPLICATIONS OF RADIOISOTOPES

Our ability to detect minute amounts of radioisotopes makes them powerful tools for studying processes in biochemistry, medicine, materials science, environmental studies, and many other scientific and industrial fields. Such uses depend on the fact that *isotopes of an element exhibit* ***very*** *similar chemical and physical behavior.* In other words, except for having a less stable nucleus, a radioisotope has nearly the same chemical properties as a nonradioactive isotope of that element.* For example, the fact that $^{14}CO_2$ is utilized by a plant in the same way as $^{12}CO_2$ forms the basis of radiocarbon dating.

Radioactive Tracers: Applications of Nonionizing Radiation

Just think how useful it could be to follow a substance through a complex process or from one region of a system to another. A tiny amount of a radioisotope mixed with a large amount of the stable isotope can act as a **tracer,** a chemical "beacon" emitting nonionizing radiation that signals the presence of the substance.

Reaction Pathways Tracers help us choose from among possible reaction pathways. One well-studied example is the formation of an organic ester and water from a carboxylic acid and alcohol. Which portions of the reactants end up in the ester and which in the water? Figure 24.9 shows how ^{18}O-tracers answer the question: an ^{18}O-alcohol gives an ^{18}O-ester, but an ^{18}O-acid gives ^{18}O-water.

As another example, consider the reaction between periodate and iodide ions:

$$IO_4^-(aq) + 2I^-(aq) + H_2O(l) \longrightarrow I_2(s) + IO_3^-(aq) + 2OH^-(aq)$$

Is IO_3^- the result of IO_4^- reduction or I^- oxidation? When we add "cold" (nonradioactive) IO_4^- to a solution of I^- that contains some "hot" (radioactive, indi-

*Although this statement is generally correct, differences in isotopic mass *can* influence bond strengths and therefore reaction rates. Such behavior is called a *kinetic isotope effect* and is particularly important for isotopes of hydrogen—^1H, ^2H, and ^3H—because their masses differ by such large proportions. Section 22.4 discussed how the kinetic isotope effect is employed in the industrial production of heavy water, D_2O.

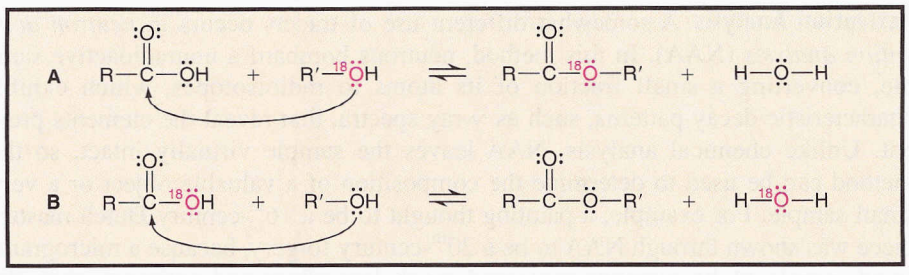


Figure 24.9 Which reactant contributes which group to the ester? An ester forms when a carboxylic acid reacts with an alcohol. To determine which reactant supplies the O atom in the —OR′ part of the ester group, acid and alcohol were labeled with the ^{18}O and used as tracers. **A,** When $R^{18}OH$ reacts with the unlabeled acid, the ester contains ^{18}O but the water doesn't. **B,** When $RCO^{18}OH$ reacts with the unlabeled alcohol, the water contains ^{18}O. Thus, the alcohol supplies the —OR′ part of the ester, and the acid supplies the RC=O part.

cated in red) $^{131}I^-$, we find that the I_2 is radioactive, not the IO_3^-:

$$IO_4^-(aq) + 2{}^{131}I^-(aq) + H_2O(l) \longrightarrow {}^{131}I_2(s) + IO_3^-(aq) + 2OH^-(aq)$$

These results show that IO_3^- forms through the reduction of IO_4^-, and that I_2 forms through the oxidation of I^-. To confirm this pathway, we add IO_4^- containing some hot $^{131}IO_4^-$ to a solution of cold I^-. As we expected, the IO_3^- is radioactive, not the I_2:

$$^{131}IO_4^-(aq) + 2I^-(aq) + H_2O(l) \longrightarrow I_2(s) + {}^{131}IO_3^-(aq) + 2OH^-(aq)$$

Thus, tracers act like "handles" we can "hold" to follow the changing reactants.

Far more complex pathways can be followed with tracers as well. The photosynthetic pathway, the most essential and widespread metabolic process on Earth, in which energy from sunlight is used to form the chemical bonds of glucose, has an overall reaction that looks quite simple:

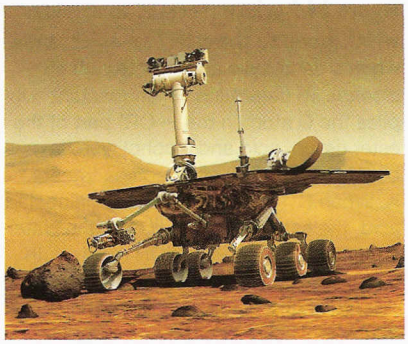
$$6CO_2(g) + 6H_2O(l) \xrightarrow[\text{chlorophyll}]{\text{light}} C_6H_{12}O_6(s) + 6O_2(g)$$

However, the actual process is extremely complex, requiring 13 enzyme-catalyzed steps for each C atom from CO_2 incorporated; thus these steps must occur six times for each molecule of $C_6H_{12}O_6$ that forms. Melvin Calvin and his coworkers took seven years to determine the pathway, using ^{14}C in CO_2 as the tracer and paper chromatography as the means of separating the products formed after different times of light exposure. Calvin won the Nobel Prize in chemistry in 1961 for this remarkable achievement.

Tracers are used in many studies of biological function. Most recently, life in space has required answers to new questions. In an animal study of red blood cell loss during extended space flight, blood plasma volume was measured with ^{125}I-labeled albumin (a blood protein), and ^{51}Cr-labeled red blood cells were used to assess survival of blood cells. In another study, blood flow in skin under long periods of microgravity was monitored using injected ^{133}Xe.

Material Flow Tracers are used in studies of solid surfaces and the flow of materials. Metal atoms hundreds of layers deep within a solid have been shown to exchange with metal ions from the surrounding solution within a matter of minutes. Chemists and engineers use tracers to study material movement in semiconductor chips, paint, and metal plating, in detergent action, and in the process of corrosion, to mention just a few of many applications.

Hydrologic engineers use tracers to study the volume and flow of large bodies of water. By following radionuclides formed during atmospheric nuclear bomb tests (^3H in H_2O, $^{90}Sr^{2+}$, and $^{137}Cs^+$), scientists have mapped the flow of water from land to lakes and streams to oceans. Surface and deep ocean currents that circulate around the globe are also studied, as are the mechanisms of hurricane formation and the mixing of the troposphere and stratosphere. Industries employ tracers to study material flow during the manufacturing process, such as the flow of ore pellets in smelting kilns, the paths of wood chips and bleach in paper mills, the diffusion of fungicide into lumber, and in a particularly important application, the porosity and leakage of oil and gas wells in geological formations.



Spirit on the surface of Mars.

Activation Analysis A somewhat different use of tracers occurs in *neutron activation analysis* (NAA). In this method, neutrons bombard a nonradioactive sample, converting a small fraction of its atoms to radioisotopes, which exhibit characteristic decay patterns, such as γ-ray spectra, that reveal the elements present. Unlike chemical analysis, NAA leaves the sample virtually intact, so the method can be used to determine the composition of a valuable object or a very small sample. For example, a painting thought to be a 16th-century Dutch masterpiece was shown through NAA to be a 20th-century forgery, because a microgram-sized sample of its pigment contained much less silver and antimony than the pigments used by the Dutch masters. Forensic chemists use NAA to detect traces of ammunition on a suspect's hand or traces of arsenic in the hair of a victim of poisoning. In 2004, space scientists used NAA instrumentation in the *Spirit* and *Opportunity* robot vehicles to analyze the composition of Martian soils and rocks (see photo).

Automotive engineers employ NAA and γ-ray detectors to measure friction and wear of moving parts without having to take the engine apart. For example, when a steel surface that has been neutron-activated to form some radioactive ^{59}Fe moves against a second steel surface, the amount of radioactivity on the second surface indicates the amount of material rubbing off. The radioactivity appearing in a lubricant placed between the surfaces can demonstrate the lubricant's ability to reduce wear.

Table 24.9 Some Radioisotopes Used as Medical Tracers

Isotope	Body Part or Process
^{11}C, ^{18}F, ^{13}N, ^{15}O	PET studies of brain, heart
^{60}Co, ^{192}Ir	Cancer therapy
^{64}Cu	Metabolism of copper
^{59}Fe	Blood flow, spleen
^{67}Ga	Tumor imaging
^{123}I, ^{131}I	Thyroid
^{111}In	Brain, colon
^{42}K	Blood flow
^{81m}Kr	Lung
^{99}Tc	Heart, thyroid, liver, lung, bone
^{201}Tl	Heart muscle
^{90}Y	Cancer, arthritis

Medical Diagnosis The largest use of radioisotopes is in medical science. In fact, over 25% of U.S. hospital admissions are for diagnoses based on data from radioisotopes. Tracers with half-lives of a few minutes to a few days are employed to observe specific organs and body parts. For example, a healthy thyroid gland incorporates dietary I^- into iodine-containing hormones at a known rate. To assess thyroid function, the patient drinks a solution containing a trace amount of $Na^{131}I$, and a scanning monitor follows the uptake of $^{131}I^-$ into the thyroid (Figure 24.10A). Technetium-99 ($Z = 43$) is also used for imaging the thyroid (Figure 24.10B), as well as the heart, lungs, and liver. Technetium does not occur naturally, so the radioisotope (actually a metastable form, ^{99m}Tc) is prepared just before use from radioactive molybdenum:

$$^{99}_{42}Mo \longrightarrow {}^{99m}_{43}Tc + {}^{0}_{-1}\beta$$

Tracers are also used to measure physiological processes, such as blood flow. The rate at which the heart pumps blood, for example, can be observed by injecting ^{59}Fe, which concentrates in the hemoglobin of blood cells. Several radioisotopes used in medical diagnosis are listed in Table 24.9.

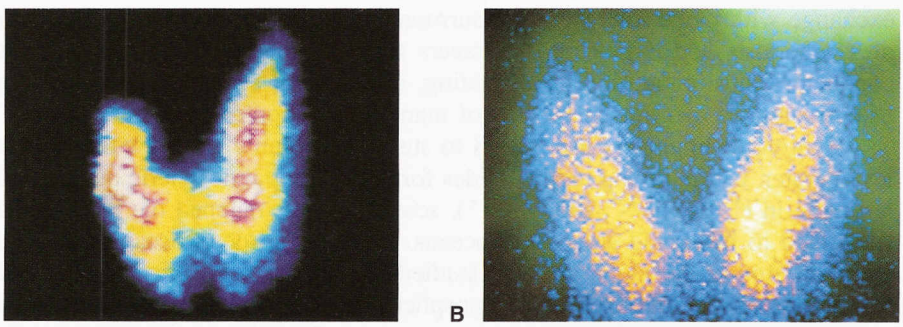


Figure 24.10 The use of radioisotopes to image the thyroid gland. Thyroid scanning is used to assess nutritional deficiencies, inflammation, tumor growth, and other thyroid-related ailments. **A,** In ^{131}I scanning, the thyroid gland absorbs $^{131}I^-$ ions whose β emissions expose a photographic film. The asymmetric image indicates disease. **B,** A ^{99}Tc scan of a healthy thyroid.

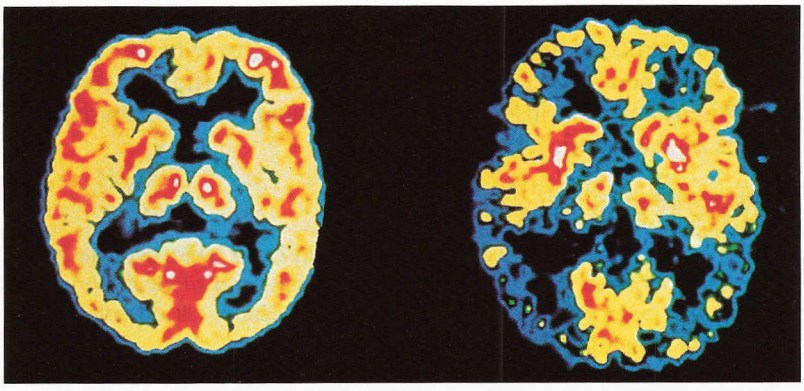

Figure 24.11 PET and brain activity. These PET scans show brain activity in a normal person (*left*) and in a patient with Alzheimer's disease (*right*). Red and yellow indicate relatively high activity within a region.

Positron-emission tomography (PET) is a powerful imaging method for observing brain structure and function. A biological substance is synthesized with one of its atoms replaced by an isotope that emits positrons. The substance is injected into a patient's bloodstream, from which it is taken up into the brain. The isotope emits positrons, each of which annihilates a nearby electron. In the annihilation process, two γ photons are emitted simultaneously 180° from each other:

$$^{0}_{1}\beta + {}^{0}_{-1}e \longrightarrow 2^{0}_{0}\gamma$$

An array of detectors around the patient's head pinpoints the sites of γ emission, and the image is analyzed by computer. Two of the isotopes used are ^{15}O, injected as $H_2{}^{15}O$ to measure blood flow, and ^{18}F bonded to a glucose analog to measure glucose uptake, which is a marker for energy metabolism. Among many fascinating PET findings are those that show how changes in blood flow and glucose uptake accompany normal or abnormal brain activity (Figure 24.11). In a recent nonmedical development, substances incorporating ^{11}C and ^{15}O are being investigated by PET to learn how molecules interact with and move along the surface of a catalyst.

Applications of Ionizing Radiation

To be used as a tracer, a radioisotope need emit only low-energy detectable radiation. Many other uses of radioisotopes, however, depend on the effects of high-energy, ionizing radiation.

The interaction between radiation and matter that causes cancer can also be used to eliminate it. Cancer cells divide more rapidly than normal cells, so radioisotopes that interfere with the cell-division process kill more cancer cells than normal ones. Implants of ^{198}Au or of a mixture of ^{90}Sr and ^{90}Y have been used to destroy pituitary and breast tumor cells, and γ rays from ^{60}Co have been used to destroy brain tumors.

Irradiation of food increases shelf life by killing microorganisms that cause food to rot (Figure 24.12), but the practice is quite controversial. Advocates point to the benefits of preserving fresh foods, grains, and seeds for long periods, whereas opponents suggest that irradiation might lower the food's nutritional content or produce harmful by-products. The increased use of antibiotics in animal feed has brought about an increased incidence of illness from newer, more resistant bacterial strains, providing a stronger argument for the use of irradiation. The United Nations has approved irradiation for potatoes, wheat, chicken, and strawberries, and the United States allows irradiation of chicken.

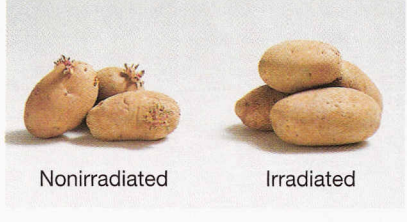

Figure 24.12 The increased shelf life of irradiated food.

Ionizing radiation has been used to control harmful insects. Captured males are sterilized by radiation and released to mate, thereby reducing the number of offspring. This method has been used to control the Mediterranean fruit fly in California and disease-causing insects, such as the tsetse fly and malarial mosquito, in other parts of the world.

SECTION SUMMARY

Radioisotopic tracers emit nonionizing radiation and have been used to study reaction mechanisms, material flow, elemental composition, and medical conditions. Ionizing radiation has been used to destroy cancerous tissue, kill organisms that spoil food, and control insect populations.

24.6 THE INTERCONVERSION OF MASS AND ENERGY

Most of the nuclear processes we've considered so far have involved radioactive decay, in which a nucleus emits one or a few small particles or photons to become a slightly lighter nucleus. Two other nuclear processes cause much greater changes. In nuclear **fission,** a heavy nucleus splits into two much lighter nuclei, emitting several small particles at the same time. In nuclear **fusion,** the opposite process occurs as two lighter nuclei combine to form a heavier one. Both fission and fusion release enormous quantities of energy. Let's take a look at the origins of this energy by first examining the change in mass that accompanies the breakup of a nucleus into its nucleons and then considering the energy that is equivalent to this mass change.

The Mass Defect

We have known for most of the 20th century that mass and energy are interconvertible. The traditional mass and energy conservation laws have been combined to state that *the total quantity of mass-energy in the universe is constant.* Therefore, when *any* reacting system releases or absorbs energy, there must be an accompanying loss or gain in mass.

This relation between mass and energy did not concern us earlier because the energy changes involved in breaking or forming chemical bonds are so small that the mass changes are negligible. When 1 mol of water breaks up into its atoms, for example, heat is absorbed:

$$H_2O(g) \longrightarrow 2H(g) + O(g) \qquad \Delta H^0_{rxn} = 2 \times \text{BE of O—H} = 934 \text{ kJ}$$

We find the mass that is equivalent to this energy from *Einstein's equation:*

$$E = mc^2 \quad \text{or} \quad \Delta E = \Delta m c^2 \quad \text{so} \quad \Delta m = \frac{\Delta E}{c^2} \tag{24.7}$$

where Δm is the change in mass between the reactants and the products. Substituting the heat of reaction (in J/mol) for ΔE and the numerical value for c (2.9979×10^8 m/s), we obtain

$$\Delta m = \frac{9.34 \times 10^5 \text{ J/mol}}{(2.9979 \times 10^8 \text{ m/s})^2} = 1.04 \times 10^{-11} \text{ kg/mol} = 1.04 \times 10^{-8} \text{ g/mol}$$

(Units of kg/mol are obtained because the joule includes the kilogram: 1 J = 1 kg·m^2/s^2.) The mass of 1 mol of H_2O (reactant) is about 10 ng *less* than the combined masses of 2 mol of H and 1 mol of O (products), a change too small to measure with even the most sophisticated balance. Such minute mass changes when bonds break or form allow us to assume that mass is conserved in *chemical* reactions.

The much larger mass change that accompanies a *nuclear* process is related to the enormous energy required to bind the nucleus together or break it apart. Consider, for example, the change in mass that occurs when one ^{12}C nucleus breaks up into its nucleons: six protons and six neutrons. We calculate this change in mass by combining the mass of six H *atoms* and six neutrons and then subtracting the mass of one ^{12}C *atom*. This procedure cancels the masses of the electrons [six e^- (in six ^1H atoms) cancel six e^- (in one ^{12}C atom)]. The mass of one ^1H atom is 1.007825 amu, and the mass of one neutron is 1.008665 amu, so

$$\begin{aligned} \text{Mass of six } ^1\text{H atoms} &= 6.046950 \text{ amu} \\ \text{Mass of six neutrons} &= 6.051990 \text{ amu} \\ \text{Total mass} &= 12.098940 \text{ amu} \end{aligned}$$

The mass of one ^{12}C atom is 12 amu (exactly). The difference in mass (Δm) is the total mass of the nucleons minus the mass of the nucleus:

$$\begin{aligned} \Delta m &= 12.098940 \text{ amu} - 12.000000 \text{ amu} \\ &= 0.098940 \text{ amu}/^{12}\text{C} = 0.098940 \text{ g/mol } ^{12}\text{C} \end{aligned}$$

Note that *the mass of the nucleus is* ***less*** *than the combined masses of its nucleons*. The mass decrease that occurs when nucleons are united into a nucleus is called the **mass defect.** The size of this mass change (9.89×10^{-2} g/mol) is nearly 10 million times that of the previous bond breakage (10.4×10^{-9} g/mol) and is easily observed on any laboratory balance.

Nuclear Binding Energy

Einstein's equation for the relation between mass and energy also allows us to find the energy equivalent of a mass defect. For ^{12}C, after converting grams to kilograms, we have

$$\begin{aligned} \Delta E = \Delta mc^2 &= (9.8940\times10^{-5} \text{ kg/mol})(2.9979\times10^{8} \text{ m/s})^2 \\ &= 8.8921\times10^{12} \text{ J/mol} = 8.8921\times10^{9} \text{ kJ/mol} \end{aligned}$$

This quantity of energy is called the **nuclear binding energy** for carbon-12. In general, the nuclear binding energy is the quantity of energy required to *break up 1 mol of nuclei into their individual nucleons:*

$$\text{Nucleus} + \text{nuclear binding energy} \longrightarrow \text{nucleons}$$

Thus, qualitatively, the nuclear binding energy is analogous to the sum of bond energies of a covalent compound or the lattice energy of an ionic compound. But, quantitatively, nuclear binding energies are typically several million times greater.

We use joules to express the binding energy per mole of nuclei, but the joule is an impractically large unit to express the binding energy of a single nucleus. Instead, nuclear scientists use the **electron volt (eV),** the energy an electron acquires when it moves through a potential difference of 1 volt:

$$1 \text{ eV} = 1.602\times10^{-19} \text{ J}$$

Binding energies are commonly expressed in millions of electron volts, that is, in *mega–electron volts* (MeV):

$$1 \text{ MeV} = 10^6 \text{ eV} = 1.602\times10^{-13} \text{ J}$$

A particularly useful factor converts a given mass defect in atomic mass units to its energy equivalent in electron volts:

$$1 \text{ amu} = 931.5\times10^6 \text{ eV} = 931.5 \text{ MeV} \qquad (24.8)$$

Earlier we found the mass defect of the ^{12}C nucleus to be 0.098940 amu. Therefore, the binding energy per ^{12}C nucleus, expressed in MeV, is

$$\frac{\text{Binding energy}}{^{12}\text{C nucleus}} = 0.098940 \text{ amu} \times \frac{931.5 \text{ MeV}}{1 \text{ amu}} = 92.16 \text{ MeV}$$

The Force That Binds Us According to current theory, the nuclear binding energy is related to the strong force, which holds nucleons together in a nucleus. There are three other fundamental forces: (1) the weak nuclear force, which is important in β decay, (2) the electrostatic force that we observe between charged particles, and (3) the gravitational force. Toward the end of his life, Albert Einstein tried unsuccessfully to develop a theory to explain how the four forces were really different aspects of one unified force that governs all nature. The 2004 Nobel Prize in physics was awarded to David J. Gross, H. David Politzer, and Frank Wilczek for their explanation of the strong force who, with others, may one day realize Einstein's dream.

We can compare the stability of nuclides of different elements by determining the *binding energy per nucleon*. For ^{12}C, we have

$$\text{Binding energy per nucleon} = \frac{\text{binding energy}}{\text{no. of nucleons}} = \frac{92.16 \text{ MeV}}{12 \text{ nucleons}} = 7.680 \text{ MeV/nucleon}$$

SAMPLE PROBLEM 24.6 Calculating the Binding Energy per Nucleon

Problem Iron-56 is an extremely stable nuclide. Compute the binding energy per nucleon for ^{56}Fe and compare it with that for ^{12}C (mass of ^{56}Fe atom = 55.934939 amu; mass of ^{1}H atom = 1.007825 amu; mass of neutron = 1.008665 amu).

Plan Iron-56 has 26 protons and 30 neutrons in its nucleus. We calculate the mass defect by finding the sum of the masses of 26 ^{1}H atoms and 30 neutrons and subtracting the given mass of 1 ^{56}Fe atom. Then we multiply Δm by the equivalent in MeV (931.5 MeV/amu) and divide by 56 (no. of nucleons) to obtain the binding energy per nucleon.

Solution Calculating the mass defect:

$$\begin{aligned}\text{Mass defect} &= [(26 \times \text{mass } ^{1}H \text{ atom}) + (30 \times \text{mass neutron})] - \text{mass } ^{56}Fe \text{ atom} \\ &= [(26)(1.007825 \text{ amu}) + (30)(1.008665 \text{ amu})] - 55.934939 \text{ amu} \\ &= 0.52846 \text{ amu}\end{aligned}$$

Calculating the binding energy per nucleon:

$$\text{Binding energy per nucleon} = \frac{0.52846 \text{ amu} \times 931.5 \text{ MeV/amu}}{56 \text{ nucleons}} = 8.790 \text{ MeV/nucleon}$$

An ^{56}Fe nucleus would require more energy to break up into its nucleons than would ^{12}C (7.680 MeV/nucleon), so ^{56}Fe is more stable than ^{12}C.

Check The answer is consistent with the great stability of ^{56}Fe. Given the number of decimal places in the values, rounding to check the math is useful only to find a *major* error. The number of nucleons (56) is an exact number, so we retain four significant figures.

FOLLOW-UP PROBLEM 24.6 Uranium-235 is the essential component of the fuel in nuclear power plants. Calculate the binding energy per nucleon for ^{235}U. Is this nuclide more or less stable than ^{12}C (mass of ^{235}U atom = 235.043924 amu)?

Fission or Fusion: Means of Increasing the Binding Energy Per Nucleon Calculations similar to Sample Problem 24.6 for other nuclides show that the binding energy per nucleon varies considerably. The essential point is that *the greater the binding energy per nucleon, the more stable the nuclide.*

Figure 24.13 shows a plot of the binding energy per nucleon vs. mass number. It provides information about nuclide stability and the two possible processes nuclides can undergo to form more stable nuclides. Nuclides with fewer than 10 nucleons have a relatively small binding energy per nucleon. The ^{4}He nucleus has an exceptionally large value, however, which is why it is emitted intact as an α particle. Above $A = 12$, the binding energy per nucleon varies from about 7.6 to 8.8 MeV.

The most important observation is that *the binding energy per nucleon peaks for elements with $A \approx 60$.* In other words, nuclides become more stable with increasing mass number up to around 60 nucleons and then become less stable with higher numbers of nucleons. The existence of a peak of stability suggests that there are two ways nuclides can increase their binding energy per nucleon:

- *Fission.* A heavier nucleus can *split into lighter ones (closer to $A \approx 60$)* by undergoing fission. The product nuclei have greater binding energy per nucleon (are more stable) than the reactant nucleus, and the difference in *energy is released.* Nuclear power plants generate energy through fission, as do atomic bombs (Section 24.7).

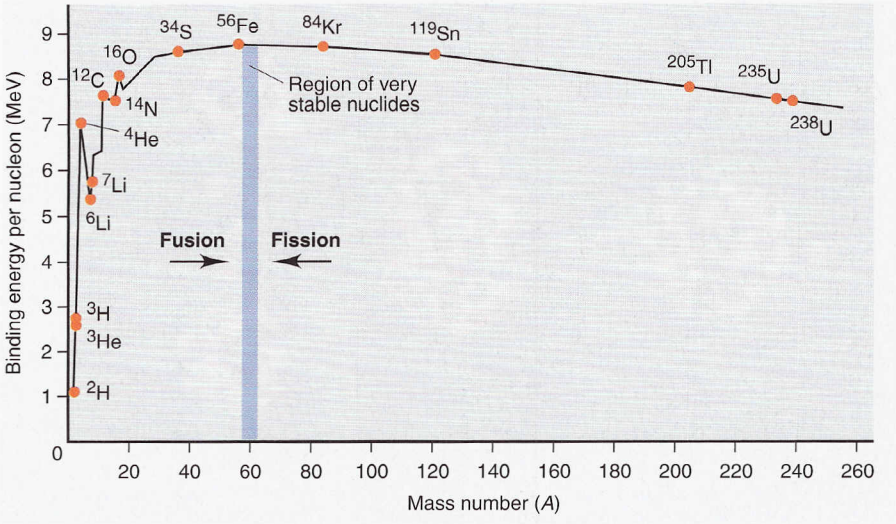

Figure 24.13 The variation in binding energy per nucleon. A plot of the binding energy per nucleon vs. mass number shows that nuclear stability is greatest in the region near ^{56}Fe. Lighter nuclei may undergo fusion to become more stable; heavier ones may undergo fission. Note the exceptional stability of ^{4}He among extremely light nuclei.

- *Fusion.* Lighter nuclei, on the other hand, can *combine to form a heavier one (closer to $A \approx 60$)* by undergoing fusion. Once again, the product is more stable than the reactants, and *energy is released.* The Sun and other stars generate energy through fusion, as do hydrogen bombs. In these examples and in all current research efforts for developing fusion as a useful energy source, hydrogen nuclei fuse to form the very stable helium-4 nucleus.

In the next section, we examine fission and fusion and the industrial energy facilities designed to utilize them.

SECTION SUMMARY

The mass of a nucleus is less than the sum of the masses of its nucleons by an amount called the mass defect. The energy equivalent to the mass defect is the nuclear binding energy, usually expressed in units of MeV. The binding energy per nucleon is a measure of nuclide stability and varies with the number of nucleons in a nuclide. Nuclides with $A \approx 60$ are most stable. Lighter nuclides can join (fusion) or heavier nuclides can split (fission) to become more stable.

24.7 APPLICATIONS OF FISSION AND FUSION

Of the many beneficial applications of nuclear reactions, the greatest is the potential for almost limitless amounts of energy, which is based on the multimillionfold increase in energy yield of nuclear reactions over chemical reactions. Our experience with nuclear energy from power plants in the late 20th century, however, has forced a realization that we must strive to improve ways to tap this energy source safely and economically. In this section, we discuss how fission and fusion occur and how we are applying them.

The Process of Nuclear Fission

During the mid-1930s, Enrico Fermi and coworkers bombarded uranium ($Z = 92$) with neutrons in an attempt to synthesize transuranium elements. Many of the

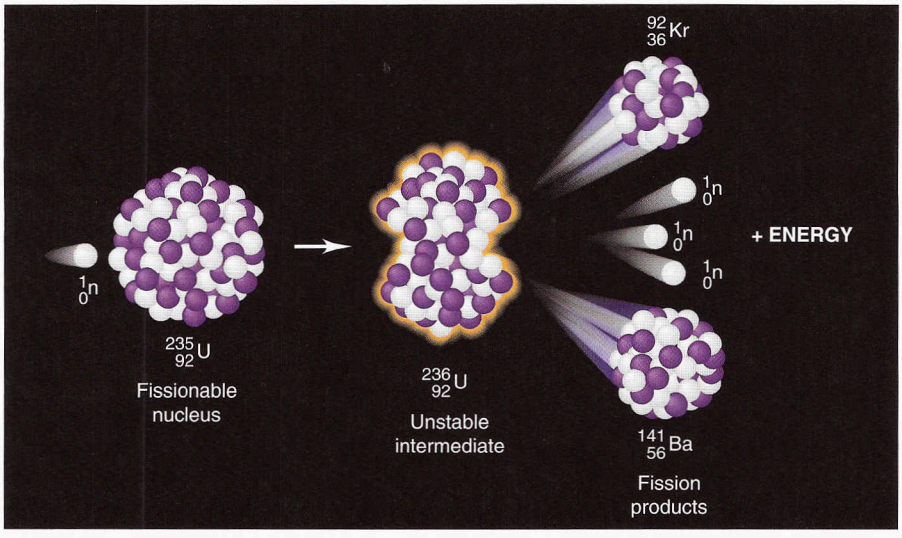

Figure 24.14 Induced fission of ^{235}U. A neutron bombarding a ^{235}U nucleus results in an extremely unstable ^{236}U nucleus, which becomes distorted in the act of splitting. In this case, which shows one of many possible splitting patterns, the products are ^{92}Kr and ^{141}Ba. Three neutrons and a great deal of energy are released also.

Lise Meitner (1878–1968) Until very recently, this extraordinary physicist received little of the acclaim she deserved. Meitner worked in the laboratory of the chemist Otto Hahn, and she was responsible for the discovery of protactinium (Pa; $Z = 91$) and numerous radioisotopes. After leaving Germany in advance of the Nazi domination, Meitner proposed the correct explanation of nuclear fission. In 1944 Hahn received the Nobel Prize in chemistry, but he did not even acknowledge Meitner in his acceptance speech. Today, most physicists believe Meitner should have received the prize. Despite controversy over names for elements 104 to 109, it was widely agreed that element 109 should be named meitnerium.

unstable nuclides produced were tentatively identified as having $Z > 92$, but other scientists were skeptical. Four years later, the German chemist Otto Hahn and his associate F. Strassmann showed that one of these unstable nuclides was an isotope of barium ($Z = 56$). The Austrian physicist Lise Meitner, a coworker of Hahn, and her nephew Otto Frisch proposed that barium resulted from the *splitting* of the uranium nucleus into *smaller* nuclei, a process that they called *fission* because of its similarity to the fission a biological cell undergoes during reproduction.

The ^{235}U nucleus can split in many different ways, giving rise to various daughter nuclei, but all routes have the same general features. Figure 24.14 depicts one of these fission patterns. Neutron bombardment results in a highly excited ^{236}U nucleus, which splits apart in 10^{-14} s. The products are two nuclei of unequal mass, two or three neutrons (average of 2.4), and a large quantity of energy. A single ^{235}U nucleus releases 3.5×10^{-11} J when it splits; 1 mol of ^{235}U (about $\frac{1}{2}$ lb) releases 2.1×10^{13} J—a billion times as much energy as burning $\frac{1}{2}$ lb of coal (about 2×10^{4} J)!

We harness the energy of nuclear fission, much of which appears as heat, by means of a **chain reaction,** illustrated in Figure 24.15: the two to three neutrons that are released by the fission of one nucleus collide with other fissionable nuclei and cause them to split, releasing more neutrons, which then collide with other nuclei, and so on, in a self-sustaining process. In this manner, the energy released increases rapidly because each fission event in a chain reaction releases two to three times as much energy as the preceding one.

Whether a chain reaction occurs depends on the mass (and thus the volume) of the fissionable sample. If the piece of uranium is large enough, the product neutrons strike another fissionable nucleus *before* flying out of the sample, and a chain reaction takes place. The mass required to achieve a chain reaction is called the **critical mass.** If the sample has less than the critical mass (called a *subcritical mass*), most of the product neutrons leave the sample before they have the opportunity to collide with and cause the fission of another ^{235}U nucleus, and thus a chain reaction does not occur.

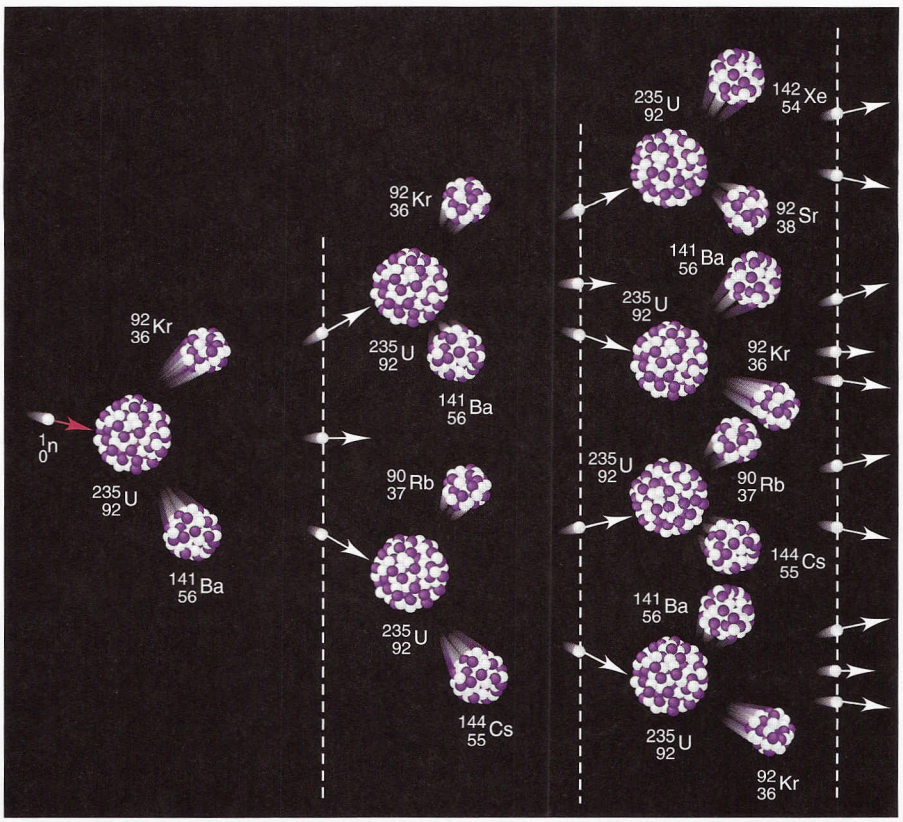

Figure 24.15 A chain reaction of ^{235}U. If a sample exceeds the critical mass, neutrons produced by the first fission event collide with other nuclei, causing their fission and the production of more neutrons to continue the process. Note that various product nuclei form. The vertical dashed lines identify succeeding "generations" of neutrons.

Uncontrolled Fission: The Atomic Bomb An uncontrolled chain reaction can be adapted to make an extremely powerful explosive, as several of the world's leading atomic physicists suspected just prior to the beginning of World War II. In August 1939, Albert Einstein wrote the president of the United States, Franklin Delano Roosevelt, to this effect, warning of the danger of allowing the Nazi government to develop this power first. It was this concern that led to the Manhattan Project, an enormous scientific effort to develop a bomb based on nuclear fission, which was initiated in 1941.* In August 1945, the United States detonated two atomic bombs over Japan, and the horrible destructive power of these bombs was a major factor in the surrender of the Japanese a few days later.

In an atomic bomb, small explosions of trinitrotoluene (TNT) bring subcritical masses of fissionable material together to exceed the critical mass, and the ensuing chain reaction brings about the explosion (Figure 24.16). The proliferation of nuclear power plants, which use fissionable materials to generate energy for electricity, has increased concern that more countries (and unscrupulous individuals) may have access to such material for making bombs. Since the devastating terrorist attacks of September 11, 2001 in the United States, this concern has been heightened. After all, only 1 kg of fissionable uranium was used in the bomb dropped on Hiroshima, Japan.

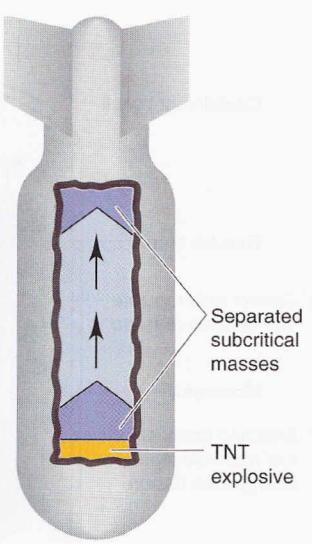

Figure 24.16 Diagram of an atomic bomb. Small TNT explosions bring subcritical masses together, and the chain reaction occurs.

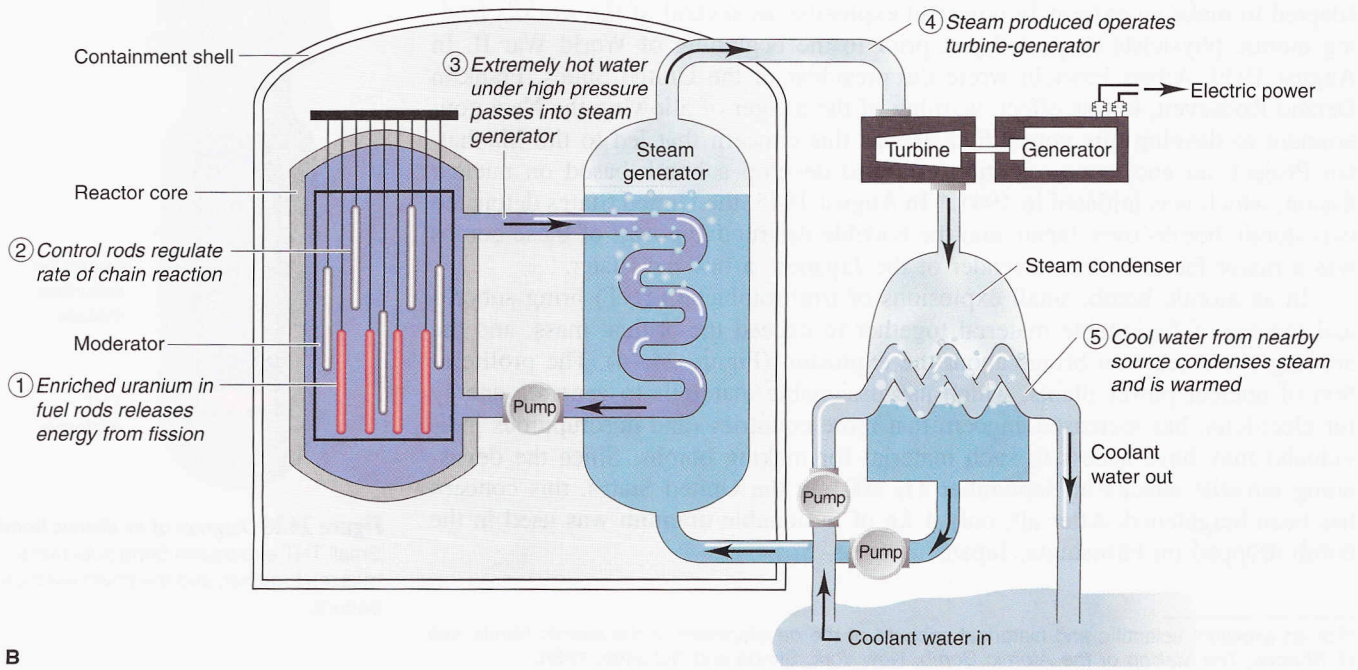
*For an excellent scientific and historical account of the development of the atomic bomb, see R. Rhodes, *The Making of the Atomic Bomb,* New York, Simon and Schuster, 1986.

Controlled Fission: Nuclear Energy Reactors Controlled fission can produce electric power more cleanly than can the combustion of coal. Like a coal-fired power plant, *a nuclear power plant generates heat to produce steam, which turns a turbine attached to an electric generator.* In a coal plant, the heat is produced by burning coal; in a nuclear plant, it is produced by splitting uranium.

Heat generation takes place in the **reactor core** of a nuclear plant (Figure 24.17). The core contains the *fuel rods,* which consist of fuel enclosed in tubes of a corrosion-resistant zirconium alloy. The fuel is uranium(IV) oxide (UO_2) that has been *enriched* from 0.7% ^{235}U, the natural abundance of this fissionable isotope, to the 3% to 4% ^{235}U required to sustain a chain reaction. (Enrichment of nuclear fuel is the most important application of Graham's law; see the margin note, p. 205.) Sandwiched between the fuel rods are movable *control rods* made of cadmium or boron (or, in nuclear submarines, hafnium), substances that absorb neutrons very efficiently. When the control rods are moved between the fuel rods, the chain reaction slows because fewer neutrons are available to bombard uranium atoms; when they are removed, the chain reaction speeds up. Neutrons that leave the fuel-rod assembly collide with a *reflector,* usually made of a beryllium

A



B

Figure 24.17 A light-water nuclear reactor. A, Photo of a facility showing the concrete containment shell and nearby water source. **B,** Schematic of a light-water reactor.

alloy, which absorbs very few neutrons. Reflecting the neutrons back to the fuel rods speeds the chain reaction.

Flowing around the fuel and control rods in the reactor core is the *moderator,* a substance that slows the neutrons, making them much better at causing fission than the fast ones emerging directly from the fission event. In most modern reactors, the moderator also acts as the *coolant,* the fluid that transfers the released heat to the steam-producing region. Because ^{1}H absorbs neutrons, *light-water reactors* use H_2O as the moderator; in heavy-water reactors, D_2O is used. The advantage of D_2O is that it absorbs very few neutrons, leaving more available for fission, so heavy-water reactors can use *unenriched* uranium. As the coolant flows around the encased fuel, pumps circulate it through coils that transfer its heat to the water reservoir. Steam formed in the reservoir turns the turbine that runs the generator. The steam is then condensed in large cooling towers (see Figure 13.22, p. 509) using water from a lake or river and returned to the water reservoir.

Some major accidents at nuclear plants have caused decidedly negative public reactions. In 1979, malfunctions of coolant pumps and valves at the Three-Mile Island facility in Pennsylvania led to melting of some of the fuel, serious damage to the reactor core, and the release of radioactive gases into the atmosphere. In 1986, a million times as much radioactivity was released when a cooling system failure at the Chernobyl plant in Ukraine caused a much greater melting of fuel and an uncontrolled reaction. High-pressure steam and ignited graphite moderator rods caused the reactor building to explode and expel radioactive debris. Carried by prevailing winds, the radioactive particles contaminated vegetables and milk in much of Europe. Health officials have evidence that thousands of people living near the accident have already or may eventually develop cancer from radiation exposure. The design of the Chernobyl plant was particularly unsafe because, unlike reactors in the United States and western Europe, the reactor was not enclosed in a massive, concrete containment building.

Despite potential safety problems, nuclear power remains an important source of electricity. In the late 1990s, nearly every European country employed nuclear power, and it is the major power source in some countries—Sweden creates 50% of its electricity this way and France almost 80%. Currently, the United States obtains about 20% of its electricity from nuclear power, and Canada slightly less. As our need for energy grows, safer reactors will be designed.

However, even a smoothly operating plant has certain inherent problems. The problem of *thermal pollution* is common to all power plants. Water used to condense the steam is several degrees warmer when returned to its source, which can harm aquatic organisms (Section 13.4). A more serious problem is *nuclear waste disposal.* Many of the fission products formed in nuclear reactors have long half-lives, and no satisfactory plan for their permanent disposal has yet been devised. Proposals to place the waste in containers and bury them in deep bedrock cannot possibly be field-tested for the thousands of years the material will remain harmful. Leakage of radioactive material into groundwater is a danger, and earthquakes can occur even in geologically stable regions. Despite studies indicating the proposed disposal site at Yucca Mountain, Nevada, may be too geologically active, the U.S. government recently approved the site. It remains to be seen whether we can operate fission reactors *and* dispose of the waste safely and economically.

"Breeding" Nuclear Fuel Uranium-235 is not an abundant isotope. One solution to a potential fuel shortage is a *breeder reactor,* designed to consume one type of nuclear fuel as it produces another. Fuel rods are surrounded by natural U_3O_8, which contains 99.3% *nonfissionable* ^{238}U atoms. As fast neutrons, formed during ^{235}U fission, escape the fuel rod, they collide with ^{238}U, transmuting it into ^{239}Pu, another fissionable nucleus:

$$^{238}_{92}U + {}^{1}_{0}n \longrightarrow {}^{239}_{92}U$$
($t_{1/2}$ of $^{239}_{92}U$ = 23.5 min)

$$^{239}_{92}U \longrightarrow {}^{239}_{93}Np + {}^{0}_{-1}\beta$$
($t_{1/2}$ of $^{239}_{93}Np$ = 2.35 days)

$$^{239}_{93}Np \longrightarrow {}^{239}_{94}Pu + {}^{0}_{-1}\beta$$
($t_{1/2}$ of $^{239}_{94}Pu = 2.4\times10^{4}$ yr)

Although breeder reactors can make fuel as they operate, they are difficult and expensive to build, and ^{239}Pu is extremely toxic and long lived. Breeder reactors are not used in the United States, although several are operating in Europe and Japan.

The Promise of Nuclear Fusion

Nuclear fusion is the ultimate source of nearly all the energy on Earth because nearly all other sources depend, directly or indirectly, on the energy produced by nuclear fusion in the Sun. But the Sun and other stars generate more than energy; in fact, *all the elements larger than hydrogen were formed in fusion and decay processes within stars,* as the upcoming Chemical Connections essay describes.

CHEMICAL CONNECTIONS to Cosmology

Origin of the Elements in the Stars

How did the universe begin? Where did matter come from? How were the elements formed? Every culture has creation myths that address such questions, but only recently have astronomers, physicists, and chemists begun to offer a scientific explanation. The most accepted current model proposes that a sphere of unimaginable properties—diameter of 10^{-28} cm, density of 10^{96} g/mL (density of a nucleus $\approx 10^{14}$ g/mL), and temperature of 10^{32} K—exploded in a "Big Bang," for reasons not yet even guessed, and distributed its contents through the void of space. Cosmologists consider this moment the beginning of time.

One second later, the universe was an expanding mixture of neutrons, protons, and electrons, denser than rock and hotter than an exploding hydrogen bomb (about 10^{10} K). During the next few minutes, it became a gigantic fusion reactor creating the first atomic nuclei: ^{2}H, ^{3}He, and ^{4}He. After 10 minutes, more than 25% of the mass of the universe existed as ^{4}He, and only about 0.025% as ^{2}H. About 100 million years later, or about 15 billion years ago, gravitational forces pulled this cosmic mixture into primitive, contracting stars.

This account of the origin of the universe is based on the observation of spectra from the Sun, other stars, nearby galaxies, and cosmic (interstellar) dust. Spectral analysis of planets and chemical analysis of Earth and Moon rocks, meteorites, and cosmic-ray particles furnish data about isotope abundance. From these, a model has been developed for **stellar nucleogenesis,** the origin of the elements in the stars. The overall process occurs in several stages during a star's evolution, and the entire sequence of steps occurs only in very massive stars, having 10 to 100 times the mass of the Sun. Each step involves a contraction of the star that produces higher temperature and heavier nuclei. Such events are forming elements in stars today. The key stages in the process are shown in Figure B24.3 and described below:

1. *Hydrogen burning produces He.* The initial contraction of a star heats its core to about 10^{7} K, at which point a fusion process called *hydrogen burning* begins, which produces helium from the abundant protons:

$$4\,{}^{1}_{1}H \longrightarrow {}^{4}_{2}He + 2\,{}^{0}_{1}\beta + 2\gamma + \text{energy}$$

2. *Helium burning produces C, O, Ne, and Mg.* After several billion years of hydrogen burning, about 10% of the ^{1}H is consumed, and the star contracts further. The ^{4}He forms a dense core, hot enough (2×10^{8} K) to fuse ^{4}He. The energy released during *helium burning* expands the remaining ^{1}H into a vast envelope: the star becomes a *red giant,* more than 100 times its original diameter. Within its core, pairs of ^{4}He nuclei (α particles) fuse into unstable ^{8}Be nuclei ($t_{1/2} = 7\times10^{-17}$ s). These collide with another ^{4}He to form stable ^{12}C. Then, further fusion with ^{4}He creates nuclei up to ^{24}Mg:

$$^{12}C \xrightarrow{\alpha} {}^{16}O \xrightarrow{\alpha} {}^{20}Ne \xrightarrow{\alpha} {}^{24}Mg$$

3. *Elements through Fe and Ni form.* For another 10 million years, ^{4}He is consumed, and the heavier nuclei created form a core. This core contracts and heats, expanding the star into a *supergiant.* Within the hot core (7×10^{8} K), *carbon and oxygen burning* occur:

$$^{12}C + {}^{12}C \longrightarrow {}^{23}Na + {}^{1}H$$
$$^{12}C + {}^{16}O \longrightarrow {}^{28}Si + \gamma$$

Absorption of α particles forms nuclei up to ^{40}Ca:

$$^{12}C \xrightarrow{\alpha} {}^{16}O \xrightarrow{\alpha} {}^{20}Ne \xrightarrow{\alpha} {}^{24}Mg \xrightarrow{\alpha} {}^{28}Si \xrightarrow{\alpha} {}^{32}S \xrightarrow{\alpha} {}^{36}Ar \xrightarrow{\alpha} {}^{40}Ca$$

Further contraction and heating to a temperature of 3×10^{9} K allow reactions in which nuclei release neutrons, protons, and α particles and then recapture them. As a result, nuclei with lower binding energies supply nucleons to create those with higher binding energies. This process, which takes only a few minutes, stops at iron ($A = 56$) and nickel ($A = 58$), the nuclei with the highest binding energies.

4. *Heavier elements form.* In very massive stars, the next stage is the most spectacular. With all the fuel consumed, the core collapses within a second. Many Fe and Ni nuclei break down into neutrons and protons. Protons capture electrons to form neutrons, and the entire core forms an incredibly dense *neutron star.* (An Earth-sized star that became a neutron star would fit in the Houston Astrodome!) As the core implodes, the outer layers explode in a *supernova,* which expels material throughout space. A supernova occurs an average of every few hundred years in each galaxy; the one shown in Figure B24.4 was observed from the southern hemisphere in 1987, about 160,000 years after the event occurred. The heavier elements are formed during supernova events and are found in *second-generation stars,* those that coalesce from interstellar ^{1}H and ^{4}He and the debris of exploded first-generation stars.

Heavier elements form through *neutron-capture* processes. In the *s-process,* a nucleus captures a neutron and emits a γ ray. Days, months, or even thousands of years after this event, the nucleus emits a β particle to form the next element, as in this conversion of ^{68}Zn to ^{70}Ge:

$$^{68}Zn \xrightarrow{n} {}^{69}Zn \xrightarrow{\beta} {}^{69}Ga \xrightarrow{n} {}^{70}Ga \xrightarrow{\beta} {}^{70}Ge$$

The stable isotopes of most heavy elements form by the s-process.

Less stable isotopes and those with A greater than 230 cannot form by the s-process because their half-lives are too short. These form by the *r-process* during the fury of the supernova. Multiple neutron captures, followed by multiple β decays, occur in a second, as when ^{56}Fe is converted to ^{79}Br:

$$^{56}_{26}Fe + 23\,{}^{1}_{0}n \longrightarrow {}^{79}_{26}Fe \longrightarrow {}^{79}_{35}Br + 9\,{}^{0}_{-1}\beta$$

We know from the heavy elements present in the Sun that it is at least a second-generation star presently undergoing hydrogen burning. Together with its planets, it was formed from the dust of exploded stars about 4.6×10^{9} years ago. This means that many of the atoms on Earth, including some within you, came from exploded stars and are older than the Solar System itself!

Any theory of element formation must be consistent with the element abundances we observe (Section 22.1). Although local compositions, such as those of Earth and Sun, differ, large regions of the universe have, on average, similar compositions. Therefore, scientists believe that element forming reaches a dynamic equilibrium, which leads to *relatively constant amounts of the isotopes.*

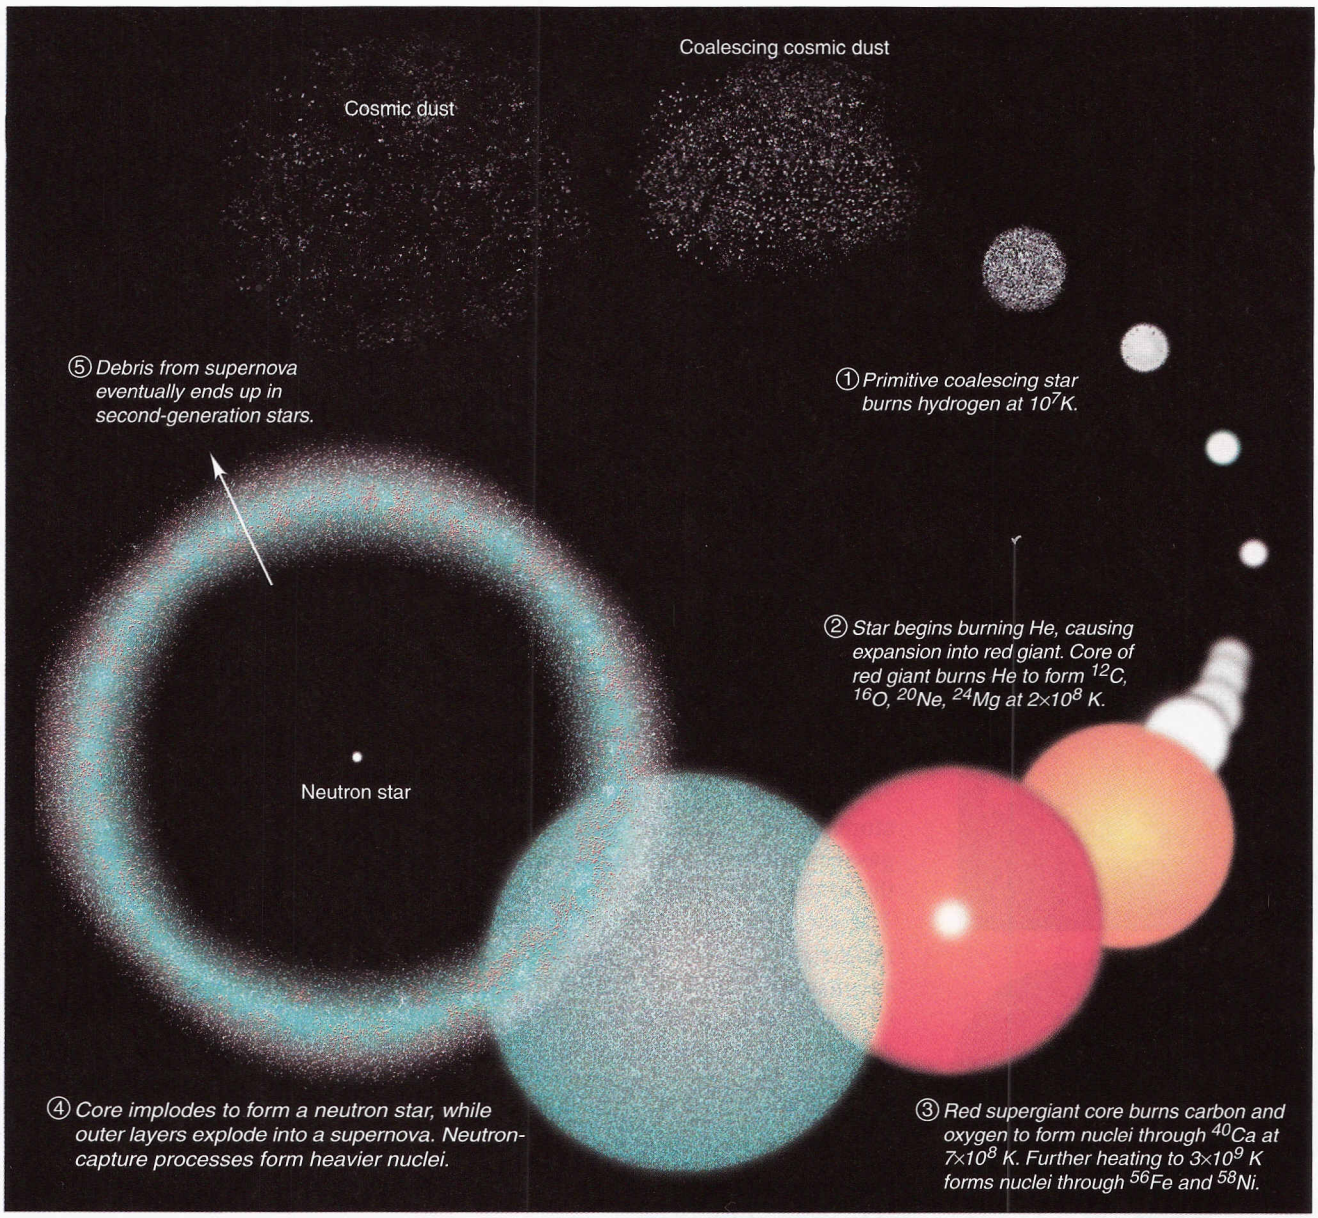


Figure B24.3 Element synthesis in the life cycle of a star.

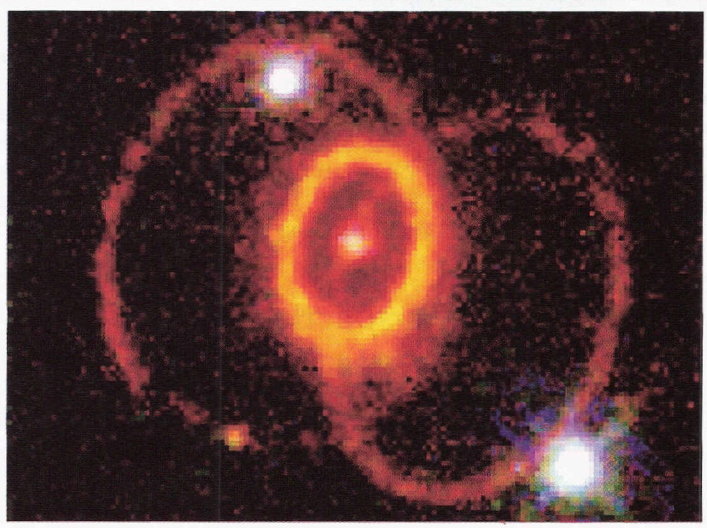

Figure B24.4 A view of Supernova 1987A.

Much research is being devoted to making nuclear fusion a practical, direct source of energy on Earth. To understand the advantages of fusion, let's consider one of the most discussed fusion reactions, in which deuterium and tritium react:

$$^{2}_{1}\text{H} + {}^{3}_{1}\text{H} \longrightarrow {}^{4}_{2}\text{He} + {}^{1}_{0}\text{n}$$

This reaction produces 1.7×10^{9} kJ/mol, an enormous quantity of energy with no radioactive by-products. Moreover, the reactant nuclei are relatively easy to come by. We obtain deuterium from the electrolysis of water (Section 22.4). In nature, tritium forms through the cosmic (neutron) irradiation of ^{14}N:

$$^{14}_{7}\text{N} + {}^{1}_{0}\text{n} \longrightarrow {}^{3}_{1}\text{H} + {}^{12}_{6}\text{C}$$

However, this process results in a natural abundance of only 10^{-7}% ^{3}H. More practically, tritium can be produced in nuclear accelerators by bombarding lithium-6 or by surrounding the fusion reactor itself with material containing lithium-6:

$$^{6}_{3}\text{Li} + {}^{1}_{0}\text{n} \longrightarrow {}^{3}_{1}\text{H} + {}^{4}_{2}\text{He}$$

Thus, fusion seems very promising, at least in principle. However, some extremely difficult problems remain. Fusion requires enormous energy in the form of heat to give the positively charged nuclei enough kinetic energy to force themselves together. The fusion of deuterium and tritium, for example, occurs at practical rates at about 10^{8} K, hotter than the Sun's core! How can such temperatures be achieved? The reaction that forms the basis of a *hydrogen, or thermonuclear, bomb* fuses lithium-6 and deuterium, with an atomic bomb inside the device providing the heat. Obviously, a power plant cannot begin operation by detonating atomic bombs.

Two research approaches are being used to achieve the necessary heat. In one, atoms are stripped of their electrons at high temperatures, which results in a gaseous *plasma*, a neutral mixture of positive nuclei and electrons. Because of the extreme temperatures needed for fusion, no *material* can contain the plasma. The most successful approach to date has been to enclose the plasma within a magnetic field. The *tokamak* design has a donut-shaped container in which a helical magnetic field confines the plasma and prevents it from contacting the walls (Figure 24.18). Scientists at the Princeton University Plasma Physics facility have achieved some success in generating energy from fusion this way. In another approach, the high temperature is reached by using many focused lasers to compress and heat the fusion reactants. In any event, as a practical, everyday source of energy, fusion still seems to be a long way off.

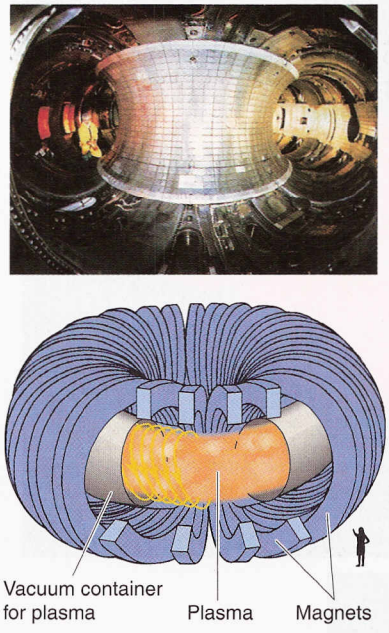

Figure 24.18 The tokamak design for magnetic containment of a fusion plasma. The donut-shaped chamber of the tokamak (photo, *top;* schematic, *bottom*) contains the plasma within a helical magnetic field.

SECTION SUMMARY

In nuclear fission, neutron bombardment causes a nucleus to split, releasing neutrons that split other nuclei to produce a chain reaction. A nuclear power plant controls the rate of the chain reaction to produce heat that creates steam, which is used to generate electricity. Potential hazards, such as radiation leaks, thermal pollution, and disposal of nuclear waste, remain current concerns. Nuclear fusion holds great promise as a source of clean abundant energy, but it requires extremely high temperatures and is not yet practical. The elements were formed through a complex series of nuclear reactions in evolving stars.

Chapter Perspective

With this chapter, our earlier picture of the nucleus as a static point of positive mass at the atom's core has changed radically. Now we picture a dynamic body, capable of a host of changes that involve incredible quantities of energy. Our attempts to apply

the behavior of this minute system to benefit society have created some of the most fascinating and challenging fields in science today.

We began our investigation of chemistry 24 chapters ago, by seeing how the chemical elements and the products we make from them influence nearly every aspect of our material existence. Now we have come full circle to learn that these elements, whose patterns of behavior we have become familiar with yet still marvel at, are continually being born in the countless infernos twinkling in the night sky.

For you, the end of this course is a beginning—a chance to apply your new abilities to visualize molecular events and solve problems in whatever field you choose. For the science of chemistry, future challenges are great: What greener energy sources can satisfy our needs while sustaining our environment? What new products can feed, clothe, and house the world's people and maintain precious resources? How can we apply our new genetic insight to defend against cancer, AIDS, and other dreaded diseases? What new materials and technologies can make life more productive and meaningful? The questions are many, but the science of chemistry will always be one of our most powerful means of answering them.

For Review and Reference (Numbers in parentheses refer to pages, unless noted otherwise.)

Learning Objectives

Relevant section and/or sample problem (SP) numbers appear in parentheses.

Understand These Concepts

1. How nuclear changes differ, in general, from chemical changes (Introduction)
2. The meanings of *radioactivity, nucleon, nuclide,* and *isotope* (Section 24.1)
3. Characteristics of three types of radioactive emissions: α, β, and γ (Section 24.1)
4. The various forms of radioactive decay and how each changes the values of A and Z (Section 24.1)
5. How the N/Z ratio and the even-odd nature of N and Z correlate with nuclear stability (Section 24.1)
6. How the N/Z ratio correlates with the mode of decay of an unstable nuclide (Section 24.1)
7. How a decay series combines numerous decay steps and ends with a stable nuclide (Section 24.1)
8. Why radioactive decay is a first-order process; the meanings of *decay rate* and *specific activity* (Section 24.2)
9. The meaning of *half-life* in the context of radioactive decay (Section 24.2)
10. How the specific activity of an isotope in an object is used to determine the object's age (Section 24.2)
11. How particle accelerators are used to synthesize new nuclides (Section 24.3)
12. The distinction between excitation and ionization and the extent of their effects on matter (Section 24.4)
13. The units of radiation dose; the effects on living tissue of various dosage levels; the inverse relationship between the mass and charge of an emission and its penetrating power (Section 24.4)
14. How ionizing radiation creates free radicals that damage tissue; sources and risks of ionizing radiation (Section 24.4)
15. How radioisotopes are used in research, analysis, and diagnosis (Section 24.5)
16. Why the mass of a nuclide is less than the sum of its nucleons' masses (mass defect) and how this mass difference is related to the nuclear binding energy (Section 24.6)
17. How nuclear stability is related to binding energy per nucleon (Section 24.6)
18. How unstable nuclides undergo either fission or fusion to increase their binding energy per nucleon (Section 24.6)
19. The current application of fission and potential application of fusion to produce energy (Section 24.7)

Master These Skills

1. Expressing the mass and charge of a particle with the ${}^{A}_{Z}\mathrm{X}$ notation (Section 24.1; see also Section 2.5)
2. Using changes in the values of A and Z to write and balance nuclear equations (SP 24.1)
3. Using the N/Z ratio and the even-odd nature of N and Z to predict nuclear stability (SP 24.2)
4. Using the N/Z ratio to predict the mode of nuclear decay (SP 24.3)
5. Converting units of radioactivity (Section 24.2)
6. Calculating specific activity, decay constant, half-life, and number of nuclei (Section 24.2 and SP 24.4)
7. Estimating the age of an object from the specific activity and half-life of carbon-14 (SP 24.5)
8. Writing and balancing equations for nuclear transmutation (Section 24.3)
9. Calculating radiation dose and converting units (Section 24.4)
10. Calculating the mass defect and its energy equivalent in J and eV (Section 24.6)
11. Calculating the binding energy per nucleon and using it to compare stabilities of nuclides (SP 24.6)

Key Equations and Relationships

24.1 Balancing a nuclear equation (1048):

$$\begin{matrix}\text{Total } A\\ \text{Total } Z\end{matrix}\ \text{Reactants} = \begin{matrix}\text{Total } A\\ \text{Total } Z\end{matrix}\ \text{Products}$$

24.2 Defining the unit of radioactivity (curie, Ci) (1054):

$$1\ \text{Ci} = 3.70\times10^{10}\ \text{disintegrations per second (d/s)}$$

24.3 Expressing the decay rate (activity) for radioactive nuclei (1054):

$$\text{Decay rate } (\mathcal{A}) = -\frac{\Delta\mathcal{N}}{\Delta t} = k\mathcal{N}$$

24.4 Finding the number of nuclei remaining after a given time, $\mathcal{N}_t$ (1056):

$$\ln\frac{\mathcal{N}_0}{\mathcal{N}_t} = kt$$

24.5 Finding the half-life of a radioactive nuclide (1056):

$$t_{1/2} = \frac{\ln 2}{k}$$

24.6 Calculating the time to reach a given specific activity (age of an object in radioisotopic dating) (1058):

$$t = \frac{1}{k}\ln\frac{\mathcal{A}_0}{\mathcal{A}_t}$$

24.7 Using Einstein's equation and the mass defect to calculate the nuclear binding energy (1070):

$$\Delta E = \Delta mc^2$$

24.8 Relating the atomic mass unit to its energy equivalent in MeV (1071):

$$1\ \text{amu} = 931.5\times10^6\ \text{eV} = 931.5\ \text{MeV}$$

Highlighted Figures and Tables

These figures (F) and tables (T) provide a review of key ideas.

T24.1 Chemical vs. nuclear reactions (1045)
F24.1 Radioactive emissions in an electric field (1047)
T24.2 Modes of radioactive decay (1048)
F24.2 *N* vs. *Z* for the stable nuclides (1051)
F24.4 Decrease in number of ^{14}C nuclei over time (1056)
F24.13 The variation in binding energy per nucleon (1073)

Brief Solutions to Follow-up Problems

24.1 $^{133}_{54}\text{Xe} \longrightarrow {}^{133}_{55}\text{Cs} + {}^{0}_{-1}\beta$

24.2 Phosphorus-31 has a slightly higher *N*/*Z* ratio and an even *N* (16).

24.3 (a) *N*/*Z* = 1.35; too high for this region of band: β decay
(b) Mass too high for stability: α decay

24.4
$$\ln\mathcal{A}_t = -kt + \ln\mathcal{A}_0$$
$$= -\left(\frac{\ln 2}{15\ \text{h}}\times 4.0\ \text{days}\times\frac{24\ \text{h}}{1\ \text{day}}\right) + \ln(2.5\times10^9)$$
$$= 17.20$$
$$\mathcal{A}_t = 3.0\times10^7\ \text{d/s}$$

24.5
$$t = \frac{1}{k}\ln\frac{\mathcal{A}_0}{\mathcal{A}_t} = \frac{5730\ \text{yr}}{\ln 2}\ln\left(\frac{15.3\ \text{d/min·g}}{9.41\ \text{d/min·g}}\right) = 4.02\times10^3\ \text{yr}$$

The mummy case is about 4000 years old.

24.6 ^{235}U has 92 $^{1}_{1}$p and 143 $^{1}_{0}$n.

$$\Delta m = [(92\times 1.007825\ \text{amu}) + (143\times 1.008665\ \text{amu})] - 235.043924\ \text{amu} = 1.9151\ \text{amu}$$

$$\frac{\text{Binding energy}}{\text{nucleon}} = \frac{1.9151\ \text{amu}\times\dfrac{931.5\ \text{MeV}}{1\ \text{amu}}}{235\ \text{nucleons}} = 7.591\ \text{MeV/nucleon}$$

Therefore, ^{235}U is less stable than ^{12}C.

Problems

Problems with colored numbers are answered in Appendix E. Sections match the text and provide the numbers of relevant sample problems. Most offer Concept Review Questions, Skill-Building Exercises (grouped in pairs covering the same concept), and Problems in Context. Comprehensive Problems are based on material from any section or previous chapter.

Radioactive Decay and Nuclear Stability

(Sample Problems 24.1 to 24.3)

Concept Review Questions

24.1 How do chemical and nuclear reactions differ in
(a) Magnitude of the energy change?
(b) Effect on rate of increasing temperature?
(c) Effect on rate of higher reactant concentration?
(d) Effect on yield of higher reactant concentration?

24.2 Sulfur has four naturally occurring isotopes. The one with the lowest mass number is sulfur-32, which is also the most abundant (95.02%).
(a) What percentage of the S atoms in a matchhead are ^{32}S?
(b) The isotopic mass of ^{32}S is 31.972070 amu. Is the atomic mass of S larger, smaller, or equal to this mass? Explain.

24.3 What led Marie Curie to draw the following conclusions?
(a) Radioactivity is a property of the element and not the compound in which it is found.
(b) A highly radioactive element, aside from uranium, occurs in pitchblende.

24.4 Which of the following types of radioactive decay produce an atom of a *different* element: (a) alpha; (b) beta; (c) gamma; (d) positron; (e) electron capture? Show how Z and N change, if at all, with each type.

24.5 Why is $^{3}_{2}He$ stable but $^{2}_{2}He$ so unstable that it has never been detected?

24.6 How do the modes of decay differ for a neutron-rich nuclide and a proton-rich nuclide?

24.7 Why can't you use the position of a nuclide's N/Z ratio relative to the band of stability to predict whether it is more likely to decay by positron emission or by electron capture?

Skill-Building Exercises *(grouped in similar pairs)*

24.8 Write balanced nuclear equations for the following:
(a) Alpha decay of $^{234}_{92}U$
(b) Electron capture by neptunium-232
(c) Positron emission by $^{12}_{7}N$

24.9 Write balanced nuclear equations for the following:
(a) Beta decay of sodium-26
(b) Beta decay of francium-223
(c) Alpha decay of $^{212}_{83}Bi$

24.10 Write balanced nuclear equations for the following:
(a) Beta emission by magnesium-27
(b) Neutron emission by $^{9}_{3}Li$
(c) Electron capture by $^{103}_{46}Pd$

24.11 Write balanced nuclear equations for the following:
(a) Simultaneous β and neutron emission by helium-8
(b) Alpha decay of polonium-218
(c) Electron capture by $^{110}_{49}In$

24.12 Write balanced nuclear equations for the following:
(a) Formation of $^{48}_{22}Ti$ through positron emission
(b) Formation of silver-107 through electron capture
(c) Formation of polonium-206 through α decay

24.13 Write balanced nuclear equations for the following:
(a) Production of $^{241}_{95}Am$ through β decay
(b) Formation of $^{228}_{89}Ac$ through β decay
(c) Formation of $^{203}_{83}Bi$ through α decay

24.14 Write balanced nuclear equations for the following:
(a) Formation of ^{186}Ir through electron capture
(b) Formation of francium-221 through α decay
(c) Formation of iodine-129 through β decay

24.15 Write balanced nuclear equations for the following:
(a) Formation of ^{52}Mn through positron emission
(b) Formation of polonium-215 through α decay
(c) Formation of ^{81}Kr through electron capture

24.16 Which nuclide(s) would you predict to be stable? Why?
(a) $^{20}_{8}O$ (b) $^{59}_{27}Co$ (c) $^{9}_{3}Li$

24.17 Which nuclide(s) would you predict to be stable? Why?
(a) $^{146}_{60}Nd$ (b) $^{114}_{48}Cd$ (c) $^{88}_{42}Mo$

24.18 Which nuclide(s) would you predict to be stable? Why?
(a) ^{127}I (b) tin-106 (c) ^{68}As

24.19 Which nuclide(s) would you predict to be stable? Why?
(a) ^{48}K (b) ^{79}Br (c) argon-32

24.20 What is the most likely mode of decay for each?
(a) $^{238}_{92}U$ (b) $^{48}_{24}Cr$ (c) $^{50}_{25}Mn$

24.21 What is the most likely mode of decay for each?
(a) $^{61}_{26}Fe$ (b) $^{41}_{17}Cl$ (c) $^{110}_{44}Ru$

24.22 What is the most likely mode of decay for each?
(a) ^{15}C (b) ^{120}Xe (c) ^{224}Th

24.23 What is the most likely mode of decay for each?
(a) ^{234}Th (b) ^{141}Eu (c) ^{241}Am

24.24 Why is $^{52}_{24}Cr$ the most stable isotope of chromium?

24.25 Why is $^{40}_{20}Ca$ the most stable isotope of calcium?

Problems in Context

24.26 Neptunium-237 is the parent nuclide of a decay series that starts with α emission, followed by β emission, and then two more α emissions. Write a balanced nuclear equation for each step.

24.27 Why is helium found in deposits of uranium and thorium ores? What kind of radioactive emission produces it?

24.28 In the natural decay series that starts with uranium-235, a sequence of α and β emissions ends with lead-207. How many α and β particles are emitted per atom of uranium-235 to result in an atom of lead-207?

The Kinetics of Radioactive Decay

(Sample Problems 24.4 and 24.5)

Concept Review Questions

24.29 What electronic process is the basis for detecting radioactivity in (a) a scintillation counter; (b) a Geiger-Müller counter?

24.30 What is the reaction order of radioactive decay? Explain.

24.31 After 1 minute, half the radioactive nuclei remain from an original sample of six nuclei. Is it valid to conclude that $t_{1/2}$ equals 1 minute? Would this conclusion be valid if the original sample contained 6×10^{12} nuclei? Explain.

24.32 Radioisotopic dating depends on the constant rate of decay and formation of various nuclides in a sample. How is the proportion of ^{14}C kept relatively constant in living organisms?

Skill-Building Exercises *(grouped in similar pairs)*

24.33 What is the specific activity (in Ci/g) if 1.55 mg of an isotope emits 1.66×10^{6} α particles per second?

24.34 What is the specific activity (in Ci/g) if 2.6 g of an isotope emits 4.13×10^{8} β particles per hour?

24.35 What is the specific activity (in Bq/g) if 8.58 μg of an isotope emits 7.4×10^{4} α particles per minute?

24.36 What is the specific activity (in Bq/g) if 1.07 kg of an isotope emits 3.77×10^{7} β particles per minute?

24.37 If one-trillionth of the atoms of a radioactive isotope disintegrate each hour, what is the decay constant of the process?

24.38 If 2.8×10^{-10}% of the atoms of a radioactive isotope disintegrate in 1.0 yr, what is the decay constant of the process?

24.39 If 1.00×10^{-12} mol of ^{135}Cs emits 1.39×10^{5} β particles in 1.00 yr, what is the decay constant?

24.40 If 6.40×10^{-9} mol of ^{176}W emits 1.07×10^{15} positrons in 1.00 h, what is the decay constant?

24.41 The isotope $^{212}_{83}Bi$ has a half-life of 1.01 yr. What mass (in mg) of a 2.00-mg sample will not decay after 3.75×10^{3} h?

24.42 The half-life of radium-226 is 1.60×10^{3} yr. How many hours will it take for a 2.50-g sample to decay to the point where 0.185 g of the isotope remains?

24.43 A rock contains 270 μmol of ^{238}U ($t_{1/2} = 4.5\times10^{9}$ yr) and 110 μmol of ^{206}Pb. Assuming that all the ^{206}Pb comes from decay of the ^{238}U, estimate the rock's age.

24.44 A fabric remnant from a burial site has a ^{14}C:^{12}C ratio of 0.735 of the original value. How old is the fabric?

Problems in Context

24.45 Due to decay of ^{40}K, cow's milk has a specific activity of about 6×10^{-11} mCi per milliliter. How many disintegrations of ^{40}K nuclei are there per minute in 1.0 qt of milk?

24.46 Plutonium-239 ($t_{1/2} = 2.41\times10^{4}$ yr) represents a serious nuclear waste disposal problem. If seven half-lives are required to reach a tolerable level of radioactivity, how long must ^{239}Pu be stored?

24.47 A rock that contains 2.1×10^{-15} mol of ^{232}Th ($t_{1/2} = 1.4\times10^{10}$ yr) has 9.5×10^{4} fission tracks, each representing the fission of one atom of ^{232}Th. How old is the rock?

24.48 A volcanic eruption melts a large area of rock, and all gases are expelled. After cooling, $^{40}_{18}Ar$ accumulates from the ongoing decay of $^{40}_{19}K$ in the rock ($t_{1/2} = 1.25\times10^{9}$ yr). When a piece of rock is analyzed, it is found to contain 1.38 mmol of ^{40}K and 1.14 mmol of ^{40}Ar. How long ago did the rock cool?

Nuclear Transmutation: Induced Changes in Nuclei

Concept Review Questions

24.49 Irene and Frederic Joliot-Curie converted $^{27}_{13}Al$ to $^{30}_{15}P$ in 1933. Why was this transmutation significant?

24.50 Early workers mistakenly thought neutron beams were γ radiation. Why were they misled? What evidence led to the correct conclusion?

24.51 Why must the electrical polarity of the tubes in a linear accelerator be reversed at very short time intervals?

24.52 Why does bombardment with protons usually require higher energies than bombardment with neutrons?

Skill-Building Exercises *(grouped in similar pairs)*

24.53 Determine the missing species in these transmutations, and write a full nuclear equation from the shorthand notation:
(a) ^{10}B (α,n) __
(b) ^{28}Si (d,__) ^{29}P (the deuteron, d, is ^{2}H)
(c) __ (α,2n) ^{244}Cf

24.54 Determine the missing species in these transmutations, and express each process in shorthand notation:
(a) Bombardment of a nuclide with a γ photon yields a proton, a neutron, and ^{29}Si.
(b) Bombardment of ^{252}Cf with ^{10}B yields five neutrons and a nuclide.
(c) Bombardment of ^{238}U with a particle yields three neutrons and ^{239}Pu.

Problem in Context

24.55 Names for elements 104, 105, and 106 have been approved as rutherfordium (Rf), dubnium (Db), and seaborgium (Sg), respectively. These elements are synthesized from californium-249 by bombarding with carbon-12, nitrogen-15, and oxygen-18 nuclei, respectively. Four neutrons are formed in each reaction as well. (a) Write balanced nuclear equations for the formation of these elements. (b) Write the equations in shorthand notation.

The Effects of Nuclear Radiation on Matter

Concept Review Questions

24.56 Gamma radiation and UV radiation cause different processes in matter. What are they and how do they differ?

24.57 What is a cation-electron pair, and how does it form?

24.58 Why is ionizing radiation more dangerous to children than to adults?

24.59 Why is ·OH more dangerous in an organism than OH^{-}?

Skill-Building Exercises *(grouped in similar pairs)*

24.60 A 135-lb person absorbs 3.3×10^{-7} J of energy from radioactive emissions. (a) How many rads does she receive? (b) How many grays (Gy) does she receive?

24.61 A 3.6-kg laboratory animal receives a single dose of 8.92×10^{-4} Gy. (a) How many rads did the animal receive? (b) How many joules did the animal absorb?

24.62 A 70.-kg person exposed to ^{90}Sr absorbs 6.0×10^{5} β particles, each with an energy of 8.74×10^{-14} J. (a) How many grays does the person receive? (b) If the RBE is 1.0, how many millirems is this? (c) What is the equivalent dose in sieverts (Sv)?

24.63 A laboratory rat weighs 265 g and absorbs 1.77×10^{10} β particles, each with an energy of 2.20×10^{-13} J. (a) How many rads does the animal receive? (b) What is this dose in Gy? (c) If the RBE is 0.75, what is the equivalent dose in Sv?

Problems in Context

24.64 If 2.50 pCi [1 pCi (picocurie) = 1×10^{-12} Ci] of radioactivity from ^{239}Pu is emitted in a 95-kg human for 65 h, and each disintegration has an energy of 8.25×10^{-13} J, how many grays does the person receive?

24.65 A small region of a cancer patient's brain is exposed for 27.0 min to 475 Bq of radioactivity from ^{60}Co for treatment of a tumor. If the brain mass exposed is 1.588 g and each β particle emitted has an energy of 5.05×10^{-14} J, what is the dose in rads?

Applications of Radioisotopes

Concept Review Questions

24.66 Describe two ways that radioactive tracers are used in organisms.

24.67 Why is neutron activation analysis (NAA) useful to art historians and criminologists?

24.68 Positrons cannot penetrate matter more than a few atomic diameters, but positron emission of radiotracers can be monitored in medical diagnosis. Explain.

24.69 A steel part is treated to form some iron-59. Oil used to lubricate the part emits 298 β particles (with the energy characteristic of ^{59}Fe) per minute per milliliter of oil. What other information would you need to calculate the rate of removal of the steel from the part during use?

Problem in Context

24.70 The oxidation of methanol to formaldehyde can be accomplished by reaction with chromic acid:

$$6H^+(aq) + 3CH_3OH(aq) + 2H_2CrO_4(aq) \longrightarrow 3CH_2O(aq) + 2Cr^{3+}(aq) + 8H_2O(l)$$

The reaction can be studied with the stable isotope tracer ^{18}O and mass spectrometry. When a small amount of $CH_3{}^{18}OH$ is present in the alcohol reactant, $H_2C^{18}O$ forms. When a small amount of $H_2Cr^{18}O_4$ is present, $H_2{}^{18}O$ forms. Does chromic acid or methanol supply the O atom to the aldehyde? Explain.

The Interconversion of Mass and Energy

(Sample Problem 24.6)

Note: Use the following data to solve the problems in this section: mass of ^{1}H atom = 1.007825 amu; mass of neutron = 1.008665 amu.

Concept Review Questions

24.71 Many scientists at first reacted skeptically to Einstein's equation, $E = mc^2$. Why?

24.72 What is a mass defect, and how does it arise?

24.73 When a nuclide forms from nucleons, is energy absorbed or released? Why?

24.74 What is the binding energy per nucleon? Why is the binding energy per nucleon, rather than per nuclide, used to compare nuclide stability?

Skill-Building Exercises *(grouped in similar pairs)*

24.75 A ^{3}H nucleus decays with an energy of 0.01861 MeV. Convert this energy into (a) electron volts; (b) joules.

24.76 Arsenic-84 decays with an energy of 1.57×10^{-15} kJ per nucleus. Convert this energy into (a) eV; (b) MeV.

24.77 How many joules are released when 1.0 mol of ^{239}Pu decays, if each nucleus releases 5.243 MeV?

24.78 How many MeV are released per nucleus when 3.2×10^{-3} mol of chromium-49 releases 8.11×10^5 kJ?

24.79 Oxygen-16 is one of the most stable nuclides. The mass of a ^{16}O atom is 15.994915 amu. Calculate the binding energy (a) per nucleon in MeV; (b) per atom in MeV; (c) per mole in kJ.

24.80 Lead-206 is the end product of ^{238}U decay. One ^{206}Pb atom has a mass of 205.974440 amu. Calculate the binding energy (a) per nucleon in MeV; (b) per atom in MeV; (c) per mole in kJ.

24.81 Cobalt-59 is the only stable isotope of this transition metal. One ^{59}Co atom has a mass of 58.933198 amu. Calculate the binding energy (a) per nucleon in MeV; (b) per atom in MeV; (c) per mole in kJ.

24.82 Iodine-131 is one of the most important isotopes used in the diagnosis of thyroid cancer. One atom has a mass of 130.906114 amu. Calculate the binding energy (a) per nucleon in MeV; (b) per atom in MeV; (c) per mole in kJ.

Problem in Context

24.83 The ^{80}Br nuclide decays either by β decay or by electron capture. (a) What is the product of each process? (b) Which process releases more energy? (Masses of atoms: ^{80}Br = 79.918528 amu; ^{80}Kr = 79.916380 amu; ^{80}Se = 79.916520 amu; neglect the mass of the electron involved.)

Applications of Fission and Fusion

Concept Review Questions

24.84 What is the minimum number of neutrons from each fission event that must be absorbed by other nuclei for a chain reaction to occur?

24.85 In what main way is fission different from radioactive decay? Are all fission events in a chain reaction identical? Explain.

24.86 What is the purpose of enrichment in the preparation of fuel rods? How is it accomplished?

24.87 Describe the nature and purpose of these components of a nuclear reactor: (a) control rods; (b) moderator; (c) reflector.

24.88 State an advantage and a disadvantage of heavy-water reactors compared to light-water reactors.

24.89 What are the expected advantages of fusion reactors over fission reactors?

24.90 Why is there more iron in Earth than any other element?

24.91 Why do so many nuclides have isotopic masses close to multiples of 4 amu?

24.92 What is the cosmic importance of unstable ^{8}Be?

Problem in Context

24.93 The reaction that will probably power the first commercial fusion reactor is

$$^3_1H + {}^2_1H \longrightarrow {}^4_2He + {}^1_0n$$

How much energy would be produced per mole of reaction? (Masses of atoms: $^3_1$H = 3.01605 amu; $^2_1$H = 2.0140 amu; $^4_2$He = 4.00260 amu; mass of $^1_0$n = 1.008665 amu.)

Comprehensive Problems

24.94 Some $^{243}_{95}$Am was present when Earth formed, but it all decayed in the next billion years. The first three steps in this decay series are emission of an α particle, a β particle, and another α particle. What other isotopes were present on the young Earth in a rock that contained some $^{243}_{95}$Am?

24.95 Curium-243 undergoes α decay to plutonium-239:

$$^{243}Cm \longrightarrow {}^{239}Pu + {}^4He$$

(a) Calculate the change in mass, Δm (in kg). (Masses: ^{243}Cm = 243.0614 amu; ^{239}Pu = 239.0522 amu; ^{4}He = 4.0026 amu; 1 amu = 1.661×10^{-24} g.)

(b) Calculate the energy released in joules.

(c) Calculate the energy released in kJ/mol of reaction, and comment on the difference between this value and a typical heat of reaction for a chemical change of a few hundred kJ/mol.

24.96 Plutonium "triggers" for nuclear weapons were manufactured at the Rocky Flats plant in Colorado. An 85-kg worker inhaled a dust particle containing 1.00 μg of $^{239}_{94}$Pu, which

resided in his body for 16 h ($t_{1/2}$ of $^{239}Pu = 2.41\times10^4$ yr; each disintegration released 5.15 MeV). (a) How many rads did he receive? (b) How many grays?

24.97 Archeologists removed some charcoal from a Native American campfire, burned it in O_2, and bubbled the CO_2 formed into $Ca(OH)_2$ solution (limewater). The $CaCO_3$ that precipitated was filtered and dried. If 4.38 g of the $CaCO_3$ had a radioactivity of 3.2 d/min, how long ago was the campfire?

24.98 A 5.4-μg sample of $^{226}RaCl_2$ has a radioactivity of 1.5×10^5 Bq. Calculate $t_{1/2}$ of ^{226}Ra.

24.99 How many rads does a 65-kg human receive each year from the approximately 10^{-8} g of $^{14}_6C$ naturally present in her body ($t_{1/2}$ = 5730 yr; each disintegration releases 0.156 MeV)?

24.100 The major reaction taking place during hydrogen burning in a young star is

$$4\,{}^1_1H \longrightarrow {}^4_2He + 2\,{}^0_1\beta + 2\,{}^0_0\gamma + \text{energy}$$

How much energy (in MeV) is released per He nucleus formed? Per mole of He? (Masses: ^1_1H atom = 1.007825 amu; ^4_2He atom = 4.00260 amu; positron = 5.48580×10^{-4} amu.)

24.101 A sample of AgCl emits 175 nCi/g. A saturated solution prepared from the solid emits 1.25×10^{-2} Bq/mL due to radioactive Ag^+ ions. What is the molar solubility of AgCl?

24.102 Due to burning of fossil fuels, the proportion of CO_2 in our atmosphere continues to increase. Moreover, as a result of nuclear explosions and similar events, the CO_2 also contains more ^{14}C. How will these factors affect the efforts of future archeologists to determine ages of our artifacts by radiocarbon dating?

24.103 What fraction of the ^{235}U ($t_{1/2} = 7.0\times10^8$ yr) created when Earth was formed would remain after 2.8×10^9 yr?

24.104 In the event of a nuclear accident, radiation officers must obtain many pieces of data to decide on appropriate action.

(a) If a person ingests radioactive material, which of the following is the *most* important quantity in deciding whether a serious medical emergency has occurred?

(1) The number of rems he receives
(2) The number of curies he absorbs
(3) The length of time he is exposed to the radiation
(4) The number of moles of radioisotopes he ingests
(5) The energy emitted per disintegration by the radioisotopes

(b) If the drinking water in a town becomes contaminated with radioactive material, what is the *most* important factor in deciding whether drastic and expensive action is warranted?

(1) The radioactivity per volume, Ci/m^3
(2) How long the water supply has been contaminated
(3) (Ci/m^3) × energy per disintegration
(4) The type of radiation emitted
(5) The radioisotopes involved

24.105 Cosmologists modeling the origin of the elements postulate nuclides with very short half-lives.

(a) One of these nuclides, ^8Be ($t_{1/2} = 7\times10^{-17}$ s), plays a key role in stellar nucleogenesis (p. 1078) because it must fuse with a ^4He to form ^{12}C before decaying. Another explanation involves the simultaneous fusion of three ^4He nuclei to form ^{12}C. Comment on the validity of this alternative mechanism.

(b) Another question involves the instability of the two nuclides with $A = 5$, ^5He and ^5Li, each of which has a $t_{1/2}$ nearly 10^{-5} times that of ^8Be. Write nuclear equations for the α decay of ^8Be, ^5He, and ^5Li.

24.106 Technetium-99m is a metastable nuclide used in numerous cancer diagnostic and treatment programs. It is prepared just before use because it decays rapidly through γ emission:

$$^{99m}Tc \longrightarrow {}^{99}Tc + \gamma$$

Use the data below to determine:

(a) The half-life of ^{99m}Tc

(b) The percentage of the isotope that is lost if it takes 2.0 h to prepare and administer the dose

Time (h)	γ Emission (photons/s)
0	5000.
4	3150.
8	2000.
12	1250.
16	788
20	495

24.107 How many curies are produced by 1.0 mol of ^{40}K ($t_{1/2} = 1.25\times10^9$ yr)? How many becquerels?

24.108 The fraction of a radioactive isotope remaining at time t is $(\frac{1}{2})^{t/t_{1/2}}$, where $t_{1/2}$ is the half-life. If the half-life of carbon-14 is 5730 yr, what fraction of carbon-14 in a piece of charcoal remains after (a) 10.0 yr; (b) 10.0×10^3 yr; (c) 10.0×10^4 yr? (d) Why is radiocarbon dating more reliable for the fraction remaining in part (b) than that in part (a) or in part (c)?

24.109 The isotopic mass of $^{210}_{86}Rn$ is 209.989669 amu. When this nuclide decays by electron capture, it emits 2.368 MeV. What is the isotopic mass of the resulting nuclide?

24.110 Exactly 0.1 of the radioactive nuclei in a sample decay each hour. Thus, after n hours, the fraction of nuclei remaining is $(0.900)^n$. Find the value of n equal to one half-life.

24.111 In neutron activation analysis (NAA), stable isotopes are bombarded with neutrons. Depending on the isotope and the energy of the neutron, various emissions are observed. What are the products when the following neutron-activated species decay? Write an overall equation in shorthand notation for the reaction starting with the stable isotope before neutron activation.

(a) $^{52}_{23}V^* \longrightarrow$ [β emission]
(b) $^{64}_{29}Cu^* \longrightarrow$ [positron emission]
(c) $^{28}_{13}Al^* \longrightarrow$ [β emission]

24.112 In the 1950s, radioactive material was spread over the land from above-ground nuclear tests. A woman drinks some contaminated milk and ingests 0.0500 g of ^{90}Sr, which is taken up by bones and teeth and not eliminated. (a) How much ^{90}Sr ($t_{1/2}$ = 29 yr) is present in her body after 10 yr? (b) How long will it take for 99.9% of the ^{90}Sr to decay?

24.113 Isotopic abundances are relatively constant throughout Earth's crust. Could the science of chemistry have developed if, for example, one sample of tin(II) oxide contained mostly ^{112}Sn and another mostly ^{124}Sn? Explain.

24.114 What volume of radon will be produced per hour at STP from 1.000 g of ^{226}Ra ($t_{1/2}$ = 1599 yr; 1 yr = 8766 h; mass of one ^{226}Ra atom = 226.025402 amu)?

24.115 A sample of ^{90}Kr ($t_{1/2}$ = 32 s) is to be used in a study of a patient's respiration. How soon after being made must it be administered to the patient if the activity must be at least 90% of the original activity?

24.116 Which isotope in each pair would you predict to be more stable? Why?
(a) $^{140}_{55}Cs$ or $^{133}_{55}Cs$ (b) $^{79}_{35}Br$ or $^{78}_{35}Br$
(c) $^{28}_{12}Mg$ or $^{24}_{12}Mg$ (d) $^{14}_{7}N$ or $^{18}_{7}N$

24.117 A sample of bone contains enough strontium-90 ($t_{1/2}$ = 29 yr) to emit 8.0×10^4 β particles per month. How long will it take for the emission to decrease to 1.0×10^4 particles per month?

24.118 The 23rd-century starship *Enterprise* uses a substance called "dilithium crystals" as its fuel.
(a) Assuming this material is the result of fusion, what is the product of the fusion of two ^{6}Li nuclei?
(b) How much energy is released per kilogram of dilithium formed? (Mass of one ^{6}Li atom is 6.015121 amu.)
(c) When four ^{1}H atoms fuse to form ^{4}He, how many positrons are released?
(d) To determine the energy potential of the fusion processes in parts (b) and (c), compare the changes in mass per kilogram of dilithium and of ^{4}He.
(e) Compare the change in mass per kilogram in part (b) to that for the formation of ^{4}He by the method used in current fusion reactors (Section 24.7). (For masses, see Problem 24.93.)
(f) Using early 21st-century fusion technology, how much tritium can be produced per kilogram of ^{6}Li in the following reaction: $^{6}_{3}Li + {}^{1}_{0}n \longrightarrow {}^{4}_{2}He + {}^{3}_{1}H$? When this amount of tritium is fused with deuterium, what is the change in mass? How does this quantity compare with the use of dilithium in part (b)?

24.119 Uranium and radium are found in many rocky soils throughout the world. Both undergo radioactive decay, and one of the products is radon-222, the heaviest noble gas ($t_{1/2}$ = 3.82 days). Inhalation of indoor air containing this gas contributes to many lung cancers. According to Environmental Protection Agency recommendations, the level of radioactivity from radon in homes should not exceed 4.0 pCi/L of air.
(a) What is the safe level of radon in Bq/L of air?
(b) A home has a radon measurement of 43.5 pCi/L. The owner vents the basement in such a way that no more radon enters the living area. What is the activity of the radon remaining in the room air (in Bq/L) after 8.5 days?
(c) How many more days does it take to reach the EPA recommended level?

24.120 Nuclear disarmament could be accomplished if weapons were not "replenished." The tritium in warheads decays to helium with a half-life of 12.26 yr and must be replaced or the weapon is useless. What fraction of the tritium is lost in 5.50 yr?

24.121 A decay series starts with the synthetic isotope $^{239}_{92}U$. The first four steps are emissions of a β particle, another β, an α particle, and another α. Write a balanced nuclear equation for each step. Which natural series could be started by this sequence?

24.122 How long can a 48-lb child be exposed to 1.0 mCi of radiation from ^{222}Rn before accumulating 1.0 mrad if the energy of each disintegration is 5.59 MeV?

24.123 The approximate date of a San Francisco earthquake is to be found by measuring the ^{14}C activity ($t_{1/2}$ = 5730 yr) of parts of a tree uprooted during the event. The tree parts have an activity of 12.9 d/min·g C, and a living tree has an activity of 15.3 d/min·g C. How long ago did the earthquake occur?

24.124 Were organisms a billion years ago exposed to more or less ionizing radiation than similar organisms today? Explain.

24.125 Tritium (^{3}H; $t_{1/2}$ = 12.26 yr) is continually formed in the upper troposphere by interaction of solar particles with nitrogen. As a result, natural waters contain a small amount of tritium. Two samples of wine are analyzed, one known to be made in 1941 and another made earlier. The water in the 1941 wine has 2.32 times as much tritium as the water in the other. When was the other wine produced?

24.126 Plutonium-239 ($t_{1/2} = 2.41\times10^4$ yr) is a serious radiation hazard present in spent uranium fuel from nuclear power plants. How many years does it take for 99% of the plutonium-239 in spent fuel to decay?

24.127 Carbon from the most recent remains of an extinct Australian marsupial, called *Diprotodon,* has a specific activity of 0.61 pCi/g. Modern carbon has a specific activity of 6.89 pCi/g. How long ago did the *Diprotodon* apparently become extinct?

24.128 The reaction that allows for radiocarbon dating is the continual formation of carbon-14 in the upper atmosphere:

$$^{14}_{7}N + {}^{1}_{0}n \longrightarrow {}^{14}_{6}C + {}^{1}_{1}H$$

What is the energy change associated with this process in eV/reaction and in kJ/mol reaction? (Masses of atoms: $^{14}_{7}N$ = 14.003074 amu; $^{14}_{6}C$ = 14.003241 amu; $^{1}_{1}H$ = 1.007825 amu; mass of $^{1}_{0}n$ = 1.008665 amu.)

24.129 What is the nuclear binding energy of a lithium-7 nucleus in units of kJ/mol and eV/nucleus? (Mass of a lithium-7 atom = 7.016003 amu.)

24.130 Suggest a reason the critical mass of a fissionable substance depends on its shape.

24.131 Using early 21st-century technology, hydrogen fusion requires temperatures around 10^8 K, but lower temperatures can be used if the hydrogen is compressed. In the late 24th century, the starship *Leinad* uses such methods to fuse hydrogen at 10^6 K.
(a) What is the kinetic energy of an H atom at 1.00×10^6 K?
(b) How many H atoms are heated to 1.00×10^6 K from the energy of one H and one anti-H atom annihilating each other?
(c) If these H atoms fuse into ^{4}He atoms (with the loss of two positrons per ^{4}He formed), how much energy (in J) is generated?
(d) How much more energy is generated by the fusion in (c) than by the hydrogen-antihydrogen collision in (b)?
(e) Should the captain of the *Leinad* change the technology and produce ^{3}He (mass = 3.01603 amu) instead of ^{4}He?

24.132 A metastable (excited) form of ^{50}Sc changes to its stable form by emitting γ radiation with a wavelength of 8.73 pm. What is the change in mass of 1 mol of the isotope when it undergoes this change?

24.133 A sample of cobalt-60 ($t_{1/2}$ = 5.27 yr), a powerful γ emitter used to treat cancer, was purchased by a hospital on March 1, 2005. The sample must be replaced when its activity reaches 70.% of the original value. On what date must it be replaced?

24.134 Uranium-233 decays to thorium-229 by α decay, but the emissions have different energies and products: 83% emit an α particle with energy 4.816 MeV and give ^{229}Th in its ground state; 15% emit an α particle of 4.773 MeV and give ^{229}Th in excited state I; and 2% emit a lower energy α particle and give ^{229}Th in the higher excited state II. Excited state II emits a γ ray of 0.060 MeV to reach excited state I. (a) Find the γ-ray energy and wavelength that would convert excited state I to the ground state. (b) Find the energy of the α particle that would convert ^{233}U to excited state II.

24.135 Uranium-238 undergoes a slow decay step ($t_{1/2} = 4.5\times10^9$ yr) followed by a series of fast steps to form the stable isotope ^{206}Pb. Thus, on a time scale of billions of years, ^{238}U effectively decays "directly" to ^{206}Pb, and the relative amounts of these isotopes are used to find the age of some rocks (see margin note, p. 1059). Two students derive equations relating number of half-lives (n) since the rock formed to the amounts of the isotopes:

Student 1: $(\frac{1}{2})^n = \dfrac{^{238}_{92}\text{U}}{^{206}_{82}\text{Pb}}$

Student 2: $(\frac{1}{2})^n = \dfrac{^{238}_{92}\text{U}}{^{238}_{92}\text{U} + ^{206}_{82}\text{Pb}}$

(a) Which equation is correct, and why?

(b) If a rock contains exactly twice as much ^{238}U as ^{206}Pb, what is its age in years?

24.136 In the naturally occurring thorium-232 decay series, the steps emit this sequence of particles: α, β, β, α, α, α, α, β, β, and α. Write a balanced equation for each step.

24.137 At death, a nobleman in ancient Egypt was mummified and his body contained 1.4×10^{-3} g of ^{40}K ($t_{1/2} = 1.25\times10^9$ yr), 1.2×10^{-8} g of ^{14}C ($t_{1/2} = 5730$ yr), and 4.8×10^{-14} g of ^{3}H ($t_{1/2} = 12.26$ yr). Which isotope would give the most accurate estimate of the mummy's age? Explain.

24.138 Assuming that many radioactive isotopes can be considered safe after 20 half-lives, how long will it take for each of the following isotopes to be safe?

(a) ^{242}Cm ($t_{1/2} = 163$ days)

(b) ^{214}Po ($t_{1/2} = 1.6\times10^{-4}$ s)

(c) ^{232}Th ($t_{1/2} = 1.39\times10^{10}$ yr)

24.139 An ancient sword has a blade from the early Roman Empire, around 100 AD, but the wooden handle, inlaid wooden decorations, leather ribbon, and leather sheath have different styles. Given the following activities, estimate the age of each part. Which part was made near the time of the blade ($t_{1/2}$ of ^{14}C = 5730 yr; $\mathcal{A}_0 = 15.3$ d/min·g)?

Part	$\mathcal{A}_t$ (d/min·g)
Handle	10.1
Inlaid wood	13.8
Ribbon	12.1
Sheath	15.0

24.140 The starship *Voyager,* like many other vessels of the newly designed 24th-century fleet, uses antimatter as fuel.

(a) How much energy is released when 1.00 kg each of antimatter and matter annihilate each other?

(b) When the antimatter is atomic antihydrogen, a small amount of it is mixed with excess atomic hydrogen (gathered from interstellar space during flight). The annihilation releases so much heat that the remaining hydrogen nuclei fuse to form ^{4}He. If each hydrogen-antihydrogen collision releases enough heat to fuse 1.00×10^5 hydrogen atoms, how much energy (in kJ) is released per kilogram of antihydrogen?

(c) Which produces more energy per kilogram of antihydrogen, the procedure in part (a) or that in part (b)?

24.141 Use Einstein's equation, the mass in grams of 1 amu, and the relation between electron volts and joules to find the energy equivalent (in MeV) of a mass defect of 1 amu.

24.142 Determine the age of a rock containing 0.065 g of uranium-238 ($t_{1/2} = 4.5\times10^9$ yr) and 0.023 g of lead-206. (Assume all the lead-206 came from ^{238}U decay.)

24.143 Plutonium-242 decays to uranium-238 by emission of an α particle with an energy of 4.853 MeV. The ^{238}U that forms is unstable and emits a γ ray (λ = 0.02757 nm). (a) Write balanced equations for these reactions. (b) What would be the energy of the α particle if ^{242}Pu decayed directly to the more stable ^{238}U?

24.144 Seaborgium-263 (Sg; $Z = 106$) was the first isotope of this element synthesized. It was made, together with four neutrons, by bombarding californium-249 with oxygen-18. It then decayed by three α emissions. Write balanced equations for the synthesis and three decay steps of ^{263}Sg.

24.145 Some nuclear power plants use plutonium-239, which is produced in breeder reactors (see margin note, p. 1077). The rate-determining step is the second β emission. How long does it take to make 1.00 kg of ^{239}Pu if the reaction is complete when the product is 90.% ^{239}Pu?

24.146 A random-number generator can be used to simulate the probability of a given atom decaying over a given time. For example, the formula "=RAND()" in the Excel spreadsheet returns a random number between 0 and 1; thus, for one radioactive atom and a time of one half-life, a number less than 0.5 means the atom decays and a number greater than 0.5 means it doesn't.

(a) Place the "=RAND()" formula in cells A1 to A10 of an Excel spreadsheet. In cell B1, place "=IF(A1<0.5, 0, 1)." This formula returns 0 if A1 is <0.5 (the atom decays) and 1 if A1 is >0.5 (the atom does not decay). Place analogous formulas in cells B2 to B10 (using the "Fill Down" procedure in Excel). To determine the number of atoms remaining after one half-life, sum cells B1 to B10 by placing "=SUM(B1:B10)" in cell B12. To create a new set of random numbers, click on an empty cell (e.g., B13) and hit "Delete." Perform 10 simulations, each time recording the total number of atoms remaining. Do half of the atoms remain after each half-life? If not, why not?

(b) Increase the number of atoms to 100 by placing suitable formulas in cells A1 to A100, B1 to B100, and B102. Perform 10 simulations, and record the number of atoms remaining each time. Are these results more realistic for radioactive decay? Explain.

24.147 In the following Excel-based simulation, the fate of 256 atoms is followed over five half-lives. Set up formulas in columns A and B, as in Problem 24.146, and simulate the fate of the sample of 256 atoms over one half-life. Cells B1 to B256 should contain 1 or 0. In cell C1, enter "=IF(B1=0, 0, RAND())." This returns 0 if the original atom decayed in the previous half-life or a random number between 0 and 1 if it did not. Fill the formula in C1 down to cell C256. Column D should have formulas similar to those in B, but with modified references, as should columns F, H, and J. Columns E, G, and I should have formulas similar to those in C, but with modified references. In cell B258, enter "=SUM(B1:B256)." This records the number of atoms remaining after the first half-life. Put formulas in cells D258, F258, H258, and J258 to record atoms remaining after subsequent half-lives.

(a) Ideally, how many atoms should remain after each half-life?

(b) Make a table of the atoms remaining after each half-life in four separate simulations. Compare these outcomes to the ideal outcome. How would you make the results more realistic?

Appendix A

COMMON MATHEMATICAL OPERATIONS IN CHEMISTRY

In addition to basic arithmetic and algebra, four mathematical operations are used frequently in general chemistry: manipulating logarithms, using exponential notation, solving quadratic equations, and graphing data. Each is discussed briefly below.

MANIPULATING LOGARITHMS

Meaning and Properties of Logarithms

A *logarithm* is an exponent. Specifically, if $x^n = A$, we can say that the logarithm to the base x of the number A is n, and we can denote it as

$$\log_x A = n$$

Because logarithms are exponents, they have the following properties:

$$\log_x 1 = 0$$
$$\log_x (A \times B) = \log_x A + \log_x B$$
$$\log_x \frac{A}{B} = \log_x A - \log_x B$$
$$\log_x A^y = y \log_x A$$

Types of Logarithms

Common and natural logarithms are used frequently in chemistry and the other sciences. For *common* logarithms, the base (x in the examples above) is 10, but they are written without specifying the base; that is, $\log_{10} A$ is written more simply as $\log A$. The common logarithm of 1000 is 3; in other words, you must raise 10 to the 3rd power to obtain 1000:

$$\log 1000 = 3 \quad \text{or} \quad 10^3 = 1000$$

Similarly, we have

$$\log 10 = 1 \quad \text{or} \quad 10^1 = 10$$
$$\log 1{,}000{,}000 = 6 \quad \text{or} \quad 10^6 = 1{,}000{,}000$$
$$\log 0.001 = -3 \quad \text{or} \quad 10^{-3} = 0.001$$
$$\log 853 = 2.931 \quad \text{or} \quad 10^{2.931} = 853$$

The last example illustrates an important point about significant figures with all logarithms: the number of significant figures in the number equals the number of digits to the right of the decimal point in the logarithm. That is, the number 853 has three significant figures, and the logarithm 2.931 has three digits to the right of the decimal point.

To find a common logarithm with an electronic calculator, you simply enter the number and press the LOG button.

For *natural* logarithms, the base is the number e, which is 2.71828 . . . , and $\log_e A$ is written ln A. The relationship between the common and natural logarithms is easily obtained: because

$$\log 10 = 1 \quad \text{and} \quad \ln 10 = 2.303$$

Therefore, we have

$$\ln A = 2.303 \log A$$

To find a natural logarithm with an electronic calculator, you simply enter the number and press the LN button. If your calculator does not have an LN button, enter the number, press the LOG button, and multiply by 2.303.

Antilogarithms

The *antilogarithm* is the number you obtain when you raise the base to the logarithm:

$$\text{antilogarithm (antilog) of } n \text{ is } 10^n$$

Using two of the earlier examples, the antilog of 3 is 1000, and the antilog of 2.931 is 853. To obtain the antilog with a calculator, you enter the number and press the 10^x button. Similarly, to obtain the natural antilogarithm, you enter the number and press the e^x button. [On some calculators, you enter the number and first press INV and then the LOG (or LN) button.]

USING EXPONENTIAL (SCIENTIFIC) NOTATION

Many quantities in chemistry are very large or very small. For example, in the conventional way of writing numbers, the number of gold atoms in 1 gram of gold is

59,060,000,000,000,000,000,000 atoms (to four significant figures)

As another example, the mass in grams of one gold atom is

0.000000000000000000000003272 g (to four significant figures)

Exponential (scientific) notation provides a much more practical way of writing such numbers. In exponential notation, we express numbers in the form

$$A \times 10^n$$

where A (the coefficient) is greater than or equal to 1 and less than 10 (that is, $1 \leq A < 10$), and n (the exponent) is an integer.

If the number we want to express in exponential notation is larger than 1, the exponent is positive ($n > 0$); if the number is smaller than 1, the exponent is negative ($n < 0$). The size of n tells the number of places the decimal point (in conventional notation) must be moved to obtain a coefficient A greater than or equal to 1 and less than 10 (in exponential notation). In exponential notation, 1 gram of gold contains 5.906×10^{22} atoms, and each gold atom has a mass of 3.272×10^{-22} g.

Changing Between Conventional and Exponential Notation

In order to use exponential notation, you must be able to convert to it from conventional notation, and vice versa.

1. To change a number from conventional to exponential notation, move the decimal point to the left for numbers equal to or greater than 10 and to the right for numbers between 0 and 1:

   75,000,000 changes to 7.5×10^7 (decimal point 7 places to the left)

   0.006042 changes to 6.042×10^{-3} (decimal point 3 places to the right)

2. To change a number from exponential to conventional notation, move the decimal point the number of places indicated by the exponent to the right for numbers with positive exponents and to the left for numbers with negative exponents:

   1.38×10^5 changes to 138,000 (decimal point 5 places to the right)

   8.41×10^{-6} changes to 0.00000841 (decimal point 6 places to the left)

3. An exponential number with a coefficient greater than 10 or less than 1 can be changed to the standard exponential form by converting the coefficient to the standard form and adding the exponents:

$$582.3\times10^{6} \text{ changes to } 5.823 \times 10^{2} \times 10^{6} = 5.823\times10^{(2+6)} = 5.823\times10^{8}$$
$$0.0043\times10^{-4} \text{ changes to } 4.3 \times 10^{-3} \times 10^{-4} = 4.3\times10^{[(-3)+(-4)]} = 4.3\times10^{-7}$$

Using Exponential Notation in Calculations

In calculations, you can treat the coefficient and exponents separately and apply the properties of exponents (see earlier section on logarithms).

1. To multiply exponential numbers, multiply the coefficients, add the exponents, and reconstruct the number in standard exponential notation:

$$(5.5\times10^{3})(3.1\times10^{5}) = (5.5 \times 3.1)\times10^{(3+5)} = 17\times10^{8} = 1.7\times10^{9}$$
$$(9.7\times10^{14})(4.3\times10^{-20}) = (9.7 \times 4.3)\times10^{[14+(-20)]} = 42\times10^{-6} = 4.2\times10^{-5}$$

2. To divide exponential numbers, divide the coefficients, subtract the exponents, and reconstruct the number in standard exponential notation:

$$\frac{2.6\times10^{6}}{5.8\times10^{2}} = \frac{2.6}{5.8} \times 10^{(6-2)} = 0.45\times10^{4} = 4.5\times10^{3}$$
$$\frac{1.7\times10^{-5}}{8.2\times10^{-8}} = \frac{1.7}{8.2} \times 10^{[(-5)-(-8)]} = 0.21\times10^{3} = 2.1\times10^{2}$$

3. To add or subtract exponential numbers, change all numbers so that they have the same exponent, then add or subtract the coefficients:

$$(1.45\times10^{4}) + (3.2\times10^{3}) = (1.45\times10^{4}) + (0.32\times10^{4}) = 1.77\times10^{4}$$
$$(3.22\times10^{5}) - (9.02\times10^{4}) = (3.22\times10^{5}) - (0.902\times10^{5}) = 2.32\times10^{5}$$

SOLVING QUADRATIC EQUATIONS

A *quadratic equation* is one in which the highest power of x is 2. The general form of a quadratic equation is

$$ax^2 + bx + c = 0$$

where a, b, and c are numbers. For given values of a, b, and c, the values of x that satisfy the equation are called *solutions* of the equation. We calculate x with the quadratic formula:

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

We commonly require the quadratic formula when solving for some concentration in an equilibrium problem. For example, we might have an expression that is rearranged into the quadratic equation

$$4.3x^2 + 0.65x - 8.7 = 0$$

Applying the quadratic formula, with $a = 4.3$, $b = 0.65$, and $c = -8.7$, gives

$$x = \frac{-0.65 \pm \sqrt{(0.65)^2 - 4(4.3)(-8.7)}}{2(4.3)}$$

The "plus or minus" sign ($\pm$) indicates that there are always two possible values for x. In this case, they are

$$x = 1.3 \quad \text{and} \quad x = -1.5$$

In any real physical system, however, only one of the values will have any meaning. For example, if x were $[H_3O^+]$, the negative value would mean a negative concentration, which has no meaning.

GRAPHING DATA IN THE FORM OF A STRAIGHT LINE

Visualizing changes in variables by means of a graph is a very useful technique in science. In many cases, it is most useful if the data can be graphed in the form of a straight line. Any equation will appear as a straight line if it has, or can be rearranged to have, the following general form:

$$y = mx + b$$

where y is the dependent variable (typically plotted along the vertical axis), x is the independent variable (typically plotted along the horizontal axis), m is the slope of the line, and b is the intercept of the line on the y axis. The intercept is the value of y when $x = 0$:

$$y = m(0) + b = b$$

The slope of the line is the change in y for a given change in x:

$$\text{Slope } (m) = \frac{y_2 - y_1}{x_2 - x_1} = \frac{\Delta y}{\Delta x}$$

The *sign* of the slope tells the *direction* of the line. If y increases as x increases, m is positive, and the line slopes upward with higher values of x; if y decreases as x increases, m is negative, and the line slopes downward with higher values of x. The *magnitude* of the slope indicates the *steepness* of the line. A line with $m = 3$ is three times as steep (y changes three times as much for a given change in x) as a line with $m = 1$.

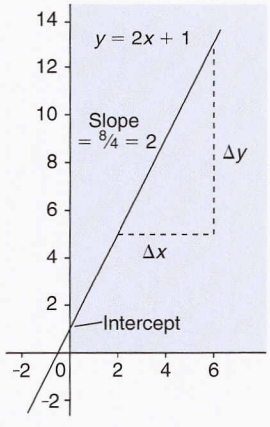

Figure A.1

Consider the linear equation $y = 2x + 1$. A graph of this equation is shown in Figure A.1. In practice, you can find the slope by drawing a right triangle to the line, using the line as the hypotenuse. Then, one leg gives Δy, and the other gives Δx. In the figure, $\Delta y = 8$ and $\Delta x = 4$.

At several places in the text, an equation is rearranged into the form of a straight line in order to determine information from the slope and/or the intercept. For example, in Chapter 16, we obtained the following expression:

$$\ln \frac{[A]_0}{[A]_t} = kt$$

Based on the properties of logarithms, we have

$$\ln [A]_0 - \ln [A]_t = kt$$

Rearranging into the form of an equation for a straight line gives

$$\ln [A]_t = -kt + \ln [A]_0$$
$$y = mx + b$$

Thus, a plot of $\ln [A]_t$ vs. t is a straight line, from which you can see that the slope is $-k$ (the negative of the rate constant) and the intercept is $\ln [A]_0$ (the natural logarithm of the initial concentration of A).

At many other places in the text, linear relationships occur that were not shown in graphical terms. For example, the conversion of temperature scales in Chapter 1 can also be expressed in the form of a straight line:

$$°F = \tfrac{9}{5}°C + 32$$
$$y = mx + b$$

Appendix B

EQUILIBRIUM CONSTANTS AT 298 K

Dissociation (Ionization) Constants (K_a) of Selected Acids

Name	Formula*	K_{a1}	K_{a2}	K_{a3}
Acetic acid	CH_3COOH	1.8×10^{-5}		
Acetylsalicylic acid†	$CH_3COOC_6H_4COOH$	3.6×10^{-4}		
Adipic acid	$HOOC(CH_2)_4COOH$	3.8×10^{-5}	3.8×10^{-6}	
Arsenic acid	H_3AsO_4	6×10^{-3}	1.1×10^{-7}	3×10^{-12}
Ascorbic acid	$H_2C_6H_6O_6$	1.0×10^{-5}	5×10^{-12}	
Benzoic acid	C_6H_5COOH	6.3×10^{-5}		
Carbonic acid	H_2CO_3	4.5×10^{-7}	4.7×10^{-11}	
Chloroacetic acid	$ClCH_2COOH$	1.4×10^{-3}		
Chlorous acid	$HClO_2$	1.1×10^{-2}		
Citric acid	$HOC(CH_2)_2(COOH)_3$	7.4×10^{-4}	1.7×10^{-5}	4.0×10^{-7}
Formic acid	$HCOOH$	1.8×10^{-4}		
Glyceric acid	$HOCH_2CH(OH)COOH$	2.9×10^{-4}		
Glycolic acid	$HOCH_2COOH$	1.5×10^{-4}		
Glyoxylic acid	$O{=}CHCOOH$	3.5×10^{-4}		
Hydrocyanic acid	HCN	6.2×10^{-10}		
Hydrofluoric acid	HF	6.8×10^{-4}		
Hydrosulfuric acid	H_2S	9×10^{-8}	1×10^{-17}	
Hypobromous acid	$HBrO$	2.3×10^{-9}		
Hypochlorous acid	$HClO$	2.9×10^{-8}		
Hypoiodous acid	HIO	2.3×10^{-11}		
Iodic acid	HIO_3	1.6×10^{-1}		
Lactic acid	$CH_3CH(OH)COOH$	1.4×10^{-4}		
Maleic acid	$HOOCCH{=}CHCOOH$	1.2×10^{-2}	4.7×10^{-7}	
Malonic acid	$HOOCCH_2COOH$	1.4×10^{-3}	2.0×10^{-6}	
Nitrous acid	HNO_2	7.1×10^{-4}		
Oxalic acid	$HOOCCOOH$	5.6×10^{-2}	5.4×10^{-5}	
Phenol	C_6H_5OH	1.0×10^{-10}		
Phenylacetic acid	$C_6H_5CH_2COOH$	4.9×10^{-5}		
Phosphoric acid	H_3PO_4	7.2×10^{-3}	6.3×10^{-8}	4.2×10^{-13}
Phosphorous acid	$HPO(OH)_2$	3×10^{-2}	1.7×10^{-7}	
Propanoic acid	CH_3CH_2COOH	1.3×10^{-5}		
Pyruvic acid	$CH_3C(O)COOH$	2.8×10^{-3}		
Succinic acid	$HOOCCH_2CH_2COOH$	6.2×10^{-5}	2.3×10^{-6}	
Sulfuric acid	H_2SO_4	Very large	1.0×10^{-2}	
Sulfurous acid	H_2SO_3	1.4×10^{-2}	6.5×10^{-8}	

*Acidic (ionizable) proton(s) shown in red.
†At 37°C in 0.15 *M* NaCl.

Dissociation (Ionization) Constants (K_b) of Selected Amine Bases

Name	Formula*	K_{b1}	K_{b2}
Ammonia	NH_3	1.76×10^{-5}	
Aniline	$C_6H_5NH_2$	4.0×10^{-10}	
Diethylamine	$(CH_3CH_2)_2NH$	8.6×10^{-4}	
Dimethylamine	$(CH_3)_2NH$	5.9×10^{-4}	
Ethanolamine	$HOCH_2CH_2NH_2$	3.2×10^{-5}	
Ethylamine	$CH_3CH_2NH_2$	4.3×10^{-4}	
Ethylenediamine	$H_2NCH_2CH_2NH_2$	8.5×10^{-5}	7.1×10^{-8}
Methylamine	CH_3NH_2	4.4×10^{-4}	
2-Methyl-2-propylamine	$(CH_3)_3CNH_2$	4.8×10^{-4}	
Piperidine	$C_5H_{10}NH$	1.3×10^{-3}	
1-Propylamine	$CH_3CH_2CH_2NH_2$	3.5×10^{-4}	
2-Propylamine	$(CH_3)_2CHNH_2$	4.7×10^{-4}	
1,3-Propylenediamine	$H_2NCH_2CH_2CH_2NH_2$	3.1×10^{-4}	3.0×10^{-6}
Pyridine	C_5H_5N	1.7×10^{-9}	
Triethylamine	$(CH_3CH_2)_3N$	5.2×10^{-4}	
Trimethylamine	$(CH_3)_3N$	6.3×10^{-5}	

*Basic nitrogen(s) shown in blue.

Dissociation (Ionization) Constants (K_a) of Some Hydrated Metal Ions

Free Ion	Hydrated Ion	K_a
Fe^{3+}	$Fe(H_2O)_6^{3+}(aq)$	6×10^{-3}
Sn^{2+}	$Sn(H_2O)_6^{2+}(aq)$	4×10^{-4}
Cr^{3+}	$Cr(H_2O)_6^{3+}(aq)$	1×10^{-4}
Al^{3+}	$Al(H_2O)_6^{3+}(aq)$	1×10^{-5}
Cu^{2+}	$Cu(H_2O)_6^{2+}(aq)$	3×10^{-8}
Pb^{2+}	$Pb(H_2O)_6^{2+}(aq)$	3×10^{-8}
Zn^{2+}	$Zn(H_2O)_6^{2+}(aq)$	1×10^{-9}
Co^{2+}	$Co(H_2O)_6^{2+}(aq)$	2×10^{-10}
Ni^{2+}	$Ni(H_2O)_6^{2+}(aq)$	1×10^{-10}

Formation Constants (K_f) of Some Complex Ions

Complex Ion	K_f
$Ag(CN)_2^-$	3.0×10^{20}
$Ag(NH_3)_2^+$	1.7×10^{7}
$Ag(S_2O_3)_2^{3-}$	4.7×10^{13}
AlF_6^{3-}	4×10^{19}
$Al(OH)_4^-$	3×10^{33}
CdI_4^{2-}	1×10^{6}
$Co(OH)_4^{2-}$	5×10^{9}
$Cr(OH)_4^-$	8.0×10^{29}
$Cu(NH_3)_4^{2+}$	5.6×10^{11}
$Fe(CN)_6^{4-}$	3×10^{35}
$Fe(CN)_6^{3-}$	4.0×10^{43}
$Hg(CN)_4^{2-}$	9.3×10^{38}
$Ni(NH_3)_6^{2+}$	2.0×10^{8}
$Pb(OH)_3^-$	8×10^{13}
$Sn(OH)_3^-$	3×10^{25}
$Zn(CN)_4^{2-}$	4.2×10^{19}
$Zn(NH_3)_4^{2+}$	7.8×10^{8}
$Zn(OH)_4^{2-}$	3×10^{15}

Solubility-Product Constants (K_{sp}) of Slightly Soluble Ionic Compounds

Name, Formula	K_{sp}
Carbonates	
Barium carbonate, $BaCO_3$	2.0×10^{-9}
Cadmium carbonate, $CdCO_3$	1.8×10^{-14}
Calcium carbonate, $CaCO_3$	3.3×10^{-9}
Cobalt(II) carbonate, $CoCO_3$	1.0×10^{-10}
Copper(II) carbonate, $CuCO_3$	3×10^{-12}
Lead(II) carbonate, $PbCO_3$	7.4×10^{-14}
Magnesium carbonate, $MgCO_3$	3.5×10^{-8}
Mercury(I) carbonate, Hg_2CO_3	8.9×10^{-17}
Nickel(II) carbonate, $NiCO_3$	1.3×10^{-7}
Strontium carbonate, $SrCO_3$	5.4×10^{-10}
Zinc carbonate, $ZnCO_3$	1.0×10^{-10}
Chromates	
Barium chromate, $BaCrO_4$	2.1×10^{-10}
Calcium chromate, $CaCrO_4$	1×10^{-8}
Lead(II) chromate, $PbCrO_4$	2.3×10^{-13}
Silver chromate, Ag_2CrO_4	2.6×10^{-12}
Cyanides	
Mercury(I) cyanide, $Hg_2(CN)_2$	5×10^{-40}
Silver cyanide, AgCN	2.2×10^{-16}
Halides	
Fluorides	
Barium fluoride, BaF_2	1.5×10^{-6}
Calcium fluoride, CaF_2	3.2×10^{-11}
Lead(II) fluoride, PbF_2	3.6×10^{-8}
Magnesium fluoride, MgF_2	7.4×10^{-9}
Strontium fluoride, SrF_2	2.6×10^{-9}
Chlorides	
Copper(I) chloride, CuCl	1.9×10^{-7}
Lead(II) chloride, $PbCl_2$	1.7×10^{-5}
Silver chloride, AgCl	1.8×10^{-10}
Bromides	
Copper(I) bromide, CuBr	5×10^{-9}
Silver bromide, AgBr	5.0×10^{-13}
Iodides	
Copper(I) iodide, CuI	1×10^{-12}
Lead(II) iodide, PbI_2	7.9×10^{-9}
Mercury(I) iodide, Hg_2I_2	4.7×10^{-29}
Silver iodide, AgI	8.3×10^{-17}
Hydroxides	
Aluminum hydroxide, $Al(OH)_3$	3×10^{-34}
Cadmium hydroxide, $Cd(OH)_2$	7.2×10^{-15}
Calcium hydroxide, $Ca(OH)_2$	6.5×10^{-6}
Cobalt(II) hydroxide, $Co(OH)_2$	1.3×10^{-15}
Copper(II) hydroxide, $Cu(OH)_2$	2.2×10^{-20}
Iron(II) hydroxide, $Fe(OH)_2$	4.1×10^{-15}
Iron(III) hydroxide, $Fe(OH)_3$	1.6×10^{-39}
Magnesium hydroxide, $Mg(OH)_2$	6.3×10^{-10}
Manganese(II) hydroxide, $Mn(OH)_2$	1.6×10^{-13}
Nickel(II) hydroxide, $Ni(OH)_2$	6×10^{-16}
Zinc hydroxide, $Zn(OH)_2$	3×10^{-16}
Iodates	
Barium iodate, $Ba(IO_3)_2$	1.5×10^{-9}
Calcium iodate, $Ca(IO_3)_2$	7.1×10^{-7}
Lead(II) iodate, $Pb(IO_3)_2$	2.5×10^{-13}
Silver iodate, $AgIO_3$	3.1×10^{-8}
Strontium iodate, $Sr(IO_3)_2$	3.3×10^{-7}
Zinc iodate, $Zn(IO_3)_2$	3.9×10^{-6}
Oxalates	
Barium oxalate dihydrate, $BaC_2O_4\cdot2H_2O$	1.1×10^{-7}
Calcium oxalate monohydrate, $CaC_2O_4\cdot H_2O$	2.3×10^{-9}
Strontium oxalate monohydrate, $SrC_2O_4\cdot H_2O$	5.6×10^{-8}
Phosphates	
Calcium phosphate, $Ca_3(PO_4)_2$	1.2×10^{-29}
Magnesium phosphate, $Mg_3(PO_4)_2$	5.2×10^{-24}
Silver phosphate, Ag_3PO_4	2.6×10^{-18}
Sulfates	
Barium sulfate, $BaSO_4$	1.1×10^{-10}
Calcium sulfate, $CaSO_4$	2.4×10^{-5}
Lead(II) sulfate, $PbSO_4$	1.6×10^{-8}
Radium sulfate, $RaSO_4$	2×10^{-11}
Silver sulfate, Ag_2SO_4	1.5×10^{-5}
Strontium sulfate, $SrSO_4$	3.2×10^{-7}
Sulfides	
Cadmium sulfide, CdS	1.0×10^{-24}
Copper(II) sulfide, CuS	8×10^{-34}
Iron(II) sulfide, FeS	8×10^{-16}
Lead(II) sulfide, PbS	3×10^{-25}
Manganese(II) sulfide, MnS	3×10^{-11}
Mercury(II) sulfide, HgS	2×10^{-50}
Nickel(II) sulfide, NiS	3×10^{-16}
Silver sulfide, Ag_2S	8×10^{-48}
Tin(II) sulfide, SnS	1.3×10^{-23}
Zinc sulfide, ZnS	2.0×10^{-22}

Appendix D

STANDARD ELECTRODE (HALF-CELL) POTENTIALS AT 298 K*

Half-Reaction	E^0 (V)
$F_2(g) + 2e^- \rightleftharpoons 2F^-(aq)$	+2.87
$O_3(g) + 2H^+(aq) + 2e^- \rightleftharpoons O_2(g) + H_2O(l)$	+2.07
$Co^{3+}(aq) + e^- \rightleftharpoons Co^{2+}(aq)$	+1.82
$H_2O_2(aq) + 2H^+(aq) + 2e^- \rightleftharpoons 2H_2O(l)$	+1.77
$PbO_2(s) + 3H^+(aq) + HSO_4^-(aq) + 2e^- \rightleftharpoons PbSO_4(s) + 2H_2O(l)$	+1.70
$Ce^{4+}(aq) + e^- \rightleftharpoons Ce^{3+}(aq)$	+1.61
$MnO_4^-(aq) + 8H^+(aq) + 5e^- \rightleftharpoons Mn^{2+}(aq) + 4H_2O(l)$	+1.51
$Au^{3+}(aq) + 3e^- \rightleftharpoons Au(s)$	+1.50
$Cl_2(g) + 2e^- \rightleftharpoons 2Cl^-(aq)$	+1.36
$Cr_2O_7^{2-}(aq) + 14H^+(aq) + 6e^- \rightleftharpoons 2Cr^{3+}(aq) + 7H_2O(l)$	+1.33

$Sr^{2+}(aq) + 2e^- \rightleftharpoons Sr(s)$	−2.89
$Ba^{2+}(aq) + 2e^- \rightleftharpoons Ba(s)$	−2.90
$K^+(aq) + e^- \rightleftharpoons K(s)$	−2.93
$Li^+(aq) + e^- \rightleftharpoons Li(s)$	−3.05

*Written as reductions; E^0 value refers to all components in their standard states: 1 *M* for dissolved species; 1 atm pressure for the gas behaving ideally; the pure substance for solids and liquids.

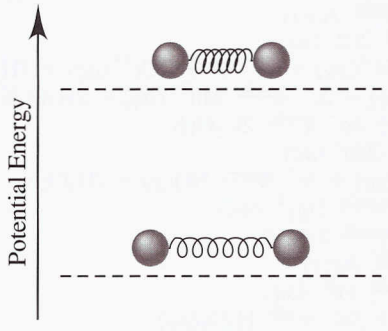
Appendix E

ANSWERS TO SELECTED PROBLEMS

Chapter 1

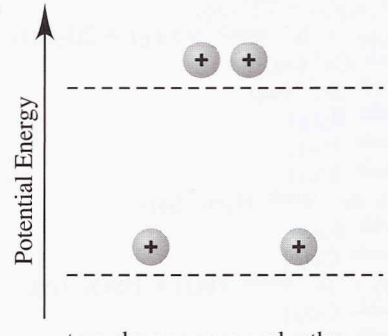
1.2 Gas molecules fill the entire container; the volume of a gas is the volume of the container. Solids and liquids have a definite volume. The volume of the container does not affect the volume of a solid or liquid. (a) gas (b) liquid (c) liquid **1.4** Physical property: a characteristic shown by a substance itself, without any interaction with or change into other substances. Chemical property: a characteristic of a substance that appears as it interacts with, or transforms into, other substances. (a) Color (yellow-green and silvery to white) and physical state (gas and metal to crystals) are physical properties. The interaction between chlorine gas and sodium metal is a chemical property. (b) Color and magnetism are physical properties. No chemical changes. **1.6**(a) Physical change; there is only a temperature change. (b) Chemical change; the change in appearance indicates an irreversible chemical change. (c) Physical change; there is only a change in size, not composition. (d) Chemical change; the wood (and air) become different substances with different compositions. **1.8**(a) fuel (b) wood **1.13** Lavoisier measured the total mass of the reactants and products, not just the mass of the solids. The total mass of the reactants and products remained constant. His measurements showed that a gas was involved in the reaction. He called this gas *oxygen* (one of his key discoveries). **1.16** A well-designed experiment must have the following essential features: (1) There must be at least two variables that are expected to be related; (2) there must be a way to control all the variables, so that only one at a time may be changed; (3) the results must be reproducible. **1.19**(a) $(2.54\ \text{cm}/1\ \text{in})^2$ (b) $(1000\ \text{m}/1\ \text{km})^2$ (c) (1.609 km/1 mi) and (1 h/3600 s) (d) $(1000\ \text{g}/2.205\ \text{lb})\left[\left(\frac{12\ \text{in}}{1\ \text{ft}}\right)\left(\frac{2.54\ \text{cm}}{1\ \text{in}}\right)\right]^3$ **1.21** An extensive property depends on the amount of material present. An intensive property is the same regardless of how much material is present. (a) extensive property (b) intensive property (c) extensive property (d) intensive property **1.23**(a) increases (b) remains the same (c) decreases (d) increases (e) remains the same **1.26** 1.43 nm **1.28** 3.94×10^3 in **1.30**(a) 1.77×10^{-9} km^2 (b) \$8.92 **1.32** Answers will vary, depending on the person's mass. **1.34**(a) 5.52×10^3 kg/m^3 (b) 345 lb/ft^3 **1.36**(a) 1.72×10^{-9} mm^3 (b) 10^{-10} L **1.38**(a) 9.626 cm^3 (b) 64.92 g **1.40** 2.70 g/cm^3 **1.42**(a) 22°C; 295 K (b) 109 K; −263°F (c) −273°C; −460.°F **1.45**(a) 2.55×10^{-7} m (b) 6830 Å **1.50** Initial zeros are never significant; internal zeros are always significant; terminal zeros to the right of a decimal point are significant; terminal zeros to the left of a decimal point are significant only if they were measured. **1.52**(a) none (b) none (c) 0.039$\underline{0}$ (d) $3.0\underline{900}\times10^4$ **1.54**(a) 0.00036 (b) 35.83 (c) 22.5 **1.56** 6×10^2 **1.58**(a) 1.34 m (b) 3.350×10^3 cm^3 (c) 443 cm **1.60**(a) 1.310000×10^5 (b) 4.7×10^{-4} (c) 2.10006×10^5 (d) 2.1605×10^3 **1.62**(a) 5550 (b) 10,070 (c) 0.000000885 (d) 0.003004 **1.64**(a) 8.025×10^4 (b) 1.0098×10^{-3} (c) 7.7×10^{-11} **1.66**(a) 4.06×10^{-19} J (b) 1.56×10^{24} molecules (c) 1.82×10^5 J/mol **1.68**(a) Height measured, not exact. (b) Planets counted, exact. (c) Number of grams in a pound is not a unit definition, not exact. (d) Definition of "millimeter," exact. **1.70** 7.50 ± 0.05 cm **1.73**(a) I_{avg} = 8.72 g; II_{avg} = 8.72 g; III_{avg} = 8.50 g; IV_{avg} = 8.56 g; sets I and II are most accurate. (b) Set III is the most precise, but is the least accurate. (c) Set I has the best combination of high accuracy and high precision. (d) Set IV has both low accuracy and low precision.

1.76(a)



compressed spring
less stable—energy
stored in spring

(b)

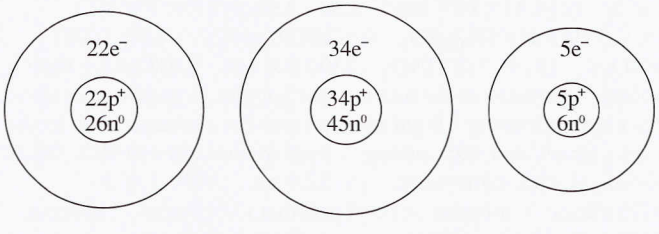


two charges near each other
less stable—repulsion of like
charges

1.80(a) \$19.40 before price increase; \$33.90 after price increase (b) 51.7 coins (c) 21.0 coins **1.82**(a) 0.21 g/L, will float (b) CO_2 is denser than air, will sink (c) 0.30 g/L, will float (d) O_2 is denser than air, will sink (e) 1.38 g/L, will sink (f) 0.50 g **1.85**(a) 8.0×10^{12} g (b) 4.1×10^5 m^3 (c) 9.5×10^{13} dollars **1.88**(a) −195.79°C (b) −320.42°F (c) 5.05 L **1.91**(a) 2.6 m/s (b) 16 km (c) 12:45 pm **1.92** 7.1×10^7 microparticles in the room; 1.2×10^3 microparticles in a breath **1.93** 2.2×10^{25} g oxygen; 1.4×10^{25} g silicon; 5×10^{15} g ruthenium (and rhodium) **1.96** freezing point = −3.7°X; boiling point = 63.3°X

Chapter 2

2.1 Compounds contain different types of atoms; there is only one type of atom in an element. **2.4**(a) The presence of more than one element makes pure calcium chloride a compound. (b) There is only one kind of atom, so sulfur is an element. (c) The presence of more than one compound makes baking powder a mixture. (d) The presence of more than one type of atom means cytosine cannot be an element. The specific, not variable, arrangement means it is a compound. **2.11**(a) elements, compounds, and mixtures (b) compounds (c) compounds **2.13**(a) Law of definite composition: the composition is the same regardless of its source. (b) Law of mass conservation: the total quantity of matter does not change. (c) Law of multiple proportions: two elements can combine to form two different compounds that have different proportions of those elements. **2.14**(a) No, the percent by mass of each element in a compound is fixed. (b) Yes, the *mass* of each element in a compound depends on the mass of the compound. **2.16** The two experiments demonstrate the law of definite composition. The unknown compound decomposes the same way both times. The experiments also demonstrate the law of conservation of mass since the total mass before reaction equals the total mass after reaction. **2.18**(a) 1.34 g F (b) 0.514 Ca; 0.486 F (c) 51.4 mass % Ca; 48.6 mass % F **2.20**(a) 0.603 (b) 262 g Mg **2.22** 3.498×10^6 g Cu; 1.766×10^6 g S **2.24** compound 1: 0.904 S/Cl; compound 2: 0.451 S/Cl; ratio: 2.00/1.00 **2.27** Coal A **2.29** Dalton postulated that atoms of an element are identical and that compounds result from the chemical combination of specific ratios of different elements. **2.30** If you know the ratio of any two quantities and the value of one of them, the other can always be calculated; in this case, the charge and the charge-to-mass ratio were known. **2.34** The identity of an element is based on the number of protons, not the number of neutrons. The mass number can vary (by a change in number of neutrons) without changing the identity of the element. **2.37** All three isotopes have 18 protons and 18 electrons. Their respective mass numbers are 36, 38, and 40, with the respective numbers of neutrons being 18, 20, and 22. **2.39**(a) These have the same number of protons and electrons, but different numbers of neutrons; same Z. (b) These have the same number of neutrons, but different numbers of protons and electrons; same N. (c) These have different numbers of protons, neutrons, and electrons; same A. **2.41**(a) $^{38}_{18}\text{Ar}$ (b) $^{55}_{25}\text{Mn}$ (c) $^{109}_{47}\text{Ag}$ **2.43**(a) $^{48}_{22}\text{Ti}$ (b) $^{79}_{34}\text{Se}$ (c) $^{11}_{5}\text{B}$



2.45 69.72 amu **2.47** $^{35}\text{Cl} = 75.774\%$, $^{37}\text{Cl} = 24.226\%$ **2.50**(a) In the modern periodic table, the elements are arranged in order of increasing atomic number. (b) Elements in a group (or family) have similar chemical properties. (c) Elements can be classified as metals, metalloids, or nonmetals. **2.53** The alkali metals [Group 1A(1)] are metals and readily lose one electron to form cations; the halogens [Group 7A(17)] are nonmetals and readily gain one electron to form anions. **2.54**(a) germanium; Ge; 4A(14); metalloid (b) sulfur; S; 6A(16); nonmetal (c) helium; He; 8A(18); nonmetal (d) lithium; Li; 1A(1); metal (e) molybdenum; Mo; 6B(6); metal **2.56**(a) Ra; 88 (b) As; 33 (c) Cu; 63.55 (d) Br; 79.90 **2.58** Atoms of these two kinds of substances will form ionic bonds, in which one or more electrons are transferred from the metal atom to the nonmetal atom to form a cation and an anion, respectively. **2.61** Coulomb's law states the energy of attraction in an ionic bond is directly proportional to the product of charges and inversely proportional to the distance between charges. The product of charges in MgO ($2+ \times 2-$) is greater than the product of charges in LiF ($1+ \times 1-$). Thus, MgO has stronger ionic bonding. **2.64** The Group 1A(1) elements form cations, and the Group 7A(17) elements form anions. **2.66** Each potassium atom loses one electron to form an ion with a $1+$ charge. Each sulfur atom gains two electrons to form an ion with a $2-$ charge. Two potassiums, giving one electron each, are required for each sulfur, which takes two electrons. The oppositely charged ions attract each other to form an ionic solid, K_2S. **2.68** K^+; I^- **2.70**(a) oxygen; 17; 6A(16); 2 (b) fluorine; 19; 7A(17); 2 (c) calcium; 40; 2A(2); 4 **2.72** Lithium forms the Li^+ ion; oxygen forms the O^{2-} ion. Number of O^{2-} ions = 2.6×10^{20} O^{2-} ions. **2.74** NaCl **2.76** An empirical formula shows the simplest ratio of atoms of each element present in a compound, whereas a molecular formula describes the type and actual number of atoms of each element in a molecule of the compound. The empirical formula and the molecular formula can be the same. The molecular formula is always a whole-number multiple of the empirical formula. **2.78** The two samples are similar in that both contain 20 billion oxygen atoms and 20 billion hydrogen atoms. They differ in that they contain different types of molecules: H_2O_2 molecules in the hydrogen peroxide sample, and H_2 and O_2 molecules in the mixture. In addition, the mixture contains 20 billion molecules (10 billion H_2 and 10 billion O_2), while the hydrogen peroxide sample contains 10 billion molecules. **2.82**(a) NH_2 (b) CH_2O **2.84**(a) Li_3N, lithium nitride (b) SrO, strontium oxide (c) $AlCl_3$, aluminum chloride **2.86**(a) MgF_2, magnesium fluoride (b) Na_2S, sodium sulfide (c) $SrCl_2$, strontium chloride **2.88**(a) $SnCl_4$ (b) iron(III) bromide (c) CuBr (d) manganese(III) oxide **2.90**(a) cobalt(II) oxide (b) Hg_2Cl_2 (c) lead(II) acetate trihydrate (d) Cr_2O_3 **2.92**(a) BaO (b) $Fe(NO_3)_2$ (c) MgS **2.94**(a) H_2SO_4; sulfuric acid (b) HIO_3; iodic acid (c) HCN; hydrocyanic acid (d) H_2S; hydrosulfuric acid **2.96**(a) ammonium ion, NH_4^+; ammonia, NH_3 (b) magnesium sulfide, MgS; magnesium sulfite, $MgSO_3$; magnesium sulfate, $MgSO_4$ (c) hydrochloric acid, HCl; chloric acid, $HClO_3$; chlorous acid, $HClO_2$ (d) cuprous bromide, CuBr; cupric bromide, $CuBr_2$ **2.98** Disulfur tetrafluoride, S_2F_4 **2.100**(a) calcium chloride (b) copper(I) oxide (c) stannic fluoride (d) hydrochloric acid **2.102**(a) 12 oxygen atoms; 342.2 amu (b) 9 hydrogen atoms; 132.06 amu (c) 8 oxygen atoms; 344.6 amu **2.104**(a) $(NH_4)_2SO_4$; 132.15 amu (b) NaH_2PO_4; 119.98 amu (c) $KHCO_3$; 100.12 amu **2.106**(a) 108.02 amu (b) 331.2 amu (c) 72.08 amu **2.108**(a) SO_3; sulfur trioxide; 80.07 amu (b) C_3H_8; propane; 44.09 amu **2.110** disulfur dichloride; SCl; 135.04 amu **2.114** Separating the components of a mixture requires physical methods only; that is, no chemical changes (no changes in composition) take place, and the components maintain their chemical identities and properties throughout. Chapter 4

4.2 ionic or polar covalent compounds **4.3** Ions must be present and they come from ionic compounds or from electrolytes such as acids and bases. **4.6** (2) **4.10** (a) Benzene is likely to be insoluble in water because it is nonpolar and water is polar. (b) Sodium hydroxide, an ionic compound, is likely to be very soluble in water. (c) Ethanol (CH_3CH_2OH) is likely to be soluble in water because the alcohol group (—OH) will hydrogen bond with a water molecule. (d) Potassium acetate, an ionic compound, is likely to be very soluble in water. **4.12**(a) Yes, CsI is a soluble salt. (b) Yes, HBr is a strong acid. **4.14**(a) 0.74 mol (b) 0.337 mol (c) 1.18×10^{-5} mol **4.16**(a) 3.3 mol (b) 8.93×10^{-5} mol (c) 8.17×10^{-3} mol **4.18**(a) 0.245 mol Al^{3+}; 0.735 mol Cl^-; 1.48×10^{23} Al^{3+} ions; 4.43×10^{23} Cl^- ions (b) 0.0848 mol Li^+; 0.0424 mol SO_4^{2-}; 5.11×10^{22} Li^+ ions; 2.55×10^{22} SO_4^{2-} ions (c) 3.78×10^{21} K^+ ions; 3.78×10^{21} Br^- ions; 6.28×10^{-3} mol K^+; 6.28×10^{-3} mol Br^-
4.20(a) 0.35 mol H^+ (b) 1.3×10^{-3} mol H^+ (c) 0.43 mol H^+
4.24 Spectator ions do not appear because they are not involved in the reaction and are present only to balance charge.
4.28 Assuming that the left beaker contains $AgNO_3$ (because it has gray Ag^+ ion), the right must contain NaCl. Then, NO_3^- is blue, Na^+ is brown, and Cl^- is green.
Molecular equation: $AgNO_3(aq) + NaCl(aq) \longrightarrow AgCl(s) + NaNO_3(aq)$
Total ionic equation: $Ag^+(aq) + NO_3^-(aq) + Na^+(aq) + Cl^-(aq) \longrightarrow AgCl(s) + Na^+(aq) + NO_3^-(aq)$
Net ionic equation: $Ag^+(aq) + Cl^-(aq) \longrightarrow AgCl(s)$
4.29(a) Molecular: $Hg_2(NO_3)_2(aq) + 2KI(aq) \longrightarrow Hg_2I_2(s) + 2KNO_3(aq)$
Total ionic: $Hg_2^{2+}(aq) + 2NO_3^-(aq) + 2K^+(aq) + 2I^-(aq) \longrightarrow Hg_2I_2(s) + 2K^+(aq) + 2NO_3^-(aq)$
Net ionic: $Hg_2^{2+}(aq) + 2I^-(aq) \longrightarrow Hg_2I_2(s)$
Spectator ions are K^+ and NO_3^-.
(b) Molecular: $FeSO_4(aq) + Ba(OH)_2(aq) \longrightarrow Fe(OH)_2(s) + BaSO_4(s)$
Total ionic: $Fe^{2+}(aq) + SO_4^{2-}(aq) + Ba^{2+}(aq) + 2OH^-(aq) \longrightarrow Fe(OH)_2(s) + BaSO_4(s)$
Net ionic: This is the same as the total ionic equation, because there are no spectator ions.
4.31(a) No precipitate will form. (b) A precipitate will form because silver ions, Ag^+, and iodide ions, I^-, will combine to form a solid salt, silver iodide, AgI. The ammonium and nitrate ions do not form a precipitate.
Molecular: $NH_4I(aq) + AgNO_3(aq) \longrightarrow AgI(s) + NH_4NO_3(aq)$
Total ionic: $NH_4^+(aq) + I^-(aq) + Ag^+(aq) + NO_3^-(aq) \longrightarrow AgI(s) + NH_4^+(aq) + NO_3^-(aq)$
Net ionic: $Ag^+(aq) + I^-(aq) \longrightarrow AgI(s)$
4.33(a) No precipitate will form.
(b) $BaSO_4$ will precipitate.
Molecular: $(NH_4)_2SO_4(aq) + BaCl_2(aq) \longrightarrow BaSO_4(s) + 2NH_4Cl(aq)$
Total ionic: $2NH_4^+(aq) + SO_4^{2-}(aq) + Ba^{2+}(aq) + 2Cl^-(aq) \longrightarrow BaSO_4(s) + 2NH_4^+(aq) + Cl^-(aq)$
Net ionic: $SO_4^{2-}(aq) + Ba^{2+}(aq) \longrightarrow BaSO_4(s)$
4.35 0.0389 *M* Pb^{2+} **4.37** 1.80 mass % Cl **4.43**(a) Formation of a gas, $SO_2(g)$, and of a nonelectrolyte (water) will cause the reaction to go to completion. (b) Formation of a precipitate $Ba_3(PO_4)_2(s)$, and of a nonelectrolyte (water) will cause the reaction to go to completion.
4.45(a) Molecular equation: $KOH(aq) + HI(aq) \longrightarrow KI(aq) + H_2O(l)$
Total ionic equation: $K^+(aq) + OH^-(aq) + H^+(aq) + I^-(aq) \longrightarrow K^+(aq) + I^-(aq) + H_2O(l)$
Net ionic equation: $OH^-(aq) + H^+(aq) \longrightarrow H_2O(l)$
The spectator ions are $K^+(aq)$ and $I^-(aq)$.
(b) Molecular equation: $NH_3(aq) + HCl(aq) \longrightarrow NH_4Cl(aq)$
Total ionic equation: $NH_3(aq) + H^+(aq) + Cl^-(aq) \longrightarrow NH_4^+(aq) + Cl^-(aq)$
NH_3, a weak base, is written in the molecular (undissociated) form. HCl, a strong acid, is written as dissociated ions. NH_4Cl is a soluble compound, because all ammonium compounds are soluble.
Net ionic equation: $NH_3(aq) + H^+(aq) \longrightarrow NH_4^+(aq)$
Cl^- is the only spectator ion.
4.47 Total ionic equation: $CaCO_3(s) + 2H^+(aq) + 2Cl^-(aq) \longrightarrow Ca^{2+}(aq) + 2Cl^-(aq) + H_2O(l) + CO_2(g)$
Net ionic equation: $CaCO_3(s) + 2H^+(aq) \longrightarrow Ca^{2+}(aq) + H_2O(l) + CO_2(g)$
4.49 0.05839 *M* CH_3COOH **4.58**(a) S has O.N. = +6 in SO_4^{2-} (i.e., H_2SO_4), and O.N. = +4 in SO_2, so S has been reduced (and I^- oxidized); H_2SO_4 acts as an oxidizing agent.
(b) The oxidation numbers remain constant throughout; H_2SO_4 transfers a proton to F^- to produce HF, so it acts as an acid.
4.60(a) +4 (b) +3 (c) +4 (d) −3 **4.62**(a) −1 (b) −2 (c) −3 (d) +3 **4.64**(a) −3 (b) +5 (c) +3 **4.66**(a) +6 (b) +3 (c) +7 **4.68**(a) MnO_4^- is the oxidizing agent; $H_2C_2O_4$ is the reducing agent. (b) Cu is the reducing agent; NO_3^- is the oxidizing agent. **4.70**(a) Oxidizing agent is NO_3^-; reducing agent is Sn. (b) Oxidizing agent is MnO_4^-; reducing agent is Cl^-. **4.72** S is in Group 6A(16), so its highest possible O.N. is +6 and its lowest possible O.N. is 6 − 8 = −2. (a) S = −2. The S can only increase its O.N. (oxidize), so S^{2-} can function only as a reducing agent. (b) S = +6. The S can only decrease its O.N. (reduce), so SO_4^{2-} can function only as an oxidizing agent. (c) S = +4. The S can increase or decrease its O.N. Therefore, SO_2 can function as either an oxidizing or reducing agent.
4.74(a) $8HNO_3(aq) + K_2CrO_4(aq) + 3Fe(NO_3)_2(aq) \longrightarrow 2KNO_3(aq) + 3Fe(NO_3)_3(aq) + Cr(NO_3)_3(aq) + 4H_2O(l)$
Oxidizing agent is K_2CrO_4; reducing agent is $Fe(NO_3)_2$.
(b) $8HNO_3(aq) + 3C_2H_6O(l) + K_2Cr_2O_7(aq) \longrightarrow 2KNO_3(aq) + 3C_2H_4O(l) + 7H_2O(l) + 2Cr(NO_3)_3(aq)$
Oxidizing agent is $K_2Cr_2O_7$; reducing agent is C_2H_6O.
(c) $6HCl(aq) + 2NH_4Cl(aq) + K_2Cr_2O_7(aq) \longrightarrow 2KCl(aq) + 2CrCl_3(aq) + N_2(g) + 7H_2O(l)$
Oxidizing agent is $K_2Cr_2O_7$; reducing agent is NH_4Cl.
(d) $KClO_3(aq) + 6HBr(aq) \longrightarrow 3Br_2(l) + 3H_2O(l) + KCl(aq)$
Oxidizing agent is $KClO_3$; reducing agent is HBr.

Chapter 8

8.1 Elements are listed in the periodic table in an ordered, systematic way that correlates with a periodicity of their chemical and physical properties. The theoretical basis for the table in terms of atomic number and electron configuration does not allow for a "new element" between Sn and Sb. **8.3**(a) predicted atomic mass = 54.23 amu (b) predicted melting point = 6.3°C **8.6** The quantum number m_s relates to just the electron; all the others describe the orbital. **8.9** Shielding occurs when inner electrons protect, or shield, outer electrons from the full nuclear attraction. The effective nuclear charge is the nuclear charge an electron actually experiences. As the number of inner electrons increases, the effective nuclear charge decreases. **8.11**(a) 6 (b) 10 (c) 2 **8.13**(a) 6 (b) 2 (c) 14 **8.16** Degenerate orbitals (those of identical energy) will be filled in such a way that the electron spins will have the same value. N: $1s^2 2s^2 2p^3$.

8.18 Main-group elements from the same group have similar outer electron configurations, and the (old) group number equals the number of outer electrons. Outer electron configurations vary in a periodic manner within a period, with each succeeding element having an additional electron. **8.20** The maximum number of electrons in any energy level *n* is $2n^2$, so the $n = 4$ energy level holds a maximum of $2(4^2) = 32$ electrons. **8.21**(a) $n = 5$, $l = 0$, $m_l = 0$, and $m_s = +\frac{1}{2}$ (b) $n = 3$, $l = 1$, $m_l = +1$, and $m_s = -\frac{1}{2}$ (c) $n = 5$, $l = 0$, $m_l = 0$, and $m_s = +\frac{1}{2}$ (d) $n = 2$, $l = 1$, $m_l = +1$, and $m_s = -\frac{1}{2}$

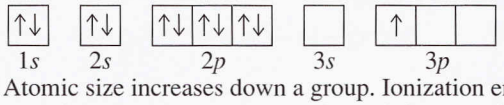
	Inner Electrons	Outer Electrons	Valence Electrons
(a) O	2	6	6
(b) Sn	46	4	4
(c) Ca	18	2	2
(d) Fe	18	2	8
(e) Se	28	6	6

8.39(a) B; Al, Ga, In, and Tl (b) S; O, Se, Te, and Po (c) La; Sc, Y, and Ac **8.41**(a) C; Si, Ge, Sn, and Pb (b) V; Nb, Ta, and Db (c) P; N, As, Sb, and Bi

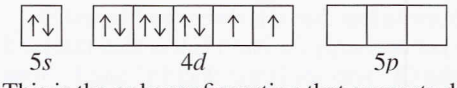
8.43 Na (first excited state): $1s^2 2s^2 2p^6 3p^1$



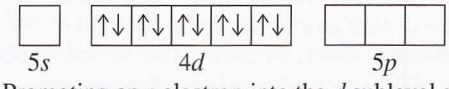
8.46 Atomic size increases down a group. Ionization energy decreases down a group. These trends result because the outer electrons are more easily removed as the atom gets larger.

8.48 For a given element, successive ionization energies always increase. As each successive electron is removed, the positive charge on the ion increases, which results in a stronger attraction between the leaving electron and the ion. When a large jump between successive ionization energies is observed, the subsequent electron must come from a lower energy level. **8.50** A high IE_1 and a very negative EA_1 suggest that the elements are halogens, in Group 7A(17), which form 1− ions. **8.53**(a) K < Rb < Cs (b) O < C < Be (c) Cl < S < K (d) Mg < Ca < K

8.55(a) Ba < Sr < Ca (b) B < N < Ne (c) Rb < Se < Br (d) Sn < Sb < As **8.57** $1s^2 2s^2 2p^1$ (boron, B) **8.59**(a) Na (b) Na (c) Be **8.61** (1) Metals conduct electricity, nonmetals do not. (2) When they form stable ions, metal ions tend to have a positive charge, nonmetal ions tend to have a negative charge. (3) Metal oxides are ionic and act as bases, nonmetal oxides are covalent and act as acids. **8.62** Metallic character increases down a group and decreases toward the right across a period. These trends are the same as those for atomic size and opposite those for ionization energy. **8.64** Possible ions are 2+ and 4+. The 2+ ions form by loss of the outermost two *p* electrons, while the 4+ ions form by loss of these and the outermost two *s* electrons. **8.68**(a) Rb (b) Ra (c) I **8.70**(a) As (b) P (c) Be **8.72** acidic solution; $SO_2(g) + H_2O(l) \longrightarrow H_2SO_3(aq)$ **8.74**(a) Cl^-: $1s^2 2s^2 2p^6 3s^2 3p^6$ (b) Na^+: $1s^2 2s^2 2p^6$ (c) Ca^{2+}: $1s^2 2s^2 2p^6 3s^2 3p^6$ **8.76**(a) Al^{3+}: $1s^2 2s^2 2p^6$ (b) S^{2-}: $1s^2 2s^2 2p^6 3s^2 3p^6$ (c) Sr^{2+}: $1s^2 2s^2 2p^6 3s^2 3p^6 4s^2 3d^{10} 4p^6$ **8.78**(a) 0 (b) 3 (c) 0 (d) 1 **8.80** a, b, and d **8.82**(a) V^{3+}, [Ar] $3d^2$, paramagnetic (b) Cd^{2+}, [Kr] $4d^{10}$, diamagnetic (c) Co^{3+}, [Ar] $3d^7$, paramagnetic (d) Ag^+, [Kr] $4d^{10}$, diamagnetic **8.84** For palladium to be diamagnetic, all of its electrons must be paired. (a) You might first write the condensed electron configuration for Pd as [Kr] $5s^2 4d^8$. However, the partial orbital diagram is not consistent with diamagnetism.



(b) This is the only configuration that supports diamagnetism, [Kr] $4d^{10}$.



(c) Promoting an *s* electron into the *d* sublevel still leaves two electrons unpaired.

9.12(a) ·Sr· (b) :P· (c) :S:

9.14(a) 6A(16); [noble gas] ns^2np^4 (b) 3(A)13; [noble gas] ns^2np^1 **9.17** Because the lattice energy is the result of electrostatic attractions between oppositely charged ions, its magnitude depends on several factors, including ionic size and ionic charge. For a particular arrangement of ions, the lattice energy increases as the charge on the ions increases and as their radii decrease. **9.20**(a) Ba^{2+}, [Xe]; Cl^-, [Ne] $3s^23p^6$, :Cl:$^-$; $BaCl_2$ (b) Sr^{2+}, [Kr]; O^{2-}, [He] $2s^22p^6$, :O:$^{2-}$; SrO (c) Al^{3+}, [Ne]; F^-, [He] $2s^22p^6$, :F:$^-$; AlF_3 (d) Rb^+, [Kr]; O^{2-}, [He] $2s^22p^6$, :O:$^{2-}$; Rb_2O. **9.22**(a) 2A(2) (b) 6A(16) (c) 1A(1) **9.24**(a) 3A(13) (b) 2A(2) (c) 6A(16) **9.26**(a) BaS; the charge on each ion is twice the charge on the ions in CsCl. (b) LiCl; Li^+ is smaller than Cs^+. **9.28**(a) BaS; Ba^{2+} is larger than Ca^{2+}. (b) NaF; the charge on each ion is less than the charge on Mg and O. **9.30** −788 kJ, the lattice energy for NaCl is less than that for LiF, because the Na^+ and Cl^- ions are larger than Li^+ and F^- ions. **9.33** −336 kJ **9.34** When two chlorine atoms are far apart, there is no interaction between them. As the atoms move closer together, the nucleus of each atom attracts the electrons of the other atom. The closer the atoms, the greater this attraction; however, the repulsions of the two nuclei and two electrons also increase at the same time. The final internuclear distance is the distance at which maximum attraction is achieved in spite of the repulsion. **9.35** The bond energy is the energy required to break the bond between H atoms and Cl atoms in one mole of HCl molecules in the gaseous state. Energy is needed to break bonds, so bond energy is always endothermic and $\Delta H^0_{\text{bond breaking}}$ is positive. The amount of energy needed to break the bond is released upon its formation, so $\Delta H^0_{\text{bond forming}}$ has the same magnitude as $\Delta H^0_{\text{bond breaking}}$ but is opposite in sign (always exothermic and negative). **9.39**(a) I—I < Br—Br < Cl—Cl (b) S—Br < S—Cl < S—H (c) C—N < C=N < C≡N **9.41**(a) C—O < C=O; the C=O bond (bond order = 2) is stronger than the C—O bond (bond order = 1). (b) C—H < O—H; O is smaller than C so the O—H bond is shorter and stronger than the C—H bond. **9.44** Less energy is required to break weak bonds. **9.46** Both are one-carbon molecules. Since methane contains fewer C—O bonds, it will have the greater heat of combustion per mole. **9.48** −168 kJ **9.50** −22 kJ **9.51** −59 kJ **9.52** Electronegativity increases from left to right and increases from bottom to top within a group. Fluorine and oxygen are the two most electronegative elements. Cesium and francium are the two least electronegative elements. **9.54** The H—O bond in water is polar covalent. A nonpolar covalent bond occurs between two atoms with identical electronegativities. A polar covalent bond occurs when the atoms have differing electronegativities. Ionic bonds result from electron transfer between atoms.

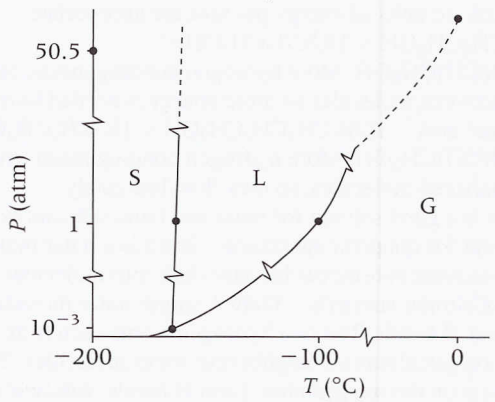
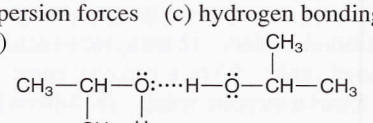
Chapter 12

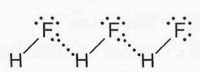
12.1 In a solid, the energy of attraction of the particles is greater than their energy of motion; in a gas, it is less. Gases have high compressibility and the ability to flow, while solids have neither. **12.4**(a) Because the intermolecular forces are only partially overcome when fusion occurs but need to be totally overcome in vaporization. (b) Because solids have greater intermolecular forces than liquids do. (c) $\Delta H_{vap} = -\Delta H_{cond}$ **12.5**(a) intermolecular (b) intermolecular (c) intramolecular (d) intramolecular **12.7**(a) condensation (b) fusion (c) vaporization **12.9** The gas molecules slow down as the gas is compressed. Therefore, much of the kinetic energy lost by the propane molecules is released to the surroundings. **12.13** At first, the vaporization of liquid molecules from the surface predominates, which increases the number of gas molecules and hence the vapor pressure. As more molecules enter the gas phase, gas molecules hit the surface of the liquid and "stick" more frequently, so the condensation rate increases. When the vaporization and condensation rates become equal, the vapor pressure becomes constant. **12.14** As intermolecular forces increase, (a) critical temperature increases (b) boiling point increases (c) vapor pressure decreases (d) heat of vaporization increases **12.18** because the condensation of the vapor supplies an additional 40.7 kJ/mol. **12.19** 4.16×10^3 J
12.21 0.692 atm **12.23** 2×10^4 J/mol
12.25



Solid ethylene is more dense than liquid ethylene.
12.28 42 atm **12.32** O is smaller and more electronegative than Se; so the electron density on O is greater, which attracts H more strongly. **12.34** All particles (atoms and molecules) exhibit dispersion forces, but the total force is weak in small molecules. Dipole-dipole forces in small polar molecules dominate the dispersion forces. **12.37**(a) hydrogen bonding (b) dispersion forces (c) dispersion forces **12.39**(a) dipole-dipole forces (b) dispersion forces (c) hydrogen bonding
12.41(a)



(b)



12.43(a) dispersion forces (b) hydrogen bonding (c) dispersion forces **12.45**(a) I^- (b) $CH_2=CH_2$ (c) H_2Se. In (a) and (c) the larger particle has the higher polarizability. In (b), the less tightly held π electron clouds are more easily distorted.
12.47(a) C_2H_6; it is a smaller molecule exhibiting weaker dispersion

forces than C_4H_{10}. (b) CH_3CH_2F; it has no H—F bonds, so it only exhibits dipole-dipole forces, which are weaker than the hydrogen bonds of CH_3CH_2OH. (c) PH_3; it has weaker intermolecular forces (dipole-dipole) than NH_3 (hydrogen bonding). **12.49**(a) Lithium chloride; it has ionic bonds versus dipole-dipole forces in HCl. (b) NH_3; it exhibits hydrogen bonding versus dipole-dipole forces in PH_3. (c) I_2; its molecules are more polarizable than Xe atoms because of their larger size. **12.51**(a) C_4H_8 (cyclobutane), because it is more compact than C_4H_{10}. (b) PBr_3; the dipole-dipole forces in PBr_3 are weaker than the ionic bonds in NaBr. (c) HBr; the dipole-dipole forces in HBr are weaker than the hydrogen bonds in water. **12.53** As atomic size decreases and electronegativity increases, the electron density of an atom increases. High electron density strengthens the attraction to an H atom on another molecule and makes its attached H atom more positive. Fluorine is the smallest of the three and the most electronegative, so its H bonds would be the strongest. Oxygen is smaller and more electronegative than nitrogen, so H bonds in water would be stronger than H bonds in ammonia. **12.57** The cohesive forces in water and mercury are stronger than the adhesive forces to the nonpolar wax on the floor. Weak adhesive forces result in spherical drops. The adhesive forces overcome the even weaker cohesive forces in the oil and so the oil drop spreads out. **12.59** Surface tension is defined as the energy needed to increase the surface area by a given amount, so units of energy per area are appropriate. **12.61** $CH_3CH_2CH_2OH < HOCH_2CH_2OH < HOCH_2CH(OH)CH_2OH$. More hydrogen bonding means more attraction between molecules so more energy is needed to increase surface area. **12.63** $CH_3CH_2CH_2OH < HOCH_2CH_2OH < HOCH_2CH(OH)CH_2OH$. More hydrogen bonding means more attraction between molecules, so they flow less easily. **12.68** Water is a good solvent for polar and ionic substances and a poor solvent for nonpolar substances. Water is a polar molecule and dissolves polar substances because their intermolecular forces are of similar strength. **12.69** A single water molecule can form four H bonds. The two hydrogen atoms each form one H bond to oxygen atoms on neighboring water molecules. The two lone pairs on the oxygen atom form H bonds with two hydrogen atoms on neighboring molecules. **12.72** Water exhibits strong capillary action, which allows it to be easily absorbed by the narrow spaces in the plant's roots and transported upward to the leaves. **12.78** simple cubic cell **12.81** The energy gap is the energy difference between the highest filled energy level (valence band) and the lowest unfilled energy level (conduction band). In conductors and superconductors, the energy gap is zero because the valence band overlaps the conduction band. In semiconductors, the energy gap is small. In insulators, the gap is large. **12.83** atomic mass and atomic radius **12.84**(a) face-centered cubic (b) body-centered cubic (c) face-centered cubic **12.86**(a) Tin, a metal, forms a metallic solid. (b) Silicon is in the same group as carbon, so it forms network covalent bonding. (c) Xenon is monatomic and forms an atomic solid. **12.88**(a) Metallic solid because nickel consists of metal atoms. (b) Molecular solid because F_2 exists as molecules. (c) Molecular solid because CH_3OH molecules are held together by hydrogen bonds. **12.90** four **12.92**(a) four Se^{2-} ions, four Zn^{2+} ions (b) 577.40 amu (c) 1.77×10^{-22} cm^3 (d) 5.61×10^{-8} cm **12.94**(a) insulator (b) conductor (c) semiconductor **12.96**(a) Conductivity increases. (b) Conductivity increases. (c) Conductivity decreases. **12.98** 1.68×10^{-8} cm **12.105** A substance whose properties are the same in all directions is isotropic; otherwise, the substance is anisotropic. Liquid crystals have a degree of order only in certain directions, so they are anisotropic. **12. 111**(a) n-type semiconductor (b) p-type semiconductor **12.113** $n = 3.4\times10^3$ **12.115** 7.9 pm **12.118**(a) 19.8 torr (b) 0.0388 g

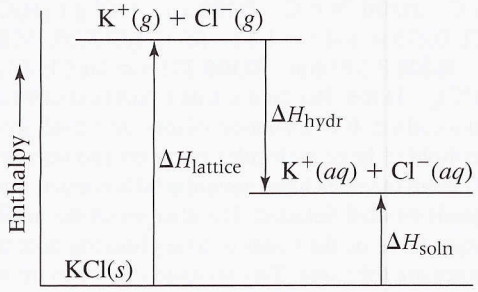
Chapter 13

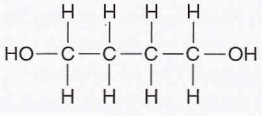
13.2 When a salt such as NaCl dissolves, ion-dipole forces cause the ions to separate, and many water molecules cluster around each ion in hydration shells. **13.4** Sodium stearate would be a more effective soap because the hydrocarbon chain in the stearate ion is longer than that in the acetate ion. The longer chain allows for more dispersion forces with grease molecules. **13.7**(a) KNO_3 is an ionic compound and is therefore more soluble in water. **13.9**(a) ion-dipole forces (b) hydrogen bonding (c) dipole–induced dipole forces **13.11**(a) hydrogen bonding (b) dipole–induced dipole forces (c) dispersion forces **13.13**(a) HCl(g), because the molecular interactions (dipole-dipole forces) in ether are like those in HCl but not like the ionic bonding in NaCl. (b) $CH_3CHO(l)$, because the molecular interactions with ether (dipole-dipole) can replace those between CH_3CHO, but not the H bonds in water. (c) $CH_3CH_2MgBr(s)$, because the molecular interactions (dispersion forces) are greater than between ether and the ions in $MgBr_2$. **13.16** Gluconic acid is soluble in water due to extensive hydrogen bonding from its —OH groups attached to five of its carbons. The dispersion forces in the nonpolar tail of caproic acid are more similar to the dispersion forces in hexane; thus, caproic acid is soluble in hexane. **13.18** The nitrogen-containing bases bond to their complementary bases. The flat, N-containing bases stack above each other, which allows extensive dispersion forces. The exterior negatively charged sugar-phosphate chains form ion-dipole and H bonds with water molecules in the aqueous surroundings, which also stabilizes the structure. **13.20** Dispersion forces are present between the nonpolar tails of the lipid molecules within the bilayer. Polar heads form H bonds and ion-dipole forces with the aqueous surroundings. **13.25** The energy change needed to separate the solvent ($\Delta H_{solvent}$), and that needed to mix the solvent and solute (ΔH_{mix}) combine to obtain $\Delta H_{solution}$. **13.29** Very soluble because a decrease in enthalpy and an increase in entropy both favor the formation of a solution.

13.30

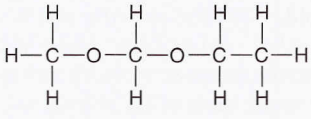


13.32(a) The volume of Na^+ is smaller, so it has the greater charge density. (b) Sr^{2+} has a larger ionic charge and a smaller volume, so it has the greater charge density. (c) Na^+ is smaller than Cl^-, so it has the greater charge density. (d) O^{2-} has a larger ionic charge with a similar ion volume, so it has the greater charge density. (e) OH^- has a smaller volume than SH^-, so it has the greater charge density. **13.34**(a) Na^+ (b) Sr^{2+} (c) Na^+ (d) O^{2-} (e) OH^- **13.36**(a) −704 kJ/mol (b) The K^+ ion contributes more because it is smaller and, therefore, has a greater charge density. **13.38**(a) increases (b) decreases (c) increases **13.41** Add a pinch of the solid solute to each solution. Addition of a "seed" crystal of solute to a supersaturated solution causes the excess solute to crystallize immediately, leaving behind a saturated solution. The solution in which the added solid solute dissolves is the unsaturated solution. The solution in which the added solid solute remains undissolved is the saturated solution. **13.44**(a) increase (b) decrease **13.46** (a) 0.0819 g O_2 (b) 0.0171 g O_2 **13.49** 0.20 mol/L **13.52**(a) molarity and % w/v or % v/v (b) parts-by-mass (% w/w) (c) molality **13.54** With just this information, you can convert between molality and molarity, but you need to know the molar mass of the solvent to convert to mole fraction. **13.56**(a) 1.24 M $C_{12}H_{22}O_{11}$ (b) 0.158 M $LiNO_3$ **13.58**(a) 0.0750 M NaOH (b) 0.31 M HNO_3 **13.60**(a) Add 4.22 g KH_2PO_4 to enough water to make 355 mL of aqueous solution. (b) Add 107 mL of 1.25 M NaOH to enough water to make 425 mL of solution. **13.62**(a) Weigh out 45.9 g KBr, dissolve it in about 1 L distilled water, and then dilute to 1.50 L with distilled water. (b) Measure 139 mL of the 0.244 M solution and add distilled water to make a total of 355 mL. **13.64**(a) 0.942 m glycine (b) 1.29 m glycerol **13.66** 3.09 m C_6H_6 **13.68**(a) Add 2.13 g $C_2H_6O_2$ to 298 g H_2O. (b) Add 0.0323 kg of 62.0% (w/w) HNO_3 to 0.968 kg H_2O to make 1.000 kg of 2.00% (w/w) HNO_3. **13.70**(a) 0.27 (b) 56 mass % (c) 21 m C_3H_7OH **13.72** 33.7 g CsCl; mole fraction = 7.67×10^{-3}; 6.74 mass % CsC **13.74** 5.11 m NH_3; 4.53 M NH_3; mole fraction = 0.0843 **13.76** 2.2 ppm Ca^{2+}, 0.66 ppm Mg^{2+} **13.80** It creates a "strong" current. A strong electrolyte dissociates completely in solution. **13.82** The boiling point is higher and the freezing point is lower for the solution compared to the solvent. **13.85** A dilute solution of an electrolyte behaves more ideally than a concentrated one. With increasing concentration, the effective concentration deviates from the molar concentration because of ionic attractions. Thus, 0.050 m NaF has a boiling point closer to its predicted value. **13.88**(a) strong electrolyte (b) strong electrolyte (c) nonelectrolyte (d) weak electrolyte **13.90**(a) 0.4 mol of solute particles (b) 0.14 mol (c) 3×10^{-4} mol (d) 0.07 mol **13.92**(a) CH_3OH in H_2O (b) H_2O in CH_3OH solution **13.94**(a) $\Pi_I = \Pi_{II} < \Pi_{III}$ (b) $bp_I = bp_{II} < bp_{III}$ (c) $fp_{III} < fp_I = fp_{II}$ (d) $vp_{III} < vp_I = vp_{II}$ **13.96** 23.36 torr

13.98 −0.206°C **13.100** 79.0°C **13.102** 1.13×10^4 g $C_2H_6O_2$
13.104(a) NaCl: 0.173 *m* and $i = 1.84$ (b) CH_3COOH: 0.0837 *m* and $i = 1.02$ **13.106** 0.240 atm **13.108** 211 torr for CH_2Cl_2; 47.2 torr for CCl_4 **13.109** The fluid inside a bacterial cell is both a solution and a colloid. It is a solution of ions and small molecules and a colloid of large molecules (proteins and nucleic acids). **13.113** Soap micelles have nonpolar tails pointed inward and anionic heads pointed outward. The charges on the heads of one micelle repel those on the heads of a neighboring micelle because the charges are the same. This repulsion between micelles keeps them from coagulating. Soap is more effective in freshwater than in seawater because the divalent cations in seawater combine with the anionic heads to form a precipitate. **13.114** Foam comes from gas bubbles trapped in the cream. The best gas for making cream foam would be one that is not very soluble in the cream. Since nitrous oxide is better at making foam than carbon dioxide, nitrous oxide must be less soluble in the cream than carbon dioxide. Henry's law constant is larger for a gas that is more soluble, so the constant for carbon dioxide must be larger than the constant for nitrous oxide. **13.119** 3.5×10^9 L
13.126 (a) 89.9 g/mol (b) C_2H_5O; $C_4H_{10}O_2$.
(c) Forms H bonds



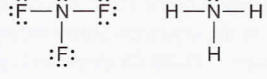
Does not form H bonds



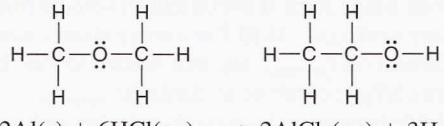
13.129(a) Mg^{2+} (b) Mg^{2+} (c) CO_3^{2-} (d) SO_4^{2-} (e) Fe^{3+} (f) Ca^{2+} **13.131**(a) 68 g/mol (b) 2.1×10^2 g/mol (c) The molar mass of CaN_2O_6 is 164.10 g/mol. This value is less than the 2.1×10^2 g/mol calculated when the compound is assumed to be a strong electrolyte and is greater than the 68 g/mol calculated when the compound is assumed to be a nonelectrolyte. Thus, the compound forms a non-ideal solution because the ions interact but do not dissociate completely in solution. (d) 2.4
13.135(a) 1.82×10^4 g/mol (b) 3.41×10^{-5}°C
13.136 9.4×10^5 ng/L **13.142** Weigh 3.11 g $NaHCO_3$ and dissolve in 247 g water. **13.146** $M = m$ (kg solvent/L solution) = $m \times d_{solution}$ Thus, for very dilute solutions molality × density = molarity. In an aqueous solution, the liters of solution have approximately the same value as the kg of solvent because the density of water is close to 1 kg/L, so $m = M$.
13.149(a) CH_4N_2O. The empirical formula mass is 60.06 g/mol. (b) 60. g/mol; CH_4N_2O. **13.152**(a) 0.088 cm^3/g H_2O (b) 1.5 cm^3/g H_2O·MPa (c) 0.74 cm^3/g H_2O, 11%
13.159(a) Yes, the phases of water can still coexist at some temperature and can therefore establish equilibrium. (b) The triple point would occur at a lower pressure and lower temperature because the dissolved air lowers the vapor pressure of the solvent. (c) Yes, this is possible because the gas-solid phase boundary exists below the new triple point. (d) No; at both temperatures, the presence of the solute lowers the vapor pressure of the liquid.

Chapter 14

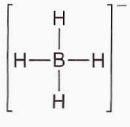
14.2(a) Z_{eff}, the effective nuclear charge, increases significantly across a period and decreases slightly down a group. (b) Moving across a period, atomic size decreases, IE_1 increases, and EN increases, all because of the increased Z_{eff}. **14.3**(a) Polarity is the molecular property that is responsible for the difference in boiling points between iodine monochloride (polar) and bromine (nonpolar). It arises from different EN values of the bonded atoms. (b) The boiling point of polar ICl is higher than the boiling point of Br_2. **14.7** The leftmost element in a period is an alkali metal [except for hydrogen in Group 1A(1)]. As we move to the right, the bonding to the other atom would change from metallic to polar covalent to ionic. The IE, EA, and EN of the two atoms become increasingly different, causing changes in the character of the bond. **14.9** The elements on the left side in Period 3 form cations. The loss of electrons leads to an ion smaller than the atom. The elements on the right side form anions. The gain of electrons leads to an ion larger than the atom.
14.11(a) The greater the electronegativity of the element, the more covalent the bonding is in its oxide. (b) The more electronegative the element, the more acidic the oxide is. **14.14** In general, network solids have very high melting and boiling points and are very hard, while molecular solids have low melting and boiling points and are soft. The properties of network solids reflect the necessity of breaking chemical bonds throughout the substances, whereas the properties of molecular solids reflect the weaker forces between individual molecules. **14.15**(a) Mg < Sr < Ba (b) Na < Al < P (c) Se < Br < Cl (d) Ga < Sn < Bi
14.17(b) and (d) **14.19** $\ddot{O}{=}C{=}\ddot{O}$ **14.21** $CF_4 < SiCl_4 < GeBr_4$
14.23(a) $Na^+ < F^- < O^{2-}$ (b) $Cl^- < S^{2-} < P^{3-}$
14.25 $O < O^- < O^{2-}$
14.27(a) $CaO(s) + H_2O(l) \longrightarrow$
$Ca(OH)_2(s) \rightleftharpoons Ca^{2+}(aq) + 2OH^-(aq)$ (more basic)
$SO_3(g) + H_2O(l) \longrightarrow H_2SO_4(aq) \longrightarrow H^+(aq) + HSO_4^-(aq)$
(b) BaO (c) CO_2 (d) K_2O **14.29**(a) LiCl (b) PCl_3 (c) NCl_3
14.31(a) Ar < Na < Si (b) Cs < Rb < Li **14.33** The outermost electron is attracted by a smaller effective nuclear charge in Li because of shielding by the inner electrons, and it is farther from the nucleus in Li. Both of these factors lead to a lower ionization energy.
14.35(a) NH_3 will hydrogen bond.



(b) CH_3CH_2OH will hydrogen bond.



14.37(a) $2Al(s) + 6HCl(aq) \longrightarrow 2AlCl_3(aq) + 3H_2(g)$
(b) $LiH(s) + H_2O(l) \longrightarrow LiOH(aq) + H_2(g)$
14.39(a) $NaBH_4$: +1 for Na, +3 for B, −1 for H
$Al(BH_4)_3$: +3 for Al, +3 for B, −1 for H
$LiAlH_4$: +1 for Li, +3 for Al, −1 for H
(b) tetrahedral



14.42 For Groups 1A(1) to 4A(14), the number of covalent bonds equals the (old) group number. For Groups 5A(15) to 7A(17), it equals 8 minus the (old) group number. There are exceptions in Period 3 to Period 6 because it is possible for the 3A(13) to 7A(17) elements to use *d* orbitals and form more bonds.
14.45(a) Group 3A(13) or 3B(3) (b) If E is in Group 3B(3), the oxide and fluoride will be more ionic. **14.48**(a) reducing agent (b) Alkali metals have relatively low ionization energies, which means they easily lose the outermost electron.
(c) $2Na(s) + 2H_2O(l) \longrightarrow 2Na^+(aq) + 2OH^-(aq) + H_2(g)$
$2Na(s) + Cl_2(g) \longrightarrow 2NaCl(s)$
14.50 Density and ionic size increase down a group; the other three properties decrease down a group. **14.52** $2Na(s) + O_2(g) \longrightarrow Na_2O_2(s)$ **14.54** $K_2CO_3(s) + 2HI(aq) \longrightarrow 2KI(aq) + H_2O(l) + CO_2(g)$ **14.58** Group 2A(2) metals have an additional bonding electron to increase the strength of metallic bonding, which leads to higher melting points, higher boiling points, greater hardness, and greater density. **14.59**(a) $CaO(s) + H_2O(l) \longrightarrow Ca(OH)_2(s)$ (b) $2Ca(s) + O_2(g) \longrightarrow 2CaO(s)$
14.62(a) $BeO(s) + H_2O(l) \longrightarrow$ no reaction (b) $BeCl_2(l) + 2Cl^-(solvated) \longrightarrow BeCl_4^{2-}(solvated)$. This behaves like other Group 2A(2) elements. **14.65** The electron removed from Group 2A(2) atoms occupies the outer *s* orbital, whereas in Group 3A(13) atoms, the electron occupies the outer *p* orbital. For example, the electron configuration for Be is $1s^22s^2$ and for B it is $1s^22s^22p^1$. It is easier to remove the *p* electron of B than an *s* electron of Be, because the energy of a *p* orbital is higher than that of the *s* orbital of the same level. Even though atomic size decreases because of increasing Z_{eff}, IE decreases from 2A(2) to 3A(13). **14.66**(a) Most atoms form stable compounds when they complete their outer shell (octet). Some compounds of Group 3A(13) elements, like boron, have only six electrons around the central atom. Having fewer than eight electrons is called an "electron deficiency."
(b) $BF_3(g) + NH_3(g) \longrightarrow F_3B{-}NH_3(g)$
$B(OH)_3(aq) + OH^-(aq) \longrightarrow B(OH)_4^-(aq)$
14.68 $In_2O_3 < Ga_2O_3 < Al_2O_3$ **14.70** Apparent O.N., +3; actual O.N., +1. The anion I_3^- has the general formula AX_2E_3 and bond angles of 180°. $(Tl^{3+})(I^-)_3$ does not exist because of the low strength of the Tl—I bond. $\left[:\ddot{I}{-}\ddot{I}{-}\ddot{I}:\right]^-$
14.75(a) $B_2O_3(s) + 2NH_3(g) \longrightarrow 2BN(s) + 3H_2O(g)$
(b) 1.30×10^2 kJ (c) 5.3 kg borax **14.76** Basicity in water is greater for the oxide of a metal. Tin(IV) oxide is more basic in water than carbon dioxide because tin has more metallic character than carbon. **14.78**(a) Ionization energy generally decreases down a group. (b) The deviations (increases) from the expected trend are due to the presence of the first transition series between Si and Ge and of the lanthanides between Sn and Pb. (c) Group 3A(13) **14.81** Atomic size increases down a group. As atomic size increases, ionization energy decreases and so it is easier to form a positive ion. An atom that is easier to ionize exhibits greater metallic character.
14.83(a)  (b) 
14.85 14.88(a) diamond, C (b) calcium carbonate, $CaCO_3$ (c) carbon dioxide, CO_2 (d) poly(dimethyl siloxane), $[(CH_3)_2SiO]_n$ (e) silicon carbide, SiC (f) carbon monoxide, CO (g) lead, Pb
14.92(a) −3 to +5 (b) For a group of nonmetals, the oxidation states range from the lowest, group number − 8, or 5 − 8 = −3 for Group 5A, to the highest, equal to the group number, or +5 for Group 5A. **14.95** $H_3AsO_4 < H_3PO_4 < HNO_3$
14.97(a) $4As(s) + 5O_2(g) \longrightarrow 2As_2O_5(s)$ (b) $2Bi(s) + 3F_2(g) \longrightarrow 2BiF_3(s)$ (c) $Ca_3As_2(s) + 6H_2O(l) \longrightarrow 3Ca(OH)_2(s) + 2AsH_3(g)$ **14.99**(a) $N_2(g) + 2Al(s) \xrightarrow{\Delta} 2AlN(s)$ (b) $PF_5(g) + 4H_2O(l) \longrightarrow H_3PO_4(aq) + 5HF(g)$
14.101 Trigonal bipyramidal, with axial F atoms and equatorial Cl atoms
14.105(a) $\ddot{O}{=}\ddot{N}{-}\ddot{N}{=}\ddot{O}$ (b) $\ddot{O}{=}\ddot{N}{-}\ddot{O}{=}\ddot{N}:$
(c)  (d) 14.107(a) $2KNO_3(s) \xrightarrow{\Delta} 2KNO_2(s) + O_2(g)$ (b) $4KNO_3(s) \xrightarrow{\Delta} 2K_2O(s) + 2N_2(g) + 5O_2(g)$ **14.109**(a) Boiling point and conductivity vary in similar ways down both groups. (b) Degree of metallic character and types of bonding vary in similar ways down both groups. (c) Both P and S have allotropes, and both bond covalently with almost every other nonmetal. (d) Both N and O are diatomic gases at normal temperatures and pressures. (e) O_2 is a reactive gas, whereas N_2 is not. Nitrogen can have any of six oxidation states, whereas oxygen has two.
14.111(a) $NaHSO_4(aq) + NaOH(aq) \longrightarrow Na_2SO_4(aq) + H_2O(l)$
(b) $S_8(s) + 24F_2(g) \longrightarrow 8SF_6(g)$
(c) $FeS(s) + 2HCl(aq) \longrightarrow H_2S(g) + FeCl_2(aq)$
(d) $Te(s) + 2I_2(s) \longrightarrow TeI_4(s)$
14.113 (a) acidic (b) acidic (c) basic (d) amphoteric (e) basic **14.115** $H_2O < H_2S < H_2Te$ **14.118**(a) SF_6, sulfur hexafluoride (b) O_3, ozone (c) SO_3, sulfur trioxide (d) SO_2, sulfur dioxide (e) SO_3, sulfur trioxide (f) $Na_2S_2O_3{\cdot}5H_2O$, sodium thiosulfate pentahydrate (g) H_2S, hydrogen sulfide
14.120 $S_2F_{10}(g) \longrightarrow SF_4(g) + SF_6(g)$; O.N. of S in S_2F_{10} is +5; O.N. of S in SF_4 is +4; O.N. of S in SF_6 is +6. **14.122**(a) −1, +1, +3, +5, +7 (b) The electron configuration for Cl is [Ne] $3s^23p^5$. By gaining one electron, Cl achieves an octet. By forming covalent bonds, Cl completes or expands its valence level by maintaining electrons pairs in bonds or as lone pairs. (c) Fluorine has only the −1 oxidation state because its small size and absence of *d* orbitals prevent it from forming more than one covalent bond. **14.124**(a) Cl—Cl bond is stronger than Br—Br bond. (b) Br—Br bond is stronger than I—I bond.
(c) Cl—Cl bond is stronger than F—F bond. The fluorine atoms are so small that electron-electron repulsion of the lone pairs decreases the strength of the bond.
14.126(a) $3Br_2(l) + 6OH^-(aq) \longrightarrow 5Br^-(aq) + BrO_3^-(aq) + 3H_2O(l)$
(b) $ClF_5(l) + 6OH^-(aq) \longrightarrow 5F^-(aq) + ClO_3^-(aq) + 3H_2O(l)$
14.127(a) $2Rb(s) + Br_2(l) \longrightarrow 2RbBr(s)$
(b) $I_2(s) + H_2O(l) \longrightarrow HI(aq) + HIO(aq)$

(c) $Br_2(l) + 2I^-(aq) \longrightarrow I_2(s) + 2Br^-(aq)$
(d) $CaF_2(s) + H_2SO_4(l) \longrightarrow CaSO_4(s) + 2HF(g)$

14.129 $HIO < HBrO < HClO < HClO_2$ **14.133** $I_2 < Br_2 < Cl_2$, because Cl_2 is able to oxidize Re to the +6 oxidation state, Br_2 only to +5, and I_2 only to +4. **14.134** helium; argon

14.136 Only dispersion forces hold atoms of noble gases together.

14.162 117.2 kJ **14.165** 25.0 g CS_2. It is not possible to determine how much S_2Cl_2 and SCl_2 formed. The ratio of S_2Cl_2 to SCl_2 is unknown. **14.168** Both compounds contain 2 mol of N per mole of compound. N_2H_4 has the higher mass of N per gram of compound.

14.170 
(a) sp^3 orbitals (b) tetrahedral (c) Since the ion is linear, the central Cl atom must be *sp* hybridized. (d) The *sp* hybridization means there are no lone pairs on the central Cl atom. Instead, the extra four electrons interact with the empty *d* orbitals on the Al atoms to form double bonds between the chlorine and each aluminum atom.

14.172 
The nitronium ion (NO_2^+) has a linear shape because the central N atom has two surrounding electron groups, which achieve maximum repulsion at 180°. The nitrite ion (NO_2^-) bond angle is more compressed than the nitrogen dioxide (NO_2) bond angle because the lone pair of electrons takes up more space than the lone electron. **14.174** 2.29×10^4 g UF_6 **14.179** O^+, O^-, and O^{2+} **14.180**(a) 39.96 mass % in $CuHAsO_3$; As, 62.42 mass % in $(CH_3)_3As$ (b) 0.35 g $CuHAsO_3$

Chapter 15

15.3(a) Carbon's electronegativity is midway between the most metallic and nonmetallic elements of Period 2. To attain a filled outer shell, carbon forms covalent bonds to other atoms in molecules, network covalent solids, and polyatomic ions. (b) Since carbon has four valence shell electrons, it forms four covalent bonds to attain an octet. (c) To reach the He electron configuration, a carbon atom must lose four electrons, requiring too much energy to form the C^{4+} cation. To reach the Ne electron configuration, the carbon atom must gain four electrons, also requiring too much energy to form the C^{4-} anion. (d) Carbon is able to bond to itself extensively because its small size allows for close approach and great orbital overlap. The extensive orbital overlap results in a strong, stable bond. (e) The C—C bond is short enough to allow sideways overlap of unhybridized *p* orbitals of neighboring C atoms. The sideways overlap of *p* orbitals results in the π bonds that are part of double and triple bonds.

15.4(a) C H, O, N, P, S, and halogens (b) Heteroatoms are atoms of any element other than carbon and hydrogen. (c) More electronegative than C: N, O, F, Cl, and Br; less electronegative than C: H and P. Sulfur and iodine have the same electronegativity as carbon. (d) Since carbon can bond to a wide variety of heteroatoms and to carbon atoms, it can form many different compounds. **15.7** The C—H and C—C bonds are unreactive because electron density is shared equally between the two atoms. The C—I bond is somewhat reactive because it is long and weak. The C=O bond is reactive because oxygen is more electronegative than carbon and the electron-rich π bond makes it attract electron-poor atoms. The C—Li bond is also reactive because the bond polarity results in an electron-rich region around carbon and an electron-poor region around lithium.

15.8(a) An alkane and a cycloalkane are organic compounds that consist of carbon and hydrogen and have only single bonds. A cycloalkane has a ring of carbon atoms. An alkene is a hydrocarbon with at least one double bond. An alkyne is a hydrocarbon with at least one triple bond. (b) alkane = C_nH_{2n+2}, cycloalkane = C_nH_{2n}, alkene = C_nH_{2n}, alkyne = C_nH_{2n-2}
(c) Alkanes and cycloalkanes are saturated hydrocarbons.

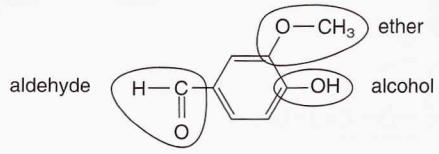
(c) Carbons 2, 3, and 5 are chiral centers, as they are each bonded to four different groups.

15.113



The shortest carbon-oxygen bond is the double bond in the aldehyde group. **15.116** The resonance structures show that the bond between carbon and nitrogen will have some double bond character that restricts rotation around the bond.

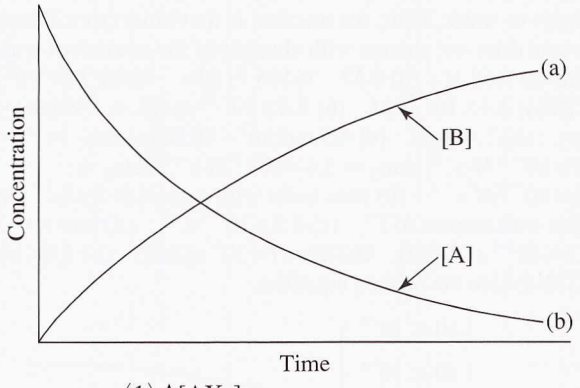
15.120(a) Hydrolysis requires the addition of water to break the peptide bonds. (b) glycine, 4; alanine, 1; valine, 3; proline, 6; serine, 7; arginine, 49 (c) 10,700 g/mol **15.122** When 2-butanone is reduced, equal amounts of both isomers are produced because the reaction does not favor the production of one over the other.

Chapter 16

16.2 Reaction rate is proportional to concentration. An increase in pressure will increase the concentration, resulting in an increased reaction rate. **16.3** The addition of water will dilute the concentrations of all dissolved solutes, and the rate of the reaction will decrease. **16.5** An increase in temperature affects the rate of a reaction by increasing the number of collisions between particles, but more importantly, the energy of collisions increases. Both these factors increase the rate of reaction. **16.8**(a) The slope of the line joining any two points on a graph of concentra-

tion versus time gives the average rate between the two points. The closer the points, the closer the average rate will be to the instantaneous rate. (b) The initial rate is the instantaneous rate at the point on the graph where time = 0, that is, when reactants are mixed.

16.10

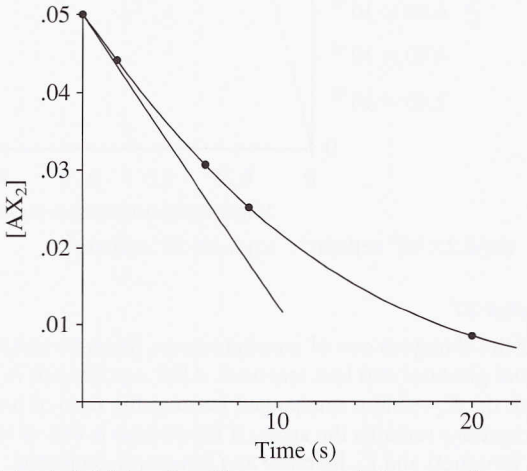


16.12(a) rate $= -\left(\frac{1}{2}\right)\frac{\Delta[AX_2]}{\Delta t}$

$= -\left(\frac{1}{2}\right)\frac{(0.0088\ M - 0.0500\ M)}{(20.0\ \text{s} - 0\ \text{s})}$

$= 0.0010\ M/\text{s}$

(b)



The initial rate is higher than the average rate because the rate will decrease as reactant concentration decreases.

16.14 rate $= -\frac{1}{2}\frac{\Delta[A]}{\Delta t} = \frac{\Delta[B]}{\Delta t} = \frac{\Delta[C]}{\Delta t}$; 4 mol/L·s

16.16 rate $= -\frac{\Delta[A]}{\Delta t} = -\frac{1}{2}\frac{\Delta[B]}{\Delta t} = \frac{\Delta[C]}{\Delta t}$; 0.2 mol/L·s

16.18 $2N_2O_5(g) \longrightarrow 4NO_2(g) + O_2(g)$

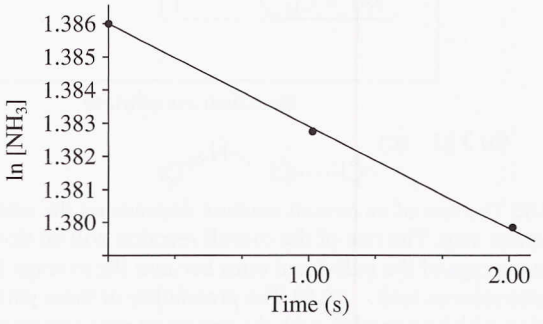
16.21 rate $= -\frac{\Delta[N_2]}{\Delta t} = -\frac{1}{3}\frac{\Delta[H_2]}{\Delta t} = \frac{1}{2}\frac{\Delta[NH_3]}{\Delta t}$

16.22(a) rate $= -\frac{1}{3}\frac{\Delta[O_2]}{\Delta t} = \frac{1}{2}\frac{\Delta[O_3]}{\Delta t}$ (b) 1.45×10^{-5} mol/L·s

16.23(a) k is the rate constant, the proportionality constant in the rate law; it is reaction and temperature specific. (b) m represents the order of the reaction with respect to [A], and n represents the order of the reaction with respect to [B]. The order of a reactant does not necessarily equal its stoichiometric coefficient in the balanced equation. (c) $L^2/mol^2\cdot min$ **16.25**(a) Rate doubles. (b) Rate decreases by a factor of four. (c) Rate increases by a factor of nine. **16.26** first order in BrO_3^-; first order in Br^-; second order in H^+; fourth order overall **16.28**(a) Rate doubles. (b) Rate is halved. (c) The rate increases by a factor of 16. **16.30** second order in NO_2; first order in Cl; third order overall **16.32**(a) Rate increases by a factor of 9. (b) Rate increases by a factor of 8. (c) Rate is halved. **16.34**(a) second order in A; first order in B (b) rate $= k[A]^2[B]$ (c) $5.00\times10^3\ L^2/mol^2\cdot min$ **16.36**(a) $time^{-1}$ (b) L/mol·time (c) $L^2/mol^2\cdot time$ (d) $L^{3/2}/mol^{3/2}\cdot time$ **16.39**(a) first order (b) second order (c) zero order **16.41** 7 s **16.43**(a) $k = 0.0660\ min^{-1}$ (b) 21.0 min

16.45(a)

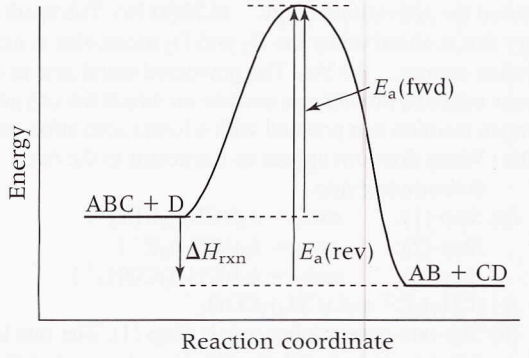
x-axis (time, s)	$[NH_3]$	y-axis (ln $[NH_3]$)
0	4.000 *M*	1.38629
1.000	3.986 *M*	1.38279
2.000	3.974 *M*	1.37977



(b) $t_{1/2} = 2\times10^2$ s

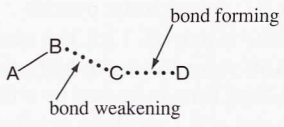
16.47 Measure the rate constant at a series of temperatures and plot ln k versus $1/T$. The slope of the line equals $-E_a/R$. **16.49** 0.033 s^{-1} **16.53** No, other factors that affect the fraction of collisions that lead to reaction are the energy and orientation of the collisions. **16.56** No, reaction is reversible and will eventually reach a state where the forward and reverse rates are equal. When this occurs, there are no concentrations equal to zero. Since some reactants are reformed from EF, the amount of EF will be less than 4×10^{-5} mol. **16.57** At the same temperature, both reaction mixtures have the same average kinetic energy, but not the same velocity. The trimethylamine molecule has greater mass than the ammonia molecule, so trimethylamine molecules will collide less often with HCl. Moreover, the bulky groups bonded to nitrogen in trimethylamine mean that collisions with HCl having the correct orientation occur less frequently. Therefore, the rate of the first reaction is greater. **16.58** 12 unique collisions **16.60** 2.96×10^{-18}

16.62(a)

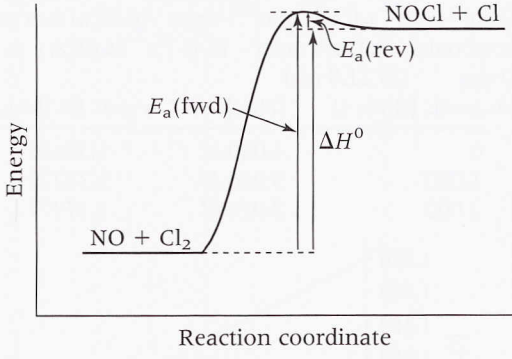


(b) 2.70×10^2 kJ/mol

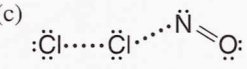
(c)



16.64(a) Because the enthalpy change is positive, the reaction is endothermic.



(b) 3 kJ (c)



16.65 The rate of an overall reaction depends on the rate of the slowest step. The rate of the overall reaction will be slower than the average of the individual rates because the average includes faster rates as well. **16.69** The probability of three particles colliding with one another with the proper energy and orientation is much less than the probability for two particles. **16.70** No, the overall rate law must contain only reactants (no intermediates), and the overall rate is determined by the slow step.

16.72(a) $A(g) + B(g) + C(g) \longrightarrow D(g)$

(b) X and Y are intermediates.

(c)

Step	Molecularity	Rate Law
$A(g) + B(g) \rightleftharpoons X(g)$	bimolecular	$rate_1 = k_1[A][B]$
$X(g) + C(g) \longrightarrow Y(g)$	bimolecular	$rate_2 = k_2[X][C]$
$Y(g) \longrightarrow D(g)$	unimolecular	$rate_3 = k_3[Y]$

(d) yes (e) yes **16.74** The proposed mechanism is valid because the individual steps are chemically reasonable and add to give the overall equation. In addition, the rate law for the mechanism matches the observed rate law. **16.77** No. A catalyst changes the mechanism of a reaction to one with lower activation energy. Lower activation energy means a faster reaction. An increase in temperature does not influence the activation energy, but increases the fraction of collisions with sufficient energy to equal or exceed the activation energy. **16.78**(a) No. The spark provides energy that is absorbed by the H_2 and O_2 molecules to achieve the activation energy. (b) Yes. The powdered metal acts as a heterogeneous catalyst, providing a surface on which the oxygen-hydrogen reaction can proceed with a lower activation energy.

16.82(a) Water does not appear as a reactant in the rate-determining step.

(b) Step (1): $rate_1 = k_1[(CH_3)_3CBr]$
Step (2): $rate_2 = k_2[(CH_3)_3C^+]$
Step (3): $rate_3 = k_3[(CH_3)_3COH_2^+]$

(c) $(CH_3)_3C^+$ and $(CH_3)_3COH_2^+$

(d) The rate-determining step is Step (1). The rate law for this step agrees with the rate law observed with $k = k_1$.

16.85 4.61×10^4 J/mol **16.89**(a) Rate increases 2.5 times. (b) Rate is halved. (c) Rate decreases by a factor of 0.01. (d) Rate does not change. **16.92** second order **16.94** 7 times faster **16.96** 57 yr **16.99** (a) 0.21 h^{-1}; 3.3 h (b) 6.6 h (c) If the concentration of sucrose is relatively low, the concentration of water remains nearly constant even with small changes in the amount of water. This gives an apparent zero-order reaction with respect to water. Thus, the reaction is first order overall because the rate does not change with changes in the amount of water. **16.101**(a) 0.68 *M* (b) 0.57 **16.104** 71 kPa **16.107** 7.3×10^3 J/mol **16.110**(a) 2.4×10^{-15} *M* (b) 2.4×10^{-11} mol/L·s **16.113**(a) 2.8 days (b) 7.4 days (c) 4.5 mol/m^3 **16.116**(a) $rate_1 = 1.7\times10^{-5}\ M\ s^{-1}$; $rate_2 = 3.4\times10^{-5}\ M\ s^{-1}$; $rate_3 = 3.4\times10^{-5}\ M\ s^{-1}$ (b) zero order with respect to $S_2O_8^{2-}$; first order with respect to I^- (c) $4.3\times10^{-4}\ s^{-1}$ (d) rate = $(4.3\times10^{-4}\ s^{-1})[KI]$ **16.119**(a) 7×10^4 cells/L (b) 2.0×10^1 min **16.122**(a) Use the Monod equation.

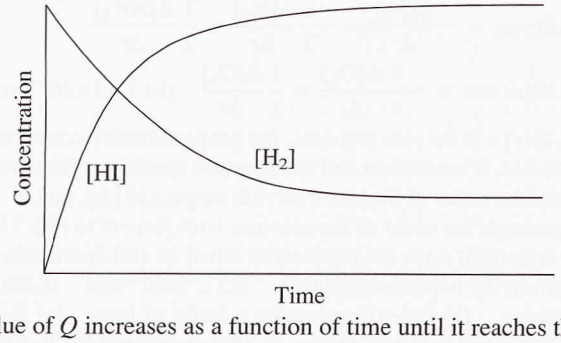
Chapter 17

17.1 If the change is one of concentrations, it results temporarily in more products and less reactants. After equilibrium is reestablished, the K_c remains unchanged because the ratio of products and reactants remains the same. If the change is one of temperature, [product] and K_c increase and [reactant] decreases.

17.5 This reaction is very exothermic, so it will probably have a large *K*. **17.7** The equilibrium constant expression is $K = [O_2]$. If the temperature remains constant, *K* remains constant. If the initial amount of Li_2O_2 present is sufficient to reach equilibrium, the amount of O_2 obtained will be constant.

17.8(a) $Q = \dfrac{[HI]^2}{[H_2][I_2]}$



The value of *Q* increases as a function of time until it reaches the value of *K*. (b) no **17.11** Yes. If Q_1 is for the formation of

1 mol NH_3 from H_2 and N_2, and Q_2 is for the formation of NH_3 from H_2 and 1 mol of N_2, then $Q_2 = {Q_1}^2$.

Chapter 18

18.2 All Arrhenius acids contain hydrogen in their formula and produce hydronium ion (H_3O^+) in aqueous solution. All Arrhenius bases produce hydroxide ion (OH^-) in aqueous solution. Neutralization occurs when each H_3O^+ ion combines with an OH^- ion to form two molecules of H_2O. Chemists found the reaction of any strong base with any strong acid always produced 56 kJ/mol ($\Delta H = -56$ kJ/mol), which was consistent with Arrhenius' hypothesis describing neutralization. **18.4** Strong acids and bases dissociate completely into ions when dissolved in water. Weak acids and bases dissociate only partially. The

characteristic property of all weak acids is that a significant number of the acid molecules are undissociated. **18.5**(a), (c), and (d) **18.7** (b) and (d)

18.9(a) $K_a = \dfrac{[CN^-][H_3O^+]}{[HCN]}$

(b) $K_a = \dfrac{[CO_3^{2-}][H_3O^+]}{[HCO_3^-]}$

(c) $K_a = \dfrac{[HCOO^-][H_3O^+]}{[HCOOH]}$

18.11(a) $K_a = \dfrac{[NO_2^-][H_3O^+]}{[HNO_2]}$

(b) $K_a = \dfrac{[CH_3COO^-][H_3O^+]}{[CH_3COOH]}$

(c) $K_a = \dfrac{[BrO_2^-][H_3O^+]}{[HBrO_2]}$

18.13 $CH_3COOH < HF < HIO_3 < HI$ **18.15**(a) weak acid (b) strong base (c) weak acid (d) strong acid **18.17**(a) strong base b) strong acid (c) weak acid (d) weak acid

18.22(a) The acid with the smaller K_a (4×10^{-5}) has the higher pH, because less dissociation yields fewer hydronium ions. (b) The acid with the larger pK_a (3.5) has the high pH, because a larger pK_a means a smaller K_a. (c) Lower concentration (0.01 *M*) gives fewer hydronium ions. (d) A 0.1 *M* weak acid solution gives fewer hydronium ions. (e) The 0.1 *M* base solution has a lower concentration of hydronium ions. (f) The pOH = 6.0 because pH = 14.0 − 6.0 = 8.0 **18.23**(a) 12.05; basic (b) 11.09; acidic **18.25**(a) 2.298; acidic (b) −0.708; basic

18.27(a) $[H_3O^+] = 1.7\times10^{-10}$ *M*, pOH = 4.22, $[OH^-] = 6.0\times10^{-5}$ *M* (b) pH = 3.57, $[H_3O^+] = 2.7\times10^{-4}$ *M*, $[OH^-] = 3.7\times10^{-11}$ *M* **18.29**(a) $[H_3O^+] = 1.7\times10^{-3}$ *M*, pOH = 11.23, $[OH^-] = 5.9\times10^{-12}$ *M* (b) pH = 8.82, $[H_3O^+] = 1.5\times10^{-9}$ *M*, $[OH^-] = 6.6\times10^{-6}$ *M* **18.31** 3.4×10^{-4} mol OH^-/L

18.33 6×10^{-5} mol OH^- **18.36**(a) Rising temperature increases the value of K_w. (b) $K_w = 2.5\times10^{-14}$; pOH = 6.80; $[OH^-] = 1.6\times10^{-7}$ *M* **18.37** The Brønsted-Lowry theory defines acids as proton donors and bases as proton acceptors, while the Arrhenius definition looks at acids as containing ionizable hydrogen atoms and at bases as containing hydroxide ions. In both definitions, an acid produces hydronium ions and a base produces hydroxide ions when added to water. Ammonia and carbonate ion are two Brønsted-Lowry bases that are not Arrhenius bases because they do not contain hydroxide ions. Brønsted-Lowry acids must contain an ionizable hydrogen atom in order to be proton donors, so a Brønsted-Lowry acid is also an Arrhenius acid. **18.40** An amphoteric species can act as either an acid or a base. The dihydrogen phosphate ion, $H_2PO_4^-$, is an example.

18.41(a) $H_3PO_4(aq) + H_2O(l) \rightleftharpoons H_2PO_4^-(aq) + H_3O^+(aq)$;

(b) In an oxygen-deficient environment the equilibrium shifts to the left to release oxygen. (c) A decrease in $[H_3O^+]$ shifts the equilibrium to the right. More oxygen is absorbed, but it will be more difficult to remove the O_2. (d) An increase in $[H_3O^+]$ shifts the equilibrium to the left. Less oxygen is bound to Hb, but it will be easier to remove it. **18.185**(a) 1.012 M (b) 0.004 M (c) 0.4%
18.186(a) 10.0 (b) The pK_b for the 3° amine group is much smaller than that for the aromatic ring, thus the K_b is significantly larger (yielding a much greater amount of OH^-). (c) 4.6 (d) 5.1

Chapter 19

19.2 The acid component neutralizes added base and the base component neutralizes added acid so the pH of the buffer solution remains relatively constant. The components of a buffer do not neutralize one another because they are a conjugate acid-base pair. **19.4** The pH of a buffer decreases only slightly with added H_3O^+. **19.7** The buffer range, the pH over which the buffer acts effectively, is greatest when the buffer-component ratio is 1; the range decreases as the component ratio deviates from 1.
19.9(a) Ratio and pH increase; added OH^- reacts with HA.
(b) Ratio and pH decrease; added H^+ reacts with A^-. (c) Ratio and pH increase; added A^- increases $[A^-]$. (d) Ratio and pH decrease; added HA increases [HA]. **19.11** $[H_3O^+] = 7.8\times10^{-6}\ M$; pH = 5.11 **19.13** $[H_3O^+] = 5.5\times10^{-4}\ M$; pH = 3.26

$H_2AsO_4^-/HAsO_4^{2-}$ **19.35**(a) $H_3AsO_4/H_2AsO_4^-$ or $H_3PO_4/H_2PO_4^-$ (b) $C_5H_5N/C_5H_5NH^+$ **19.38** 1.6 **19.40** To see a distinct color in a mixture of two colors, you need one to have about 10 times the intensity of the other. For this to be the case, the concentration ratio [HIn]/[In^-] has to be greater than 10:1 or less than 1:10. This occurs when pH = $pK_a - 1$ or pH = $pK_a + 1$, respectively, giving a pH range of about two units. **19.42** The equivalence point in a titration is the point at which the number of moles of base equals the number of moles of acid. The endpoint is the point at which the added indicator changes color. If an appropriate indicator is selected, the endpoint is close to the equivalence point, but they are not usually the same. The endpoint, or color change, may precede or follow the equivalence point, depending on the indicator chosen. **19.44**(a) initial pH: *strong acid*–strong base < *weak acid*–strong base < strong acid–*weak base* (b) equivalence point: strong acid–*weak base* < *strong acid*–strong base < *weak acid*–strong base **19.46** At the center of the buffer region, the concentrations of weak acid and conjugate base are equal, so the pH = pK_a of the acid. **19.48** pH range from 7.3 to 9.3 **19.50**(a) bromthymol blue (b) thymol blue or phenolphthalein **19.52**(a) methyl red (b) bromthymol blue **19.54**(a) 1.00 (b) 1.48 (c) 3.00 (d) 4.00 (e) 7.00 (f) 10.00 (g) 11.96 **19.56**(a) 2.91 (b) 4.81 (c) 5.29 (d) 6.09 (e) 7.40 (f) 8.76 (g) 10.10 (h) 12.05 **19.58**(a) 59.0 mL and 8.54 (b) 45.2 mL and 7.14, total 90.4 mL and 9.69 **19.60**(a) 96.2 mL and 5.16 (b) 146 mL and 5.78 **19.63** Fluoride ion is the conjugate base of a weak acid and reacts with H_2O: $F^-(aq) + H_2O(l) \rightleftharpoons HF(aq) + OH^-(aq)$. As the pH increases, the equilibrium shifts to the left and [F^-] increases. As the pH decreases, the equilibrium shifts to the right and [F^-] decreases. The changes in [F^-] influence the solubility of CaF_2. Chloride ion is the conjugate base of a strong acid so it does not react with water and its concentration is not influenced by pH. **19.65** The compound precipitates. **19.66**(a) $K_{sp} = [Ag^+]^2[CO_3^{2-}]$ (b) $K_{sp} = [Ba^{2+}][F^-]^2$ (c) $K_{sp} = [Cu^{2+}][HS^-][OH^-]$ **19.68**(a) $K_{sp} = [Ca^{2+}][CrO_4^{2-}]$ (b) $K_{sp} = [Ag^+][CN^-]$ (c) $K_{sp} = [Ni^{2+}][HS^-][OH^-]$ **19.70** 1.3×10^{-4} **19.72** 2.8×10^{-11} **19.74**(a) $2.3\times10^{-5}\ M$ (b) $4.2\times10^{-9}\ M$ **19.76**(a) $1.7\times10^{-3}\ M$ (b) $2.0\times10^{-4}\ M$ **19.78**(a) $Mg(OH)_2$ (b) PbS (c) Ag_2SO_4 **19.80**(a) $CaSO_4$ (b) $Mg_3(PO_4)_2$ (c) $PbSO_4$ **19.82**(a) $AgCl(s) \rightleftharpoons Ag^+(aq) + Cl^-(aq)$. The chloride ion is the anion of a strong acid, so it does not react with H_3O^+. No change with pH. (b) $SrCO_3(s) \rightleftharpoons Sr^{2+}(aq) + CO_3^{2-}(aq)$. The strontium ion is the cation of a strong base so pH will not affect its solubility. The carbonate ion acts as a base: $CO_3^{2-}(aq) + H_2O(l) \rightleftharpoons HCO_3^-(aq) + OH^-(aq)$; also $CO_2(g)$ forms and escapes: $CO_3^{2-}(aq) + 2H_3O^+(aq) \longrightarrow CO_2(g) + 2H_2O(l)$. Therefore, the solubility of $SrCO_3$ will increase with addition of H_3O^+ (decreasing pH). **19.84**(a) $Fe(OH)_2(s) \rightleftharpoons Fe^{2+}(aq) + 2OH^-(aq)$. The OH^- ion reacts with added H_3O^+: $OH^-(aq) + H_3O^+(aq) \longrightarrow 2H_2O(l)$. The added H_3O^+ consumes the OH^-, driving the equilibrium toward the right to dissolve more $Fe(OH)_2$. Solubility increases with addition of H_3O^+ (decreasing pH). (b) $CuS(s) + H_2O(l) \rightleftharpoons Cu^{2+}(aq) + HS^-(aq) + OH^-(aq)$. Both HS^- and OH^- are anions of weak acids, so both ions react with added H_3O^+. Solubility increases with addition of H_3O^+ (decreasing pH). **19.86** yes **19.88** yes **19.93** No, because it indicates that a complex ion forms between the lead ion and hydroxide ions: $Pb^{2+}(aq) + nOH^-(aq) \rightleftharpoons Pb(OH)_n^{2-n}(aq)$ **19.94** $Hg(H_2O)_4^{2+}(aq) + 4CN^-(aq) \rightleftharpoons Hg(CN)_4^{2-}(aq) + 4H_2O(l)$ **19.96** $Ag(H_2O)_2^+(aq) + 2S_2O_3^{2-}(aq) \rightleftharpoons Ag(S_2O_3)_2^{3-}(aq) + 2H_2O(l)$ **19.98** $1\times10^{-5}\ M$ **19.100** $7.0\times10^{-17}\ M\ Zn^{2+}$; 0.024 $M\ Zn(CN)_4^{2-}$; 0.053 $M\ CN^-$ **19.102** $9.4\times10^{-5}\ M$ **19.104**(a) $Fe(OH)_3$ (b) The two metal ions are separated by adding just enough NaOH to precipitate iron(III) hydroxide. (c) $2.0\times10^{-7}\ M$ **19.106** 0.121 L of 2.00 M NaOH and 0.379 L of 0.200 M HCOOH **19.108**(a) 0.99 (b) Assuming the volumes are additive: 0.401 L of 1.0 M HCOOH and 0.199 L of 1.0 M NaOH (c) 0.34 M **19.110** $1.3\times10^{-4}\ M$ **19.114**(a) 14 (b) 1 g **19.117**(a) 0.88 (b) 0.14 **19.119** TRIS = 0.260 M; 8.53 **19.121** Lower the pH below 6.6. **19.124** 8×10^{-5}

Chapter 20

20.2 A spontaneous process occurs by itself, whereas a nonspontaneous process requires a continuous input of energy to make it happen. It is possible to cause a nonspontaneous process to occur, but the process stops once the energy source is removed. A reaction that is nonspontaneous under one set of conditions may be spontaneous under a different set of conditions. **20.5** The transition from liquid to gas involves a greater increase in dispersal of energy and freedom of motion than does the transition from solid to liquid. **20.6** In an exothermic reaction, $\Delta S_{surr} > 0$. In an endothermic reaction, $\Delta S_{surr} < 0$. A chemical cold pack for injuries is an example of an application using a spontaneous endothermic process. **20.8**(a), (b), and (c) **20.10**(a) and (b) **20.12**(a) positive (b) negative (c) negative **20.14**(a) positive (b) positive (c) positive **20.16**(a) negative (b) negative (c) positive **20.18**(a) positive (b) negative (c) positive **20.20**(a) positive (b) negative (c) positive **20.22**(a) Butane. The double bond in 2-butene restricts freedom of rotation. (b) Xe(*g*) because it has the greater molar mass (c) $CH_4(g)$. Gases have greater entropy than liquids. **20.24**(a) $C_2H_5OH(l)$ is a more complex molecule. (b) $KClO_3(aq)$. Ions in solution have their energy more dispersed than those in a solid. (c) K(*s*), because it has a greater molar mass. **20.26**(a) diamond < graphite < charcoal. Freedom of motion is least in the network solid; more freedom between graphite sheets; most freedom in amorphous solid. (b) ice < liquid water < water vapor. Entropy increases as a substance changes from solid to liquid to gas. (c) O atoms < O_2 < O_3. Entropy increases with molecular complexity. **20.28**(a) $ClO_4^-(aq) > ClO_3^-(aq) > ClO_2^-(aq)$; decreasing molecular complexity (b) $NO_2(g) > NO(g) > N_2(g)$. N_2 has lower standard molar entropy because it consists of two of the same atoms; the other species have two different types of atoms. NO_2 is more complex than NO. (c) $Fe_3O_4(s) > Fe_2O_3(s) > Al_2O_3(s)$. Fe_3O_4 is more complex and more massive. Fe_2O_3 is more massive than Al_2O_3. **20.31** For a system at equilibrium, $\Delta S_{univ} = \Delta S_{sys} + \Delta S_{surr} = 0$. For a system moving to equilibrium, $\Delta S_{univ} > 0$. **20.32** $S^0_{Cl_2O(g)} = 2S^0_{HClO(g)} - S^0_{H_2O(g)} - \Delta S^0_{rxn}$ **20.33**(a) negative; $\Delta S^0 = -172.4$ J/K (b) positive; $\Delta S^0 = 141.6$ J/K (c) negative; $\Delta S^0 = -837$ J/K **20.35** $\Delta S^0 = 93.1$ J/K; yes, the positive sign of ΔS is expected because there is a net increase in the number of gas molecules. **20.37** $\Delta S^0 = -311$ J/K. Yes, the negative entropy change matches the decrease in moles of gas. **20.39** −75.6 J/K **20.41** −242 J/K **20.44** −97.2 J/K **20.46** A spontaneous process has $\Delta S_{univ} > 0$. Since the absolute temperature is always positive, ΔG_{sys} must be negative ($\Delta G_{sys} < 0$) for a spontaneous process. **20.48** ΔH^0_{rxn} is positive and ΔS^0_{sys} is positive. Melting is an example. **20.49** The entropy changes little within a phase. As long as the substance does not change phase, the value of ΔS^0 is relatively unaffected by temperature. **20.50**(a) −1138.0 kJ (b) −1379.4 kJ (c) −224 kJ **20.52**(a) −1138 kJ (b) −1379 kJ (c) −226 kJ **20.54**(a) Entropy decreases (ΔS^0 is negative) because the number of moles of gas decreases. The combustion of CO releases energy (ΔH^0 is negative). (b) −257.2 kJ or 257.3 kJ, depending on the method **20.56**(a) −0.409 kJ/mol·K (b) −197 kJ/mol **20.58**(a) $\Delta H^0_{rxn} = 90.7$ kJ; $\Delta S^0_{rxn} = 221$ J/K (b) at 38°C, $\Delta G^0 = 22.1$ kJ; at 138°C, $\Delta G^0 = 0.0$ kJ; at 238°C, $\Delta G^0 = -22.1$ kJ (c) For the substances in their standard states, the reaction is nonspontaneous at 38°C, near equilibrium at 138°C, and spontaneous at 238°C. **20.60** $\Delta H^0 = 30910$ J, $\Delta S^0 = 93.15$ J/K, $T = 331.8$ K **20.62**(a) $\Delta H^0_{rxn} = -241.826$ kJ, $\Delta S^0_{rxn} = -44.4$ J/K, $\Delta G^0_{rxn} = -228.60$ kJ (b) Yes. The reaction will become nonspontaneous at higher temperatures. (c) The reaction is spontaneous below 5.45×10^3 K. **20.64**(a) ΔG^0 is a relatively large positive value. (b) $K >> 1$. Q depends on initial conditions, not equilibrium conditions. **20.67** The standard free energy change, ΔG^0, applies when all components of the system are in their standard states; $\Delta G^0 = \Delta G$. **20.68**(a) 1.7×10^6 (b) 3.89×10^{-34} (c) 1.26×10^{48} **20.70**(a) 6.57×10^{173} (b) 4.46×10^{-15} (c) 3.46×10^4 **20.72** 4.89×10^{-51} **20.74** 3.36×10^5 **20.76** 2.7×10^4 J/mol; no **20.78**(a) 2.9×10^4 J/mol (b) The reverse direction, formation of reactants, is spontaneous so the reaction proceeds to the left. (c) 7.0×10^3 J/mol; the reaction proceeds to the left to reach equilibrium. **20.80**(a) no T (b) 163 kJ (c) 1×10^2 kJ/mol **20.83**(a) spontaneous (b) + (c) + (d) − (e) −, not spontaneous (f) − **20.87**(a) 2.3×10^2 (b) Administer oxygen-rich air to counteract the CO poisoning. **20.90** −370. kJ **20.92**(a) $2N_2O_5(g) + 6F_2(g) \longrightarrow 4NF_3(g) + 5O_2(g)$ (b) $\Delta G^0_{rxn} = -569$ kJ (c) $\Delta G_{rxn} = -5.60\times10^2$ kJ/mol **20.95** $\Delta H^0_{rxn} = -137.14$ kJ; $\Delta S^0_{rxn} = -120.3$ J/K; $\Delta G^0_{rxn} = -101.25$ kJ **20.96**(a) $\Delta H^0_{rxn} = 470.5$ kJ; $\Delta S^0_{rxn} = 558.4$ J/K (b) The reaction will be spontaneous at high T, because the $-T\Delta S$ term will be larger in magnitude than ΔH. (c) no (d) 842.5 K **20.98**(a) yes, negative Gibbs free energy (b) Yes. It becomes spontaneous at 362.8 K. (c) 414 K. The temperature is different because the ΔH and ΔS values for N_2O_5 vary with physical state. **20.100**(a) 1.203×10^{23} molecules ATP/g glucose (b) 3.073×10^{23} molecules ATP/g tristearin **20.106**(a) 1.67×10^3 J/mol (b) 7.37×10^3 J/mol (c) -4.04×10^3 J/mol (d) 0.19 **20.110**(a) 465 K (b) 6.59×10^{-4} (c) The reaction rate is higher at the higher temperature. The shorter time required (kinetics) overshadows the lower yield (thermodynamics).

Chapter 21

21.1 Oxidation is the loss of electrons and results in a higher oxidation number; reduction is the gain of electrons and results in a lower oxidation number. **21.3** No, one half-reaction cannot take place independently because there is a transfer of electrons from

one substance to another. If one substance loses electrons, another substance must gain them. **21.6** To remove H^+ ions from an equation, add an equal number of OH^- ions to both sides to neutralize the H^+ ions and produce water. **21.8** Spontaneous reactions, $\Delta G_{sys} < 0$, take place in voltaic cells (also called galvanic cells). Nonspontaneous reactions, $\Delta G_{sys} > 0$, take place in electrolytic cells. **21.10**(a) Cl^- (b) MnO_4^- (c) MnO_4^- (d) Cl^- (e) from Cl^- to MnO_4^-

(f) $8H_2SO_4(aq) + 2KMnO_4(aq) + 10KCl(aq) \longrightarrow 2MnSO_4(aq) + 5Cl_2(g) + 8H_2O(l) + 6K_2SO_4(aq)$

21.12(a) $ClO_3^-(aq) + 6H^+(aq) + 6I^-(aq) \longrightarrow Cl^-(aq) + 3H_2O(l) + 3I_2(s)$

Oxidizing agent is ClO_3^- and reducing agent is I^-.

(b) $2MnO_4^-(aq) + H_2O(l) + 3SO_3^{2-}(aq) \longrightarrow 2MnO_2(s) + 3SO_4^{2-}(aq) + 2OH^-(aq)$

Oxidizing agent is MnO_4^- and reducing agent is SO_3^{2-}.

(c) $2MnO_4^-(aq) + 6H^+(aq) + 5H_2O_2(aq) \longrightarrow 2Mn^{2+}(aq) + 8H_2O(l) + 5O_2(g)$

Oxidizing agent is MnO_4^- and reducing agent is H_2O_2.

21.14(a) $Cr_2O_7^{2-}(aq) + 14H^+(aq) + 3Zn(s) \longrightarrow 2Cr^{3+}(aq) + 7H_2O(l) + 3Zn^{2+}(aq)$

Oxidizing agent is $Cr_2O_7^{2-}$ and reducing agent is Zn.

(b) $MnO_4^-(aq) + 3Fe(OH)_2(s) + 2H_2O(l) \longrightarrow MnO_2(s) + 3Fe(OH)_3(s) + OH^-(aq)$

Oxidizing agent is MnO_4^- and reducing agent is $Fe(OH)_2$.

(c) $2NO_3^-(aq) + 12H^+(aq) + 5Zn(s) \longrightarrow N_2(g) + 6H_2O(l) + 5Zn^{2+}(aq)$

Oxidizing agent is NO_3^- and reducing agent is Zn.

21.16(a) $4NO_3^-(aq) + 4H^+(aq) + 4Sb(s) \longrightarrow 4NO(g) + 2H_2O(l) + Sb_4O_6(s)$

Oxidizing agent is NO_3^- and reducing agent is Sb.

(b) $5BiO_3^-(aq) + 14H^+(aq) + 2Mn^{2+}(aq) \longrightarrow 5Bi^{3+}(aq) + 7H_2O(l) + 2MnO_4^-(aq)$

Oxidizing agent is BiO_3^- and is reducing agent is Mn^{2+}.

(c) $Pb(OH)_3^-(aq) + 2Fe(OH)_2(s) \longrightarrow Pb(s) + 2Fe(OH)_3(s) + OH^-(aq)$

Oxidizing agent is $Pb(OH)_3^-$ and reducing agent is $Fe(OH)_2$.

21.18(a) $5As_4O_6(s) + 8MnO_4^-(aq) + 18H_2O(l) \longrightarrow 20AsO_4^{3-}(aq) + 8Mn^{2+}(aq) + 36H^+(aq)$

Oxidizing agent is MnO_4^- and reducing agent is As_4O_6.

(b) $P_4(s) + 6H_2O(l) \longrightarrow 2HPO_3^{2-}(aq) + 2PH_3(g) + 4H^+(aq)$

P_4 is both the oxidizing agent and reducing agent.

(c) $2MnO_4^-(aq) + 3CN^-(aq) + H_2O(l) \longrightarrow 2MnO_2(s) + 3CNO^-(aq) + 2OH^-(aq)$

Oxidizing agent is MnO_4^- and reducing agent is CN^-.

21.21(a) $Au(s) + 3NO_3^-(aq) + 4Cl^-(aq) + 6H^+(aq) \longrightarrow AuCl_4^-(aq) + 3NO_2(g) + 3H_2O(l)$ (b) Oxidizing agent is NO_3^- and reducing agent is Au. (c) HCl provides chloride ions that combine with the gold(III) ion to form the stable $AuCl_4^-$ ion.

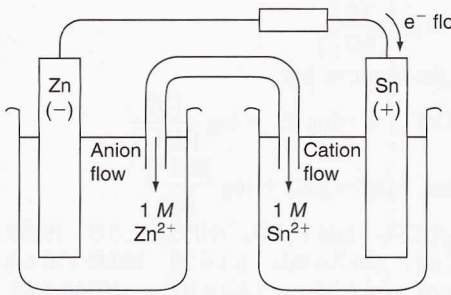
21.22(a) A (b) E (c) C (d) A (e) E (f) E **21.25** An active electrode is a reactant or product in the cell reaction. An inactive electrode does not take part in the reaction and is present only to conduct a current. Platinum and graphite are commonly used as inactive electrodes. **21.26**(a) A (b) B (c) A (d) Hydrogen bubbles will form when metal A is placed in acid. Metal A is a better reducing agent than metal B, so if metal B reduces H^+ in acid, then metal A will also.

21.27(a) Oxidation: $Zn(s) \longrightarrow Zn^{2+}(aq) + 2e^-$

Reduction: $Sn^{2+}(aq) + 2e^- \longrightarrow Sn(s)$

Overall: $Zn(s) + Sn^{2+}(aq) \longrightarrow Zn^{2+}(aq) + Sn(s)$

(b)



21.29(a) left to right (b) left (c) right (d) Ni (e) Fe (f) Fe (g) 1 *M* $NiSO_4$ (h) K^+ and NO_3^- (i) Fe (j) from right to left

(k) Oxidation: $Fe(s) \longrightarrow Fe^{2+}(aq) + 2e^-$

Reduction: $Ni^{2+}(aq) + 2e^- \longrightarrow Ni(s)$

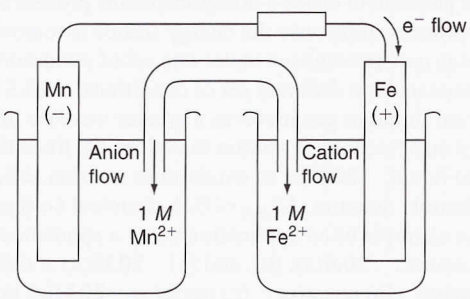
Overall: $Fe(s) + Ni^{2+}(aq) \longrightarrow Fe^{2+}(aq) + Ni(s)$

21.31(a) Reduction: $Fe^{2+}(aq) + 2e^- \longrightarrow Fe(s)$

Oxidation: $Mn(s) \longrightarrow Mn^{2+}(aq) + 2e^-$

Overall: $Fe^{2+}(aq) + Mn(s) \longrightarrow Fe(s) + Mn^{2+}(aq)$

(b)



21.33(a) $Al(s) \mid Al^{3+}(aq) \parallel Cr^{3+}(aq) \mid Cr(s)$

(b) $Pt(s) \mid SO_2(g) \mid SO_4^{2-}(aq), H^+(aq) \parallel Cu^{2+}(aq) \mid Cu(s)$

21.36 A negative E^0_{cell} indicates that the redox reaction is not spontaneous, that is, $\Delta G^0 > 0$. The reverse reaction is spontaneous with $E^0_{cell} > 0$. **21.37** Similar to other state functions, E^0 changes sign when a reaction is reversed. Unlike ΔG^0, ΔH^0, and S^0, E^0 (the ratio of energy to charge) is an intensive property. When the coefficients in a reaction are multiplied by a factor, the values of ΔG^0, ΔH^0, and S^0 are multiplied by that factor. However, E^0 does not change because both the energy and charge are multiplied by the factor and thus their ratio remains unchanged.

21.38(a) Oxidation: $Se^{2-}(aq) \longrightarrow Se(s) + 2e^-$

Reduction: $2SO_3^{2-}(aq) + 3H_2O(l) + 4e^- \longrightarrow S_2O_3^{2-}(aq) + 6OH^-(aq)$

(b) $E^0_{anode} = E^0_{cathode} - E^0_{cell} = -0.57\text{ V} - 0.35\text{ V} = -0.92\text{ V}$

21.40(a) $Br_2 > Fe^{3+} > Cu^{2+}$ (b) $Ca^{2+} < Ag^+ < Cr_2O_7^{2-}$

21.42(a) $Co(s) + 2H^+(aq) \longrightarrow Co^{2+}(aq) + H_2(g)$

$E^0_{cell} = 0.28\text{ V}$; spontaneous

(b) $2Mn^{2+}(aq) + 5Br_2(l) + 8H_2O(l) \longrightarrow 2MnO_4^-(aq) + 10Br^-(aq) + 16H^+(aq)$

$E^0_{cell} = -0.44\text{ V}$; not spontaneous

(c) $Hg_2^{2+}(aq) \longrightarrow Hg^{2+}(aq) + Hg(l)$

$E^0_{cell} = -0.07\text{ V}$; not spontaneous

21.44(a) $2Ag(s) + Cu^{2+}(aq) \longrightarrow 2Ag^+(aq) + Cu(s)$

$E^0_{cell} = -0.46\text{ V}$; not spontaneous

(b) $Cr_2O_7^{2-}(aq) + 3Cd(s) + 14H^+(aq) \longrightarrow 2Cr^{3+}(aq) + 3Cd^{2+}(aq) + 7H_2O(l)$

$E^0_{cell} = 1.73\text{ V}$; spontaneous

(c) $Pb(s) + Ni^{2+}(aq) \longrightarrow Pb^{2+}(aq) + Ni(s)$
$E^0_{cell} = -0.12$ V; not spontaneous

21.46 $3N_2O_4(g) + 2Al(s) \longrightarrow 6NO_2^-(aq) + 2Al^{3+}(aq)$
$E^0_{cell} = 0.867\text{ V} - (-1.66\text{ V}) = 2.53$ V
$2Al(s) + 3SO_4^{2-}(aq) + 3H_2O(l) \longrightarrow 2Al^{3+}(aq) + 3SO_3^{2-}(aq) + 6OH^-(aq)$
$E^0_{cell} = 2.59$ V
$SO_4^{2-}(aq) + 2NO_2^-(aq) + H_2O(l) \longrightarrow SO_3^{2-}(aq) + N_2O_4(g) + 2OH^-(aq)$
$E^0_{cell} = 0.06$ V
Oxidizing agents: $Al^{3+} < N_2O_4 < SO_4^{2-}$
Reducing agents: $SO_3^{2-} < NO_2^- < Al$

21.48 $2HClO(aq) + Pt(s) + 2H^+(aq) \longrightarrow Cl_2(g) + Pt^{2+}(aq) + 2H_2O(l)$
$E^0_{cell} = 0.43$ V
$2HClO(aq) + Pb(s) + SO_4^{2-}(aq) + 2H^+(aq) \longrightarrow Cl_2(g) + PbSO_4(s) + 2H_2O(l)$
$E^0_{cell} = 1.94$ V
$Pt^{2+}(aq) + Pb(s) + SO_4^{2-}(aq) \longrightarrow Pt(s) + PbSO_4(s)$
$E^0_{cell} = 1.51$ V
Oxidizing agent: $PbSO_4 < Pt^{2+} < HClO$
Reducing agent: $Cl_2 < Pt < Pb$

21.50 Yes; C > A > B **21.53** $A(s) + B^+(aq) \longrightarrow A^+(aq) + B(s)$ with $Q = [A^+]/[B^+]$. (a) $[A^+]$ increases and $[B^+]$ decreases. (b) E_{cell} decreases. (c) $E_{cell} = E^0_{cell} - (RT/nF)\ln([A^+]/[B^+])$; $E_{cell} = E^0_{cell}$ when $(RT/nF)\ln([A^+]/[B^+]) = 0$. This occurs when $\ln([A^+]/[B^+]) = 0$, that is, $[A^+]$ equals $[B^+]$. (d) Yes, when $[A^+] > [B^+]$. **21.55** In a concentration cell, the overall reaction decreases the concentration of the more concentrated electrolyte because it is reduced in the cathode compartment.

21.56(a) 3×10^{35} (b) 4×10^{-31} **21.58**(a) 1×10^{-67} (b) 6×10^{9} **21.60** (a) -2.03×10^5 J (b) 1.73×10^5 J **21.62**(a) -3.82×10^5 J (b) -5.6×10^4 J **21.64** $\Delta G^0 = -2.1\times10^4$ J; $E^0 = 0.22$ V **21.66** $E^0_{cell} = 0.056$ V; $\Delta G^0 = -1.1\times10^4$ J **21.68** $9\times10^{-4}\,M$ **21.70** (a) 0.05 V (b) 0.60 M (c) $[Co^{2+}] = 0.91\,M$; $[Ni^{2+}] = 0.09\,M$ **21.72** A; 0.085 V **21.74** Electrons flow from the anode, where oxidation occurs, to the cathode, where reduction occurs. The electrons always flow from the anode to the cathode no matter what type of battery. **21.76** A D-sized alkaline battery is much larger than an AAA-sized one, so the D-sized battery contains greater amounts of the cell components. The cell potential is an intensive property and does not depend on the amounts of the cell components. The total charge, however, depends on the amount of cell components so the D-sized battery produces more charge than the AAA-sized battery. **21.78** The Teflon spacers keep the two metals separated so the copper cannot conduct electrons that would promote the corrosion (rusting) of the iron skeleton. **21.81** Sacrificial anodes are made of metals with E^0 less than that of iron, −0.44 V, so they are more easily oxidized than iron. Only (b), (f), and (g) will work for iron. (a) will form an oxide coating that prevents further oxidation. (c) would react with groundwater quickly. **21.83** To reverse the reaction requires 0.34 V with the cell in its standard state. A 1.5 V cell supplies more than enough potential, so the cadmium metal is oxidized to Cd^{2+} and chromium plates out. **21.85** The oxidation number of N in NO_3^- is +5, the maximum O.N. for N. In the nitrite ion, NO_2^-, the O.N. of N is +3, so nitrogen can be further oxidized. **21.87**(a) Br_2 (b) Na **21.89** Anode is I_2 gas; cathode is magnesium (liquid). **21.91** Bromine gas forms at the anode; calcium metal forms at the cathode. **21.93** copper and bromine

21.95 iodine, zinc, and silver

21.97(a) Anode: $2H_2O(l) \longrightarrow O_2(g) + 4H^+(aq) + 4e^-$
Cathode: $2H_2O(l) + 2e^- \longrightarrow H_2(g) + 2OH^-(aq)$
(b) Anode: $2H_2O(l) \longrightarrow O_2(g) + 4H^+(aq) + 4e^-$
Cathode: $Sn^{2+}(aq) + 2e^- \longrightarrow Sn(s)$

21.99(a) Anode: $2H_2O(l) \longrightarrow O_2(g) + 4H^+(aq) + 4e^-$
Cathode: $NO_3^-(aq) + 4H^+(aq) + 3e^- \longrightarrow NO(g) + 2H_2O(l)$
(b) Anode: $2Cl^-(aq) \longrightarrow Cl_2(g) + 2e^-$
Cathode: $2H_2O(l) + 2e^- \longrightarrow H_2(g) + 2OH^-(aq)$

21.101(a) 2.93 mol e^- (b) 2.83×10^5 C (c) 31.4 A **21.103** 0.282 g Ra **21.105** 1.10×10^4 s **21.107**(a) The sodium and sulfate ions make the water conductive so the current will flow through the water, facilitating electrolysis. Pure water, which contains very low ($10^{-7}\,M$) concentrations of H^+ and OH^-, conducts electricity very poorly. (b) The reduction of H_2O has a more positive half-potential than does the reduction of Na^+; the oxidation of H_2O is the only reaction possible because SO_4^{2-} cannot be oxidized. Thus, it is easier to reduce H_2O than Na^+ and easier to oxidize H_2O than SO_4^{2-}. **21.109** 44.2 g Zn **21.111**(a) 2.0×10^{11} C (b) 2.4×10^{11} J (c) 6.1×10^3 kg **21.114** 69.4 mass % Cu **21.116** (a) 13 days (b) 5.2×10^1 days (c) \$310 **21.119**(a) 91 days (b) 50. g Ag (c) \$8.90

21.122(a) Pb/Pb^{2+}: $E^0_{cell} = 0.13$ V; Cu/Cu^{2+}: $E^0_{cell} = 0.34$ V (b) The anode (negative electrode) is Pb. The anode in the other cell is platinum in the standard hydrogen electrode. (c) The precipitation of PbS decreases $[Pb^{2+}]$, which increases the potential. (d) −0.13 V **21.125** The three steps equivalent to the overall reaction $M^+(aq) + e^- \longrightarrow M(s)$ are

(1) $M^+(aq) \longrightarrow M^+(g)$ ΔH is $-\Delta H_{hydration}$
(2) $M^+(g) + e^- \longrightarrow M(g)$ ΔH is −IE
(3) $M(g) \longrightarrow M(s)$ ΔH is $-\Delta H_{atomization}$

The energy for step 3 is similar for all three elements, so the difference in energy for the overall reactions depends on the values for $\Delta H_{hydration}$ and IE. The Li^+ ion has a much greater hydration energy than Na^+ and K^+ because it is smaller, with large charge density that holds the water molecules more tightly. The energy required to remove the waters surrounding the Li^+ offsets the lower ionization energy, making the overall energy for the reduction of lithium larger than expected. **21.127** The very high and very low standard electrode potentials involve extremely reactive substances, such as F_2 (a powerful oxidizer) and Li (a powerful reducer). These substances react directly with water because any aqueous cell with a voltage of more than 1.23 V has the ability to electrolyze water into hydrogen and oxygen.

21.129(a) 1.073×10^5 s (b) 1.5×10^4 kW·h (c) 6.8¢

21.131 F < D < E. If metal E and a salt of metal F are mixed, the salt is reduced, producing metal F because E has the greatest reducing strength of the three metals.

21.134(a) Cell I: 4 mol electrons; $\Delta G = -4.75\times10^5$ J
Cell II: 2 mol electrons; $\Delta G = -3.94\times10^5$ J
Cell III: 2 mol electrons; $\Delta G = -4.53\times10^5$ J
(b) Cell I: −13.2 kJ/g
Cell II: −0.613 kJ/g
Cell III: −2.62 kJ/g
Cell I has the highest ratio (most energy released per gram) because the reactants have very low mass, while Cell II has the lowest ratio because the reactants have large masses.

Chapter 22

22.2 Fe from Fe_2O_3; Ca from $CaCO_3$; Na from NaCl; Zn from ZnS **22.3**(a) Differentiation refers to the processes involved in the formation of Earth into regions (core, mantle, and crust) of differing composition. Substances separated according to their densities, with the more dense material in the core and the less dense in the crust. (b) O, Si, Al, and Fe (c) O **22.7** Plants produced O_2, slowly increasing the oxygen concentration in the atmosphere and creating an oxidative environment for metals. The oxygen-free decay of plant and animal material created large fossil fuel deposits. **22.9** Fixation refers to the process of converting a substance in the atmosphere into a form more readily usable by organisms. Carbon and nitrogen; fixation of carbon dioxide gas by plants and fixation of nitrogen gas by nitrogen-fixing bacteria. **22.12** Atmospheric nitrogen is fixed by three pathways: atmospheric, industrial, and biological. Atmospheric fixation requires high-temperature reactions (e.g., lightning) to convert N_2 into NO and other oxidized species. Industrial fixation involves mainly the formation of ammonia, NH_3, from N_2 and H_2. Biological fixation occurs in nitrogen-fixing bacteria that live on the roots of legumes. Human activity is an example of industrial fixation. It contributes about 17% of the nitrogen fixed.
22.14(a) the atmosphere (b) Plants excrete acid from their roots to convert PO_4^{3-} ions into more soluble $H_2PO_4^-$ ions, which the plant can absorb. Through excretion and decay, organisms return soluble phosphate compounds to the cycle. **22.17**(a) 1.1×10^3 L (b) $4.2\times10^2\ m^3$ **22.18**(a) The iron ions form an insoluble salt, $Fe_3(PO_4)_2$, that decreases the yield of phosphorus. (b) 8.8 t
22.20(a) Roasting involves heating the mineral in air at high temperatures to convert the mineral to the oxide. (b) Smelting is the reduction of the metal oxide to the free metal using heat and a reducing agent such as coke. (c) Flotation is a separation process in which the ore is removed from the gangue by exploiting the difference in density in the presence of detergent. The gangue sinks to the bottom and the lighter ore-detergent mix is skimmed off the top. (d) Refining is the final step in the purification process to yield the pure metal. **22.25**(a) Slag is a by-product of steel-making and contains the impurity SiO_2. (b) Pig iron is the impure product of iron metallurgy (containing 3–4% C and other impurities). (c) Steel refers to iron alloyed with other elements to attain desirable properties. (d) The basic-oxygen process is used to purify pig iron and obtain carbon steel. **22.27** Iron and nickel are more easily oxidized and less easily reduced than copper. They are separated from copper in the roasting step and converted to slag. In the electrorefining process, all three metals are in solution, but only Cu^{2+} ions are reduced at the cathode to form Cu(*s*). **22.30** Le Châtelier's principle says that the system shifts toward formation of K as the gaseous metal leaves the cell. **22.31**(a) $E^0_{half\text{-}cell} = -3.05$ V, −2.93 V, and −2.71 V for Li^+, K^+, and Na^+, respectively. In all of these cases, it is energetically more favorable to reduce H_2O to H_2 than to reduce M^+ to M. (b) $2RbX + Ca \longrightarrow CaX_2 + 2Rb$, where $\Delta H = IE_1(Ca) + IE_2(Ca) - 2IE_1(Rb) = 929$ kJ/mol. Based on the IEs and positive ΔH for the forward reaction, it seems more reasonable that Rb metal will reduce Ca^{2+} than the reverse. (c) If the reaction is carried out at a temperature greater than the boiling point of Rb, the product mixture will contain gaseous Rb, which can be removed from the reaction vessel; this would cause a shift in equilibrium to form more Rb as product. (d) $2CsX + Ca \longrightarrow CaX_2 + 2Cs$, where $\Delta H = IE_1(Ca) + IE_2(Ca) - 2IE_1(Cs) = 983$ kJ/mol. This reaction is more unfavorable than for Rb, but Cs has a lower boiling point.
22.32(a) 4.6×10^4 L (b) 1.26×10^8 C (c) 1.68×10^6 s
22.35(a) Mg^{2+} is more difficult to reduce than H_2O, so $H_2(g)$ would be produced instead of Mg metal. $Cl_2(g)$ forms at the anode due to overvoltage. (b) The ΔH^0_f of $MgCl_2(s)$ is −641.6 kJ/mol. High temperature favors the reverse (endothermic) reaction, the formation of magnesium metal and chlorine gas.
22.37(a) Sulfur dioxide is the reducing agent and is oxidized to the +6 state (SO_4^{2-}). (b) $HSO_4^-(aq)$ (c) $H_2SeO_3(aq) + 2SO_2(g) + H_2O(l) \longrightarrow Se(s) + 2HSO_4^-(aq) + 2H^+(aq)$
22.42(a) O.N. for Cu: in Cu_2S, +1; in Cu_2O, +1; in Cu, 0
(b) Cu_2S is the reducing agent, and Cu_2O is the oxidizing agent.
22.44(a) 1.0×10^6 C (b) 1.2×10^3 A **22.47** $2ZnS(s) + C(\text{graphite}) \longrightarrow 2Zn(s) + CS_2(g)$; $\Delta G^0_{rxn} = 463$ kJ. Since ΔG^0_{rxn} is positive, this reaction is not spontaneous at standard-state conditions. $2ZnO(s) + C(s) \longrightarrow 2Zn(s) + CO_2(g)$; $\Delta G^0_{rxn} = 242.0$ kJ. This reaction is also not spontaneous, but is less unfavorable. **22.48** The formation of sulfur trioxide is very slow at ordinary temperatures. Increasing the temperature can speed up the reaction, but because the reaction is exothermic, increasing the temperature decreases the yield. Adding a catalyst increases the rate of the reaction, so a lower temperature can be used to enhance the yield. **22.51**(a) Cl_2, H_2, and NaOH

(b) The mercury-cell process yields higher purity NaOH, but releases some Hg, which is discharged into the environment. **22.52**(a) $\Delta G^0 = -142$ kJ; yes (b) The rate of the reaction is very slow at 25°C. (c) $\Delta G^0_{500} = -53$ kJ, so the reaction is spontaneous. (d) $K_{25} = 7.8\times10^{24} > K_{500} = 3.8\times10^{3}$ (e) 1.05×10^{3} K **22.53** 7×10^{2} lb Cl_2 **22.57**(a) $P_4O_{10}(s) + 6H_2O(l) \longrightarrow 4H_3PO_4(l)$ (b) 1.55 **22.59**(a) 9.006×10^{9} g CO_2 (b) The 4.3×10^{10} g CO_2 produced by automobiles is much greater than that from the blast furnace. **22.61**(a) If $[OH^-] > 1.1\times10^{-4}$ *M* (i.e., if pH > 10.04), $Mg(OH)_2$ will precipitate. (b) 1 (To the correct number of significant figures, all the magnesium has precipitated.) **22.63**(a) K_{25}(step 1) $= 1\times10^{168}$; K_{25}(side rxn) $= 7\times10^{228}$; (b) K_{900}(step 1) $= 4.6\times10^{49}$; K_{900}(side rxn) $= 1.4\times10^{58}$ (c) $\$3.5\times10^{7}$

22.67 (1) $2H_2O(l) + 2FeS_2(s) + 7O_2(g) \longrightarrow 2Fe^{2+}(aq) + 4SO_4^{2-}(aq) + 4H^+(aq)$ increases acidity

(2) $4H^+(aq) + 4Fe^{2+}(aq) + O_2(g) \longrightarrow 4Fe^{3+}(aq) + 2H_2O(l)$

(3) $Fe^{3+}(aq) + 3H_2O(l) \longrightarrow Fe(OH)_3(s) + 3H^+(aq)$ increases acidity

(4) $8H_2O(l) + FeS_2(s) + 14Fe^{3+}(aq) \longrightarrow 15Fe^{2+}(aq) + 2SO_4^{2-}(aq) + 16H^+(aq)$ increases acidity

22.69 density of ferrite: 7.86 g/cm^3; density of austenite: 7.55 g/cm^3

22.71(a) Cathode: $Na^+(l) + e^- \longrightarrow Na(l)$

Anode: $4OH^-(l) \longrightarrow O_2(g) + 2H_2O(g) + 4e^-$

(b) 50%

22.74(a) $nCO_2(g) + nH_2O(l) \longrightarrow (CH_2O)_n(s) + nO_2(g)$ (b) 25 L (c) 7.6×10^{4} L **22.75** 66 mg/L **22.77** 794 kg Na_3AlF_6 **22.78**(a) 20.4 min (b) 14 effusion steps **22.80**(a) 1.890 t Al_2O_3 (b) 0.3339 t C (c) 100% (d) 74% (e) 2.813×10^{3} m^3 **22.85** Acid rain increases the leaching of phosphate into the groundwater, due to the protonation of PO_4^{3-} to form HPO_4^{2-} and $H_2PO_4^-$. As shown in calculations (a) and (b), solubility of $Ca_3(PO_4)_2$ increases from 6.4×10^{-7} *M* (in pure water) to 1.1×10^{-2} *M* (in acidic rainwater). (a) 6.4×10^{-7} *M* (b) 1.1×10^{-2} *M* **22.86**(a) 5.60 mol % (b) 237.4 g/mol **22.88** density of silver = 10.51 g/cm^3; density of sterling silver = 10.2 g/cm^3

Chapter 23

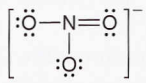
23.2(a) $1s^22s^22p^63s^23p^64s^23d^{10}4p^65s^24d^x$ (b) $1s^22s^22p^63s^23p^64s^23d^{10}4p^65s^24d^{10}5p^66s^24f^{14}5d^x$ **23.4** Five; examples are Mn, [Ar] $4s^23d^5$, and Fe^{3+}, [Ar] $3d^5$. **23.6**(a) The elements should increase in size as they increase in mass from Period 5 to Period 6. Because 14 additional elements lie between Periods 5 and 6, the effective nuclear charge increases significantly; so the atomic size decreases, or "contracts." This effect is significant enough that Zr^{4+} and Hf^{4+} are almost the same size but differ greatly in atomic mass. (b) The atomic size increases from Period 4 to Period 5, but stays fairly constant from Period 5 to Period 6. (c) Atomic mass increases significantly from Period 5 to Period 6, but atomic radius (and thus volume) increases slightly, so Period 6 elements are very dense. **23.9**(a) A paramagnetic substance is attracted to a magnetic field, while a diamagnetic substance is slightly repelled by one. (b) Ions of transition elements often have half-filled *d* orbitals whose unpaired electrons make the ions paramagnetic. Ions of main-group elements usually have a noble gas configuration with no partially filled levels. (c) Some *d* orbitals in the transition element ions are empty, which allows an electron from one *d* orbital to move to a slightly higher energy one. The energy required for this transition is small and falls in the visible wavelength range. All orbitals are filled in ions of main-group elements, so enough energy would have to be added to move an electron to the next principal energy level, not just another orbital within the same energy level. This amount of energy is very large and much greater than the visible range of wavelengths.

23.10(a) $1s^22s^22p^63s^23p^64s^23d^3$ (b) $1s^22s^22p^63s^23p^64s^23d^{10}4p^65s^24d^1$ (c) [Xe] $6s^24f^{14}5d^{10}$ **23.12**(a) [Xe] $6s^24f^{14}5d^6$ (b) [Ar] $4s^23d^7$ (c) [Kr] $5s^14d^{10}$ **23.14**(a) [Ar], no unpaired electrons (b) [Ar] $3d^9$, one unpaired electron (c) [Ar] $3d^5$, five unpaired electrons (d) [Kr] $4d^2$, two unpaired electrons **23.16**(a) +5 (b) +4 (c) +7 **23.18** Cr, Mo, and W **23.20** In CrF_2, because the chromium is in a lower oxidation state. **23.22** Atomic size increases slightly down a group of transition elements, but nuclear charge increases much more, so the first ionization energy generally increases. The reduction potential for Mo is lower, so it is more difficult to oxidize Mo than Cr. In addition, the ionization energy of Mo is higher than that of Cr, so it is more difficult to remove electrons from Mo. **23.24** CrO_3, with Cr in a higher oxidation state, yields a more acidic aqueous solution. **23.28**(a) seven (b) This corresponds to a half-filled *f* subshell. **23.30** (a) [Xe] $6s^25d^1$ (b) [Xe] $4f^1$ (c) [Rn] $7s^25f^{11}$ (d) [Rn] $5f^2$ **23.32**(a) Eu^{2+}: [Xe] $4f^7$; Eu^{3+}: [Xe] $4f^6$; Eu^{4+}: [Xe] $4f^5$ The stability of the half-filled *f* subshell makes Eu^{2+} most stable. (b) Tb^{2+}: [Xe] $4f^9$; Tb^{3+}: [Xe] $4f^8$; Tb^{4+}: [Xe] $4f^7$; Tb should show a +4 oxidation state because that gives the half-filled subshell. **23.34** Gd has the electron configuration [Xe] $6s^24f^75d^1$ with eight unpaired electrons. Gd^{3+} has seven unpaired electrons: [Xe] $4f^7$. **23.36** Valence-state electronegativity is the apparent electronegativity of an element in a given oxidation state. As Mn is bonded to more O atoms in its different oxides, its O.N. becomes more positive. In solution, an H_2O molecule is attracted to the increasingly positive Mn, and one of its protons becomes easier to lose. **23.40** Mercury exists in the liquid state at room temperature. Mercury occurs in the +1 oxidation state, unusual for its group, because two mercury 1+ ions form a dimer, Hg_2^{2+}, by sharing their unpaired 6*s* electrons in a covalent bond. **23.42** $2Cr^{3+}(aq) + Cr(s) \longrightarrow 3Cr^{2+}$; $E^0 = +0.50$ V; yes, the reaction is spontaneous. **23.44** $3Mn^{2+}(aq) + 2MnO_4^-(aq) + 2H_2O(l) \longrightarrow 5MnO_2(s) + 4H^+(aq)$; $E^0 = +0.28$ V; the reaction is spontaneous, so the Mn^{2+} will react with remaining MnO_4^- to form MnO_2. **23.47** The coordination number indicates the number of ligand atoms bonded to the metal ion. The oxidation number represents the number of electrons lost to form the ion. The coordination number is unrelated to the oxidation number. **23.49** 2, linear; 4, tetrahedral or square planar; 6, octahedral **23.52** The complex ion has a negative charge. **23.55**(a) hexaaquanickel(II) chloride (b) tris(ethylenediamine)chromium(III) perchlorate (c) potassium hexacyanomanganate(II) **23.57**(a) 2+, 6 (b) 3+, 6 (c) 2+, 6 **23.59**(a) potassium dicyanoargentate(I) (b) sodium tetrachlorocadmate(II) (c) tetraammineaquabromocobalt(III) bromide **23.61**(a) 1+, 2 (b) 2+, 4 (c) 3+, 6 **23.63**(a) $[Zn(NH_3)_4]SO_4$ (b) $[Cr(NH_3)_5Cl]Cl_2$ (c) $Na_3[Ag(S_2O_3)_2]$ **23.65**(a) 4, two ions (b) 6, three ions

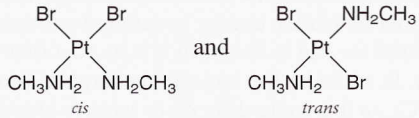
(c) 2, four ions **23.67**(a) $[Cr(H_2O)_6]_2(SO_4)_3$ (b) $Ba[FeBr_4]_2$ (c) $[Pt(en)_2]CO_3$ **23.69**(a) 6, five ions (b) 4, three ions (c) 4, two ions **23.71**(a) The nitrite ion forms linkage isomers because it can bind to the metal ion through either the nitrogen or one of the oxygen atoms—both have a lone pair of electrons.

(b) Sulfur dioxide molecules form linkage isomers because both the sulfur and the oxygen atoms can bind the central metal ion.

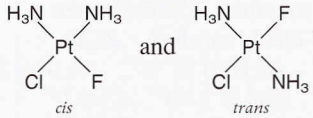
(c) Nitrate ions have three oxygen atoms, all with a lone pair that can bond to the metal ion, but all of the oxygen atoms are equivalent, so there are no linkage isomers.



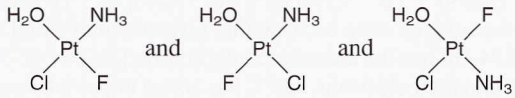
23.73(a) geometric isomerism



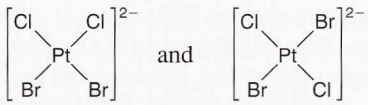
(b) geometric isomerism



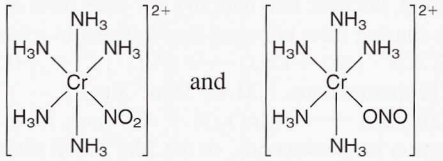
(c) geometric isomerism



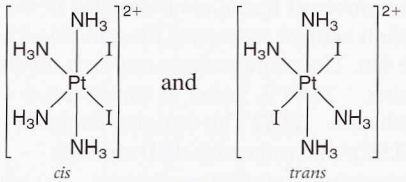
23.75(a) geometric isomerism



(b) linkage isomerism

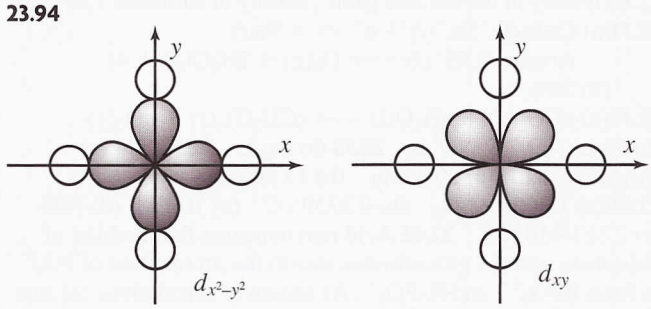


(c) geometric isomerism



23.77 The compound with the traditional formula is $CrCl_3 \cdot 4NH_3$; the actual formula is $[Cr(NH_3)_4Cl_2]Cl$. **23.79**(a) $K[Pd(NH_3)Cl_3]$ (b) $[PdCl_2(NH_3)_2]$ (c) $K_2[PdCl_6]$ (d) $[Pd(NH_3)_4Cl_2]Cl_2$ **23.81**(a) dsp^2 (b) sp^3 **23.84** absorption of orange or yellow **23.85**(a) The crystal field splitting energy (Δ) is the energy difference between the two sets of *d* orbitals that result from the bonding of ligands to a central transition metal atom. (b) In an octahedral field of ligands, the ligands approach along the *x*-, *y*-, and *z*- axes. The $d_{x^2-y^2}$ and d_{z^2} orbitals are located *along* the *x*-, *y*-, and *z*-axes, so ligand interaction is higher in energy. The other orbital-ligand interactions are lower in energy because the d_{xy}, d_{yz}, and d_{xz} orbitals are located *between* the *x*-, *y*-, and *z*-axes. (c) In a tetrahedral field of ligands, the ligands do not approach along the *x*-, *y*-, and *z*-axes. The ligand interaction is greater for the d_{xy}, d_{yz}, and d_{xz} orbitals and lesser for the $d_{x^2-y^2}$ and d_{z^2} orbitals. Therefore, the crystal field splitting is reversed, and the d_{xy}, d_{yz}, and d_{xz} orbitals are higher in energy than the $d_{x^2-y^2}$ and d_{z^2} orbitals. **23.88** If Δ is greater than $E_{pairing}$, electrons will pair their spins in the lower energy *d* orbitals before adding as unpaired electrons to the higher energy *d* orbitals. If Δ is less than $E_{pairing}$, electrons will add as unpaired electrons to the higher energy *d* orbitals before pairing in the lower energy *d* orbitals. **23.90**(a) no *d* electrons (b) eight *d* electrons (c) six *d* electrons **23.92**(a) five (b) ten (c) seven

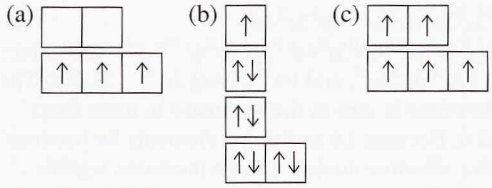
23.94



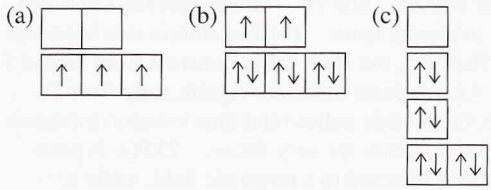
In an octahedral field of ligands, the ligands approach along the *x*, *y*, and *z* axes. The $d_{x^2-y^2}$ orbital is located along the *x* and *y* axes, so ligand interaction is greater. The d_{xy} orbital is offset from the *x* and *y* axes by 90°, so ligand interaction is less. The greater interaction of the $d_{x^2-y^2}$ orbital results in its higher energy.

23.96(a) and (d)

23.98



23.100



23.102 $[Cr(H_2O)_6]^{3+} < [Cr(NH_3)_6]^{3+} < [Cr(NO_2)_6]^{3-}$

23.104 A violet complex absorbs yellow-green light. The light absorbed by a complex with a weaker field ligand would be at a lower energy and higher wavelength. Light of lower energy than yellow-green light is yellow, orange, or red. The color observed would be blue or green. **23.107** The H_2O ligand is weaker than the NH_3 ligand. The weaker field ligand results in a lower splitting energy and absorbs a lower energy of visible light. The hexaaqua complex appears green because it absorbs red light. The hexaammine complex appears violet because it absorbs yellow light, which has higher energy (shorter λ) than red light.

23.111 Hg^+ is [Xe] $6s^14f^{14}5d^{10}$ and Cu^+ is [Ar] $3d^{10}$. The mercury(I) ion has one electron in the 6*s* orbital that can form a covalent bond with the electron in the 6*s* orbital of another mercury(I) ion. In the copper(I) ion there are no electrons in the *s* orbital, so these ions cannot bond with one another.

trans-dichlorobis(triethylphosphine)platinum(II)

23.140(a) The first reaction shows no change in the number of particles. In the second reaction, the number of reactant particles is greater than the number of product particles. A decrease in the number of particles means a decrease in entropy. Based on entropy change only, the first reaction is favored.

(b) The ethylenediamine complex will be more stable with respect to ligand exchange in water because the entropy change for that exchange is unfavorable.

Chapter 24

24.1(a) Chemical reactions are accompanied by relatively small changes in energy; nuclear reactions are accompanied by relatively large changes in energy. (b) Increasing temperature increases the rate of a chemical reaction but has no effect on a nuclear reaction. (c) Both chemical and nuclear reaction rates increase with higher reactant concentrations. (d) If the reactant is limiting in a chemical reaction, then more reactant produces more product and the yield increases. The presence of more radioactive reactant results in more decay product, so a higher reactant concentration increases the yield. **24.2**(a) 95.02% (b) The atomic mass is larger than the isotopic mass of ^{32}S. Sulfur-32 is the lightest isotope. **24.4**(a) Z down by 2, N down by 2 (b) Z up by 1, N down by 1 (c) no change in Z or N (d) Z down by 1, N up by 1; a different element is produced in all cases except (c). **24.6** A neutron-rich nuclide decays by beta decay. A neutron-poor nuclide undergoes positron decay or electron capture. **24.8**(a) $^{234}_{92}U \longrightarrow {}^{4}_{2}He + {}^{230}_{90}Th$ (b) $^{232}_{93}Np + {}^{0}_{-1}e \longrightarrow {}^{232}_{92}U$ (c) $^{12}_{7}N \longrightarrow {}^{0}_{1}\beta + {}^{12}_{6}C$ **24.10**(a) $^{27}_{12}Mg \longrightarrow {}^{0}_{-1}\beta + {}^{27}_{13}Al$ (b) $^{9}_{3}Li \longrightarrow {}^{1}_{0}n + {}^{8}_{3}Li$ (c) $^{103}_{46}Pd + {}^{0}_{-1}e \longrightarrow {}^{103}_{45}Rh$ **24.12**(a) $^{48}_{23}V \longrightarrow {}^{48}_{22}Ti + {}^{0}_{1}\beta$ (b) $^{107}_{48}Cd + {}^{0}_{-1}e \longrightarrow {}^{107}_{47}Ag$ (c) $^{210}_{86}Rn \longrightarrow {}^{206}_{84}Po + {}^{4}_{2}He$ **24.14**(a) $^{186}_{78}Pt + {}^{0}_{-1}e \longrightarrow {}^{186}_{77}Ir$ (b) $^{225}_{89}Ac \longrightarrow {}^{221}_{87}Fr + {}^{4}_{2}He$ (c) $^{129}_{52}Te \longrightarrow {}^{129}_{53}I + {}^{0}_{-1}\beta$ **24.16**(a) Appears stable because its N and Z values are both magic numbers, but its N/Z ratio (1.50) is too high; it is unstable. (b) Appears unstable because its Z value is an odd number, but its N/Z ratio (1.19) is in the band of stability, so it is stable. (c) Unstable because its N/Z ratio is too high. **24.18**(a) The N/Z ratio for ^{127}I is 1.4; it is stable. (b) The N/Z ratio for ^{106}Sn is 1.1; it is unstable because this ratio is too low. (c) The N/Z is 1.1 for ^{68}As. The ratio is within the range of stability, but the nuclide is most likely unstable because there is an odd number of both protons and neutrons. **24.20**(a) alpha decay (b) positron decay or electron capture (c) positron decay or electron capture **24.22**(a) beta decay (b) positron decay or electron capture (c) alpha decay **24.24** Stability results from a favorable N/Z ratio, even numbered N and/or Z, and the occurrence of magic numbers. The N/Z ratio of ^{52}Cr is 1.17, which is within the band of stability. The fact that Z is even does not account for the variation in stability because all isotopes of chromium have the same Z. However, ^{52}Cr has 28 neutrons, so N is both an even number and a magic number for this isotope only. **24.28** $4\,{}^{0}_{-1}\beta + 7\,{}^{4}_{2}He$ **24.31** No, it is not valid to conclude that $t_{1/2}$ equals 1 min because the number of nuclei is so small. Decay rate is an average rate and is only meaningful when the sample is macroscopic and contains a large number of nuclei. For the sample containing 6×10^{12} nuclei, the conclusion is valid. **24.33** 2.89×10^{-2} Ci/g **24.35** 1.4×10^{8} Bq/g **24.37** $1\times10^{-12}\ h^{-1}$ **24.39** $2.31\times10^{-7}\ yr^{-1}$ **24.41** 1.49 mg **24.43** 2.2×10^{9} yr **24.45** 1×10^{2} dpm **24.47** 1.5×10^{6} yr **24.50** Both γ radiation and neutron beams have no charge, but a neutron has a mass approximately equal to that of a proton. **24.52** Protons are repelled from the target nuclei due to interaction with like (positive) charges. Higher energy is required to overcome the repulsion. **24.53**(a) $^{10}_{5}B + {}^{4}_{2}He \longrightarrow {}^{1}_{0}n + {}^{13}_{7}N$ (b) $^{28}_{14}Si + {}^{2}_{1}H \longrightarrow {}^{1}_{0}n + {}^{29}_{15}P$ (c) $^{242}_{96}Cm + {}^{4}_{2}He \longrightarrow 2\,{}^{1}_{0}n + {}^{244}_{98}Cf$ **24.58** Ionizing radiation is more dangerous to children because their rapidly dividing cells are more susceptible to radiation than an adult's slowly dividing cells. **24.60**(a) 5.4×10^{-7} rad (b) 5.4×10^{-9} Gy **24.62**(a) 7.5×10^{-10} Gy (b) 7.5×10^{-5} mrem (c) 7.5×10^{-10} Sv **24.65** 2.45×10^{-3} rad **24.67** NAA does not destroy the sample, while chemical analyses do. Neutrons bombard a nonradioactive sample, inducing some atoms within the sample to be radioactive. The radioisotopes decay by emitting radiation characteristic of each isotope. **24.70** The oxygen isotope in the methanol reactant appears in the formaldehyde product. The oxygen isotope in the chromic acid reactant appears in the water product. The isotope traces the oxygen in methanol to the oxygen in formaldehyde. **24.73** Energy is released when a nuclide forms from nucleons. The nuclear binding energy is the amount of energy holding the nucleus together. This energy must be absorbed to break up the nucleus into nucleons and is released when nucleons come together. **24.75**(a) 1.861×10^{4} eV (b) 2.981×10^{15} J **24.77** 5.1×10^{11} J **24.79**(a) 7.976 MeV/nucleon (b) 127.6 MeV/atom (c) 1.231×10^{10} kJ/mol **24.81**(a) 8.768 MeV/nucleon (b) 517.3 MeV/atom (c) 4.99×10^{10} kJ/mol **24.85** Radioactive decay is a spontaneous process in which unstable nuclei emit radioactive particles and energy. Fission occurs as the result of high-energy bombardment of nuclei with small particles that cause the nuclei to break into smaller nuclides, radioactive particles, and energy. **24.88** The water serves to slow the neutrons so that they are better able to cause a fission reaction. Heavy water is a better moderator because it does not absorb neutrons as well as light water does, so more neutrons are available to initiate the fission process. However, D_2O does not occur naturally in great abundance, so its production adds to the cost of a heavy-water reactor. **24.91** In the stellar nucleogenesis model, the lighter nuclides (up to ^{24}Mg) are produced in a helium-burning stage in which heavier nuclei are formed by the fusion of helium nuclei, each with a mass of 4 amu. **24.95**(a) 1.1×10^{-29} kg (b) 9.8×10^{-13} J (c) 5.9×10^{8} kJ/mol. This is approximately 1 million times larger than a typical heat of reaction. **24.97** 7.6×10^{3} yr **24.101** $1.35\times10^{-5}\ M$ **24.103** 6.3×10^{-2} **24.106**(a) 5.99 h (b) 21% **24.108**(a) 0.999 (b) 0.298 (c) 5.58×10^{-6} (d) Radiocarbon dating is more reliable for the fraction in (b) because a significant quantity of ^{14}C has decayed and a significant quantity remains. Therefore, a change in the amount of ^{14}C will be noticeable. For the fraction in (a), very little ^{14}C has decayed, and for (c) very little ^{14}C remains. In either case, it will be more difficult to measure the change, so the error will be relatively large. **24.110** 6.58 h **24.114** 4.904×10^{-9} L/h **24.117** 87 yr **24.119**(a) 0.15 Bq/L (b) 0.34 Bq/L (c) 4.6 days; a total of 13.1 days **24.122** 6.6 s **24.125** 1926 **24.128** 6.27×10^{5} eV, 6.05×10^{7} kJ/mol **24.131**(a) 2.07×10^{-17} J (b) 1.45×10^{7} H atoms (c) 1.4960×10^{-5} J (d) 1.4959×10^{-5} J (e) No, the Captain should continue using the current technology. **24.134**(a) 0.043 MeV, 2.9×10^{-11} m (b) 4.713 MeV **24.138**(a) 3.26×10^{3} days (b) 3.2×10^{-3} s (c) 2.78×10^{11} yr **24.140**(a) 1.80×10^{17} J (b) 6.15×10^{10} kJ (c) The procedure in part (b) produces more energy per kilogram of antihydrogen. **24.141** 9.316×10^{2} MeV **24.145** 0.357 days

Glossary

Numbers in parentheses refer to the page(s) on which a term is introduced and/or discussed.

A

absolute scale (also *Kelvin scale*) The preferred temperature scale in scientific work, which has absolute zero (0 K, or −273.15°C) as the lowest temperature. (23) [See also *kelvin* (*K*).]

absorption spectrum The spectrum produced when atoms absorb specific wavelengths of incoming light and become excited from lower to higher energy levels. (269)

abundance The amount of an element in a particular region of the natural world. (961)

accuracy The closeness of a measurement to the actual value. (29)

acid In common laboratory terms, any species that produces H^+ ions when dissolved in water. (144) [See also *Brønsted-Lowry, classical (Arrhenius),* and *Lewis acid-base definitions.*]

acid anhydride A compound, sometimes formed by a dehydration-condensation reaction of an oxoacid, that yields two molecules of the acid when it reacts with water. (646)

acid-base buffer (also *buffer*) A solution that resists changes in pH when a small amount of either strong acid or strong base is added. (815)

acid-base indicator A species whose color is different in acid and in base, which is used to monitor the equivalence point of a titration or the pH of a solution. (146, 777, 824)

acid-base reaction Any reaction between an acid and a base. (144) (See also *neutralization reaction.*)

acid-base titration curve A plot of the pH of a solution of acid (or base) versus the volume of base (or acid) added to the solution. (824)

acid-dissociation (acid-ionization) constant (K_a) An equilibrium constant for the dissociation of an acid (HA) in H_2O to yield the conjugate base (A^-) and H_3O^+:

$$K_a = \frac{[H_3O^+][A^-]}{[HA]} \qquad (771)$$

actinides The Period 7 elements that constitute the second inner transition series (5*f* block), which includes thorium (Th; $Z = 90$) through lawrencium (Lr; $Z = 103$). (304, 1010)

activated complex (See *transition state.*)

activation energy (E_a) The minimum energy with which molecules must collide to react. (692)

active site The region of an enzyme formed by specific amino acid side chains at which catalysis occurs. (709)

activity ($\mathcal{A}$) (also *decay rate*) The change in number of nuclei ($\mathcal{N}$) of a radioactive sample divided by the change in time (t). (1054)

activity series of the metals A listing of metals arranged in order of decreasing strength of the metal as a reducing agent in aqueous reactions. (161)

actual yield The amount of product actually obtained in a chemical reaction. (114)

addition polymer (also *chain-reaction,* or *chain-growth, polymer*) A polymer formed when monomers (usually containing C=C) combine through an addition reaction. (651)

addition reaction A type of organic reaction in which atoms linked by a multiple bond become bonded to more atoms. (635)

adduct The product of a Lewis acid-base reaction characterized by the formation of a new covalent bond. (801)

adenosine triphosphate (ATP) A high-energy molecule that serves most commonly as a store and source of energy in organisms. (889)

alchemy An occult study of nature that flourished for 1500 years in northern Africa and Europe and resulted in the development of several key laboratory methods. (8)

alcohol An organic compound (ending, *-ol*) that contains a  functional group. (638)

aldehyde An organic compound (ending, *-al*) that contains the carbonyl functional group ( ) in which the carbonyl C is also bonded to H. (643)

alkane A hydrocarbon that contains only single bonds (general formula, C_nH_{2n+2}). (623)

alkene A hydrocarbon that contains at least one C=C bond (general formula, C_nH_{2n}). (628)

alkyl group A saturated hydrocarbon chain with one bond available. (634)

alkyl halide (See *haloalkane.*)

alkyne A hydrocarbon that contains at least one C≡C bond (general formula, C_nH_{2n-2}). (631)

allotrope One of two or more crystalline or molecular forms of an element. In general, one allotrope is more stable than another at a particular pressure and temperature. (573)

alloy A mixture with metallic properties that consists of solid phases of two or more pure elements, a solid-solid solution, or distinct intermediate phases. (358, 494, 977)

alpha (α) decay A radioactive process in which an alpha particle is emitted from a nucleus. (1048)

alpha particle (α or $^4_2$He) A positively charged particle, identical to a helium nucleus, that is one of the common types of radioactive emissions. (1047)

amide An organic compound that contains the  functional group. (646)

amine An organic compound (general formula, ) derived structurally by replacing one or more H atoms of ammonia with alkyl groups; a weak organic base. (640, 789)

amino acid An organic compound [general formula, $H_2N—CH(R)—COOH$] with at least one carboxyl and one amine group on the same molecule; the monomer unit of a protein. (495, 655)

amorphous solid A solid that occurs in different shapes because it lacks extensive molecular-level ordering of its particles. (449)

ampere (A) The SI unit of electric current; 1 ampere of current results when 1 coulomb flows through a conductor in 1 second. (945)

amphoteric Able to act as either an acid or a base. (315)

amplitude The height of the crest (or depth of the trough) of a wave; related to the intensity of the energy. (258)

angular momentum quantum number (l) (also *orbital-shape quantum number*) An integer from 0 to $n - 1$ that is related to the shape of an atomic orbital. (277)

anion A negatively charged ion. (57)

anode The electrode at which oxidation occurs in an electrochemical cell. Electrons are given up by the reducing agent and leave the cell at the anode. (909)

antibonding MO A molecular orbital formed when wave functions are subtracted from each other, which decreases electron density between the nuclei and leaves a node. Electrons occupying such an orbital destabilize the molecule. (410)

apatite A compound of general formula $Ca_5(PO_4)_3X$, where X is generally F, Cl, or OH. (970)

aqueous solution A solution in which water is the solvent. (73)

aromatic hydrocarbon A compound of C and H with one or more rings of C atoms (often drawn with alternating C—C and C=C bonds), in which there is extensive delocalization of π electrons. (632)

Arrhenius acid-base definition [See *classical (Arrhenius) acid-base definition.*]

Arrhenius equation An equation that expresses the exponential relationship between temperature and the rate constant: $k = Ae^{-E_a/RT}$. (692)

atmosphere The mixture of gases that extends from a planet's surface and eventually merges with outer space; the gaseous portion of Earth's crust. (207, 963) (For the unit, see *standard atmosphere*.)

atom The smallest particle of an element that retains the chemical nature of the element. A neutral, spherical entity composed of a positively charged central nucleus surrounded by one or more negatively charged electrons. (44)

atomic mass (also *atomic weight*) The average of the masses of the naturally occurring isotopes of an element weighted according to their abundances. (51)

atomic mass unit (amu) (also *dalton, Da*) A mass exactly equal to $\frac{1}{12}$ the mass of a carbon-12 atom. (51)

atomic number (Z) The unique number of protons in the nucleus of each atom of an element (equal to the number of electrons in the neutral atom). An integer that expresses the positive charge of a nucleus in multiples of the electronic charge. (50)

atomic orbital (also *wave function*) A mathematical expression that describes the motion of the electron's matter-wave in terms of time and position in the region of the nucleus. The term is used qualitatively to mean the region of space in which there is a high probability of finding the electron. (275)

atomic size A term referring to the atomic radius, one-half the distance between nuclei of identical bonded elements. (305, 543) (See also *covalent radius* and *metallic radius*.)

atomic solid A solid consisting of individual atoms held together by dispersion forces; the frozen noble gases are the only examples. (456)

atomic symbol (also *element symbol*) A one- or two-letter abbreviation for the English, Latin, or Greek name of an element. (50)

aufbau principle (also *building-up principle*) The conceptual basis of a process of building up atoms by adding one proton (and one or more neutrons) at a time to the nucleus and one electron around it to obtain the ground-state electron configurations of the elements. (296)

autoionization (also *self-ionization*) A reaction in which two molecules of a substance react to give ions. The most important example is for water:

$$2H_2O(l) \rightleftharpoons H_3O^+(aq) + OH^-(aq) \qquad (773)$$

average rate The change in concentration of reactants (or products) divided by a finite time period. (676)

Avogadro's law The gas law stating that, at fixed temperature and pressure, equal volumes of any ideal gas contain equal numbers of particles, and, therefore, the volume of a gas is directly proportional to its amount (mol): $V \propto n$. (187)

Avogadro's number A number (6.022×10^{23} to four significant figures) equal to the number of atoms in exactly 12 g of carbon-12; the number of atoms, molecules, or formula units in one mole of an element or compound. (87)

axial group An atom (or group) that lies above or below the trigonal plane of a trigonal bipyramidal molecule, or a similar structural feature in a molecule. (380)

B

background radiation Natural ionizing radiation, the most important form of which is cosmic radiation. (1064)

balancing coefficient (also *stoichiometric coefficient*) A numerical multiplier of all the atoms in the formula immediately following it in a chemical equation. (102)

band of stability The narrow band of stable nuclides that appears on a plot of number of neutrons versus number of protons for all nuclides. (1050)

band theory An extension of molecular orbital (MO) theory that explains many properties of metals, in particular, the differences in electrical conductivity of conductors, semiconductors, and insulators. (460)

barometer A device used to measure atmospheric pressure. Most commonly, a tube open at one end, which is filled with mercury and inverted into a dish of mercury. (179)

base In common laboratory terms, any species that produces OH^- ions when dissolved in water. (144) [See also *Brønsted-Lowry, classical (Arrhenius),* and *Lewis acid-base definitions.*]

base-dissociation (base-ionization) constant (K_b) An equilibrium constant for the reaction of a base (B) with H_2O to yield the conjugate acid (BH^+) and OH^-:

$$K_b = \frac{[BH^+][OH^-]}{[B]} \qquad (788)$$

base pair Two complementary bases in mononucleotides that are H bonded to each other; guanine (G) always pairs with cytosine (C), and adenine (A) always pairs with thymine (T) (or uracil, U). (659)

base unit (also *fundamental unit*) A unit that defines the standard for one of the seven physical quantities in the International System of Units (SI). (16)

basic-oxygen process The method used to convert pig iron to steel, in which O_2 is blown over and through molten iron to oxidize impurities and decrease the content of carbon. (982)

battery A self-contained group of voltaic cells arranged in series. (932)

becquerel (Bq) The SI unit of radioactivity; 1 Bq = 1 d/s (disintegration per second). (1054)
bent shape (also *V shape*) A molecular shape that arises when a central atom is bonded to two other atoms and has one or two lone pairs; occurs as the AX_2E shape class (bond angle $< 120°$) in the trigonal planar arrangement and as the AX_2E_2 shape class (bond angle $< 109.5°$) in the tetrahedral arrangement. (378)
beta (β) decay A radioactive process in which a beta particle is emitted from a nucleus. (1049)
beta particle (β, β^-, or $_{-1}^{0}\beta$) A negatively charged particle identified as a high-speed electron that is one of the common types of radioactive emissions. (1047)
bimolecular reaction An elementary reaction involving the collision of two reactant species. (701)
binary covalent compound A compound that consists of atoms of two elements in which bonding occurs primarily through electron sharing. (68)
binary ionic compound A compound that consists of the oppositely charged ions of two elements. (57)
biomass conversion The process of applying chemical and biological methods to convert plant and/or animal matter into fuels. (245)
biosphere The living systems that have inhabited Earth. (963)
blast furnace A tower-shaped furnace made of brick material in which intense heat and blasts of air are used to convert iron ore and coke to iron metal and carbon dioxide. (980)
body-centered cubic unit cell A unit cell in which a particle lies at each corner and in the center of a cube. (450)
boiling point (bp or T_b) The temperature at which the vapor pressure of a gas equals the external (atmospheric) pressure. (433)
boiling point elevation (ΔT_b) The increase in the boiling point of a solvent caused by the presence of dissolved solute. (517)
bond angle The angle formed by the nuclei of two surrounding atoms with the nucleus of the central atom at the vertex. (376)
bond energy (BE) (also *bond strength*) The enthalpy change accompanying the breakage of a given bond in a mole of gaseous molecules. (341, 545)
bond length The distance between the nuclei of two bonded atoms. (342, 545)
bond order The number of electron pairs shared by two bonded atoms. (340, 545)
bonding MO A molecular orbital formed when wave functions are added to each other, which increases electron density between the nuclei. Electrons occupying such an orbital stabilize the molecule. (410)
bonding pair (also *shared pair*) An electron pair shared by two nuclei; the mutual attraction between the nuclei and the electron pair forms a covalent bond. (340)
Born-Haber cycle A series of hypothetical steps and their enthalpy changes needed to convert elements to an ionic compound and devised to calculate the lattice energy. (334)
Boyle's law The gas law stating that, at constant temperature and amount of gas, the volume occupied by a gas is inversely proportional to the applied (external) pressure: $V \propto 1/P$. (184)
branch A side chain appended to a polymer backbone. (476)
bridge bond (also *three-center, two-electron bond*) A covalent bond in which three atoms are held together by two electrons. (571)
Brønsted-Lowry acid-base definition A model of acid-base behavior based on proton transfer, in which an acid and a base are defined, respectively, as species that donate and accept a proton. (777)
buffer (See *acid-base buffer.*)
buffer capacity A measure of the ability of a buffer to resist a change in pH; related to the total concentrations and relative proportions of buffer components. (821)
buffer range The pH range over which a buffer acts effectively. (821)

C

calibration The process of correcting for systematic error of a measuring device by comparing it to a known standard. (30)
calorie (cal) A unit of energy defined as exactly 4.184 joules; originally defined as the heat needed to raise the temperature of 1 g of water 1°C (from 14.5°C to 15.5°C). (229)
calorimeter A device used to measure the heat released or absorbed by a physical or chemical process taking place within it. (236)
capillarity (or *capillary action*) A property that results in a liquid rising through a narrow space against the pull of gravity. (444)
carbon steel The steel that is produced by the basic-oxygen process, contains about 1% to 1.5% C and other impurities, and is alloyed with metals that prevent corrosion and increase strength. (982)
carbonyl group The C=O grouping of atoms. (643)
carboxylic acid An organic compound (ending, *-oic acid*) that contains the $-\overset{\displaystyle :O:}{\overset{\|}{C}}-\ddot{O}H$ group. (645)
catalyst A substance that increases the rate of a reaction without being used up in the process. (707)
cathode The electrode at which reduction occurs in an electrochemical cell. Electrons enter the cell and are acquired by the oxidizing agent at the cathode. (909)
cathode ray The ray of light emitted by the cathode (negative electrode) in a gas discharge tube; travels in straight lines, unless deflected by magnetic or electric fields. (46)
cation A positively charged ion. (57)
cell potential (E_{cell}) (also *electromotive force,* or *emf; cell voltage*) The potential difference between the electrodes of an electrochemical cell when no current flows. (914)
Celsius scale (formerly *centigrade scale*) A temperature scale in which the freezing and boiling points of water are defined as 0°C and 100°C, respectively. (23)
ceramic A nonmetallic material that is hardened by heating it to high temperatures and, in most cases, consists of silicate microcrystals suspended in a glassy cementing medium. (469)
chain reaction In nuclear fission, a self-sustaining process in which neutrons released by splitting of one nucleus cause other nuclei to split, which releases more neutrons, and so on. (1074)
change in enthalpy (ΔH) The change in internal energy plus the product of the constant pressure and the change in volume: $\Delta H = \Delta E + P\Delta V$; the heat lost or gained at constant pressure: $\Delta H = q_P$. (232)
charge density The ratio of the charge of an ion to its volume. (504)
Charles's law The gas law stating that at constant pressure, the volume occupied by a fixed amount of gas is directly proportional to its absolute temperature: $V \propto T$. (185)
chelate A complex ion in which the metal ion is bonded to a bidentate or polydentate ligand. (1020)

chemical bond The force that holds two atoms together in a molecule (or formula unit). (57)
chemical change (also *chemical reaction*) A change in which a substance is converted into a substance with different composition and properties. (3)
chemical equation A statement that uses chemical formulas to express the identities and quantities of the substances involved in a chemical or physical change. (101)
chemical formula A notation of atomic symbols and numerical subscripts that shows the type and number of each atom in a molecule or formula unit of a substance. (62)
chemical kinetics The study of the rates and mechanisms of reactions. (673)
chemical property A characteristic of a substance that appears as it interacts with, or transforms into, other substances. (3)
chemical reaction (See *chemical change*.)
chemistry The scientific study of matter and the changes it undergoes. (3)
chiral molecule One that is not superimposable on its mirror image; an optically active molecule. In organic compounds, a chiral molecule typically contains a C atom bonded to four different groups (asymmetric C). (627)
chlor-alkali process An industrial method that electrolyzes concentrated aqueous NaCl and produces Cl_2, H_2, and NaOH. (994)
chromatography A separation technique in which a mixture is dissolved in a fluid (gas or liquid), and the components are separated through differences in adsorption to (or solubility in) a solid surface (or viscous liquid). (75)
***cis-trans* isomers** (See *geometric isomers*.)
classical (Arrhenius) acid-base definition A model of acid-base behavior in which an acid is a substance that has H in its formula and produces H^+ in water, and a base is a substance that has OH in its formula and produces OH^- in water. (768)
Clausius-Clapeyron equation An equation that expresses the relationship between vapor pressure P of a liquid and temperature T:

$$\ln P = \frac{-\Delta H_{vap}}{R}\left(\frac{1}{T}\right) + C, \text{ where } C \text{ is a constant} \qquad (432)$$

coal gasification An industrial process for altering the large molecules in coal to sulfur-free gaseous fuels. (245)
colligative property A property of a solution that depends on the number, not the identity, of solute particles. (515) (See also *boiling point elevation, freezing point depression, osmotic pressure,* and *vapor pressure lowering*.)
collision frequency The average number of collisions per second that a particle undergoes. (206)
collision theory A model that explains reaction rate as the result of particles colliding with a certain minimum energy. (694)
colloid A suspension in which a solute-like phase is dispersed throughout a solvent-like phase. (527)
combustion The process of burning in air, often with release of heat and light. (9)
combustion analysis A method for determining the formula of a compound from the amounts of its combustion products; used commonly for organic compounds. (97)
common-ion effect The shift in the position of an ionic equilibrium away from an ion involved in the process that is caused by the addition or presence of that ion. (816)
complex (See *coordination compound*.)
complex ion An ion consisting of a central metal ion bonded covalently to molecules and/or anions called ligands. (844, 1017)
composition The types and amounts of simpler substances that make up a sample of matter. (2)
compound A substance composed of two or more elements that are chemically combined in fixed proportions. (40)
concentration A measure of the quantity of solute dissolved in a given quantity of solution. (117)
concentration cell A voltaic cell in which both compartments contain the same components but at different concentrations. (928)
condensation The process of a gas changing into a liquid. (426)
condensation polymer A polymer formed by monomers with two functional groups that are linked together in a dehydration-condensation reaction. (652)
conduction band In band theory, the empty, higher energy portion of the band of molecular orbitals into which electrons move when conducting heat and electricity. (462)
conductor A substance (usually a metal) that conducts an electric current well. (462)
conjugate acid-base pair Two species related to each other through the gain or loss of a proton; the acid has one more proton than its conjugate base. (779)
constitutional isomers (also *structural isomers*) Compounds with the same molecular formula but different arrangements of atoms. (625, 1023)
contact process An industrial process for the manufacture of sulfuric acid based on the catalyzed oxidation of SO_2. (992)
controlled experiment An experiment that measures the effect of one variable at a time by keeping other variables constant. (11)
conversion factor A ratio of equivalent quantities that is equal to 1 and used to convert the units of a quantity. (12)
coordinate covalent bond A covalent bond formed when one atom donates both electrons to give the shared pair and, once formed, is identical to any covalent single bond. (1026)
coordination compound (also *complex*) A substance containing at least one complex ion. (1017)
coordination isomers Two or more coordination compounds with the same composition in which the complex ions have different ligand arrangements. (1023)
coordination number In a crystal, the number of nearest neighbors surrounding a particle. (450) In a complex, the number of ligand atoms bonded to the central metal ion. (1018)
copolymer A polymer that consists of two or more types of monomer. (477)
core The dense, innermost region of Earth. (961)
core electrons (See *inner electrons*.)
corrosion The natural redox process that results in unwanted oxidation of a metal. (936)
coulomb (C) The SI unit of electric charge. One coulomb is the charge of 6.242×10^{18} electrons; one electron possesses a charge of 1.602×10^{-19} C. (914)
Coulomb's law A law stating that the electrostatic force associated with two charges A and B is directly proportional to the product of their magnitudes and inversely proportional to the square of the distance between them:

$$\text{electrostatic force} \propto \frac{\text{charge A} \times \text{charge B}}{(\text{distance})^2} \qquad (335)$$

counter ion A simple ion associated with a complex ion in a coordination compound. (1017)
coupling of reactions The pairing of reactions of which one releases enough free energy for the other to occur. (888)
covalent bond A type of bond in which atoms are bonded through the sharing of two electrons; the mutual attraction of the nuclei and an electron pair that holds atoms together in a molecule. (60, 339)
covalent bonding The idealized bonding type that is based on localized electron-pair sharing between two atoms with little difference in their tendencies to lose or gain electrons (most commonly nonmetals). (330, 544)
covalent compound A compound that consists of atoms bonded together by shared electron pairs. (57)
covalent radius One-half the distance between nuclei of identical covalently bonded atoms. (305)
critical mass The minimum mass needed to achieve a chain reaction. (1074)
critical point The point on a phase diagram above which the vapor cannot be condensed to a liquid; the end of the liquid-gas curve. (434)
crosslink A branch that covalently joins one polymer chain to another. (476)
crust The thin, light, heterogeneous outer layer of Earth. (961)
crystal defect Any of a variety of disruptions in the regularity of a crystal structure. (464)
crystal field splitting energy (Δ) The difference in energy between two sets of metal-ion *d* orbitals that results from electrostatic interactions with the surrounding ligands. (1030)
crystal field theory A model that explains the color and magnetism of coordination compounds based on the effects of ligands on metal-ion *d*-orbital energies. (1028)
crystalline solid Solid with a well-defined shape because of the orderly arrangement of the atoms, molecules, or ions. (449)
crystallization A technique used to separate and purify the components of a mixture through differences in solubility in which a component comes out of solution as crystals. (74)
cubic closest packing A crystal structure based on the face-centered cubic unit cell in which the layers have an *abcabc* . . . pattern. (452)
cubic meter (m^3) The SI-derived unit of volume. (17)
curie (Ci) The most common unit of radioactivity, defined as the number of nuclei disintegrating each second in 1 g of radium-226; 1 Ci = 3.70×10^{10} d/s (disintegrations per second). (1054)
cyclic hydrocarbon A hydrocarbon with one or more rings in its structure. (625)

D

***d* orbital** An atomic orbital with $l = 2$. (282)
dalton (Da) A unit of mass identical to *atomic mass unit*. (51)
Dalton's law of partial pressures A gas law stating that, in a mixture of unreacting gases, the total pressure is the sum of the partial pressures of the individual gases: $P_{total} = P_1 + P_2 + \cdots$. (196)
data Pieces of quantitative information obtained by observation. (11)
de Broglie wavelength The wavelength of a moving particle obtained from the de Broglie equation: $\lambda = h/mu$. (272)
decay constant The rate constant *k* for radioactive decay. (1054)
decay series (also *disintegration series*) The succession of steps a parent nucleus undergoes as it decays into a stable daughter nucleus. (1053)
degree of polymerization (*n*) The number of monomer repeat units in a polymer chain. (472)
dehydration-condensation reaction A reaction in which H and OH groups on two molecules react to form water as one of the products. (590)
delocalization (See *electron-pair delocalization*.)
density (*d*) An intensive physical property of a substance at a given temperature and pressure, defined as the ratio of the mass to the volume: $d = m/V$. (20)
deposition The process of changing directly from gas to solid. (427)
derived unit Any of various combinations of the seven SI base units. (16)
desalination A process used to remove large amounts of ions from seawater, usually by reverse osmosis. (530)
deuterons Nuclei of the stable hydrogen isotope deuterium, ^2H. (1060)
diagonal relationship Physical and chemical similarities between a Period 2 element and one located diagonally down and to the right in Period 3. (563)
diamagnetism The tendency of a species not to be attracted (or to be slightly repelled) by a magnetic field as a result of its electrons being paired. (318, 1009)
differentiation The geochemical process of forming regions in Earth based on differences in composition and density. (961)
diffraction The phenomenon in which a wave striking the edge of an object bends around it. A wave passing through a slit as wide as its wavelength forms a circular wave. (261)
diffusion The movement of one fluid through another. (205)
dimensional analysis (also *factor-label method*) A calculation method in which arithmetic steps are accompanied by the appropriate canceling of units. (14)
dipole-dipole force The intermolecular attraction between oppositely charged poles of nearby polar molecules. (438)
dipole–induced dipole force The intermolecular attraction between a polar molecule and the oppositely charged pole it induces in a nearby molecule. (491)
dipole moment (μ) A measure of molecular polarity; the magnitude of the partial charges on the ends of a molecule (in coulombs) times the distance between them (in meters). (387)
disaccharide An organic compound formed by a dehydration-condensation reaction between two simple sugars (monosaccharides). (654)
disintegration series (See *decay series*.)
dispersion force (also *London force*) The intermolecular attraction between all particles as a result of instantaneous polarizations of their electron clouds; the intermolecular force primarily responsible for the condensed states of nonpolar substances. (441)
disproportionation reaction A reaction in which a given substance is both oxidized and reduced. (588)
distillation A separation technique in which a more volatile component of a mixture vaporizes and condenses separately from the less volatile components. (74)
donor atom An atom that donates a lone pair of electrons to form a covalent bond, usually from ligand to metal ion in a complex. (1019)

doping Adding small amounts of other elements into the crystal structure of a semiconductor to enhance a specific property, usually conductivity. (464)
double bond A covalent bond that consists of two bonding pairs; two atoms sharing four electrons in the form of one σ and one π bond. (340, 407)
double helix The two intertwined polynucleotide strands held together by H bonds that form the structure of DNA (deoxyribonucleic acid). (501, 659)
Downs cell An industrial apparatus that electrolyzes molten NaCl to produce sodium and chlorine. (979)
dynamic equilibrium The condition at which the forward and reverse reactions are taking place at the same rate, so there is no net change in the amounts of reactants or products. (165)

E

e_g orbitals The set of orbitals (composed of $d_{x^2-y^2}$ and d_{z^2}) that results when the energies of the metal-ion *d* orbitals are split by a ligand field. This set is higher in energy than the other (t_{2g}) set in an octahedral field of ligands and lower in energy in a tetrahedral field. (1030)
effective collision A collision in which the particles meet with sufficient energy and an orientation that allows them to react. (696)
effective nuclear charge (Z_{eff}) The nuclear charge an electron actually experiences as a result of shielding effects due to the presence of other electrons. (294)
effusion The process by which a gas escapes from its container through a tiny hole into an evacuated space. (205)
elastomer A polymeric material that can be stretched and springs back to its original shape when released. (476)
electrochemical cell A system that incorporates a redox reaction to produce or use electrical energy. (903)
electrochemistry The study of the relationship between chemical change and electrical work. (903)
electrode The part of an electrochemical cell that conducts the electricity between the cell and the surroundings. (908)
electrolysis The nonspontaneous lysing (splitting) of a substance, often to its component elements, by supplying electrical energy. (941)
electrolyte A substance that conducts a current when it dissolves in water. (136, 515) A mixture of ions, in which the electrodes of an electrochemical cell are immersed, that conducts a current. (908)
electrolytic cell An electrochemical system that uses electrical energy to drive a nonspontaneous chemical reaction ($\Delta G > 0$). (908)
electromagnetic (EM) radiation (also *electromagnetic energy* or *radiant energy*) Oscillating, perpendicular electric and magnetic fields moving simultaneously through space as waves and manifested as visible light, x-rays, microwaves, radio waves, and so on. (257)
electromagnetic spectrum The continuum of wavelengths of radiant energy. (259)
electromotive force (emf) (See *cell potential.*)
electron (e^-) A subatomic particle that possesses a unit negative charge (1.60218×10^{-19} C) and occupies the space around the atomic nucleus. (49)
electron affinity (EA) The energy change (in kJ) accompanying the addition of one mole of electrons to one mole of gaseous atoms or ions. (312)
electron capture A type of radioactive decay in which a nucleus draws in an orbital electron, usually one from the lowest energy level, and releases energy. (1049)
electron cloud An imaginary representation of an electron's rapidly changing position around the nucleus over time. (276)
electron configuration The distribution of electrons within the orbitals of the atoms of an element; also the notation for such a distribution. (291, 542)
electron deficient Referring to a bonded atom, such as Be or B, that has fewer than eight valence electrons. (372)
electron density diagram (also *electron probability density diagram*) The pictorial representation for a given energy sublevel of the quantity ψ^2 (the probability density of the electron lying within a particular tiny volume) as a function of *r* (distance from the nucleus). (276)
electron-pair delocalization (also *delocalization*) The process by which electron density is spread over several atoms rather than remaining between two. (370)
electron-sea model A qualitative description of metallic bonding proposing that metal atoms pool their valence electrons into a delocalized "sea" of electrons in which the metal cores (metal ions) are submerged in an orderly array. (357)
electron volt (eV) The energy (in joules, J) that an electron acquires when it moves through a potential difference of 1 volt; $1\text{ eV} = 1.602\times10^{-19}$ J. (1071)
electronegativity (EN) The relative ability of a bonded atom to attract shared electrons. (351, 543)
electronegativity difference (ΔEN) The difference in electronegativities between the atoms in a bond. (354)
electrorefining An industrial electrolytic process in which a sample of impure metal acts as the anode and a sample of the pure metal acts as the cathode. (977)
element The simplest type of substance with unique physical and chemical properties. An element consists of only one kind of atom, so it cannot be broken down into simpler substances. (39)
elementary reaction (also *elementary step*) A simple reaction that describes a single molecular event in a proposed reaction mechanism. (701)
elimination reaction A type of organic reaction in which C atoms are bonded to fewer atoms in the product than in the reactant, which leads to multiple bonding. (636)
emission spectrum The line spectrum produced when excited atoms return to lower energy levels and emit photons characteristic of the element. (269)
empirical formula A chemical formula that shows the lowest relative number of atoms of each element in a compound. (62)
enantiomers (See *optical isomers.*)
end point The point in a titration at which the indicator changes color. (147, 826)
end-to-end overlap Overlap of *s*, *p*, or hybrid atomic orbitals that yields a sigma (σ) bond. (545)
endothermic Occurring with an absorption of heat from the surroundings and therefore an increase in the enthalpy of the system ($\Delta H > 0$). (233)
energy The capacity to do work, that is, to move matter. (6) [See also *kinetic energy* (E_k) and *potential energy* (E_p).]
enthalpy (*H*) A thermodynamic quantity that is the sum of the internal energy plus the product of the pressure and volume. (238)
enthalpy diagram A graphic depiction of the enthalpy change of a system. (233)

enthalpy of hydration (ΔH_{hydr}) (See *heat of hydration.*)
enthalpy of solution (ΔH_{soln}) (See *heat of solution.*)
entropy (S) A thermodynamic quantity related to the number of ways the energy of a system can be dispersed through the motions of its particles. (505, 867)
environmental cycle The physical, chemical, and biological paths through which the atoms of an element move within Earth's crust. (966)
enzyme A biological macromolecule (usually a protein) that acts as a catalyst. (709)
enzyme-substrate complex (ES) The intermediate in an enzyme-catalyzed reaction, which consists of enzyme and substrate(s) and whose concentration determines the rate of product formation. (710)
equatorial group An atom (or group) that lies in the trigonal plane of a trigonal bipyramidal molecule, or a similar structural feature in a molecule. (380)
equilibrium constant (K) The value obtained when equilibrium concentrations are substituted into the reaction quotient. (725)
equivalence point The point in a titration when the number of moles of the added species is stoichiometrically equivalent to the original number of moles of the other species. (147, 825)
ester An organic compound that contains the  group. (646)
exact number A quantity, usually obtained by counting or based on a unit definition, that has no uncertainty associated with it and, therefore, contains as many significant figures as a calculation requires. (29)
excitation The process by which a substance absorbs energy from low-energy radioactive particles, causing its electrons to move to higher energy levels. (1062)
excited state Any electron configuration of an atom or molecule other than the lowest energy (ground) state. (266)
exclusion principle A principle developed by Wolfgang Pauli stating that no two electrons in an atom can have the same set of four quantum numbers. The principle arises from the fact that an orbital has a maximum occupancy of two electrons and their spins are paired. (293)
exothermic Occurring with a release of heat to the surroundings and therefore a decrease in the enthalpy of the system ($\Delta H < 0$). (233)
expanded valence shell A valence level that can accommodate more than 8 electrons by using available *d* orbitals; occurs only for elements in Period 3 or higher. (373)
experiment A clear set of procedural steps that tests a hypothesis. (11)
extensive property A property, such as mass, that depends on the quantity of substance present. (20)
extraction A method of separating the components of a mixture based on differences in their solubility in a nonmiscible solvent. (74)

F

face-centered cubic unit cell A unit cell in which a particle occurs at each corner and in the center of each face of a cube. (450)
Faraday constant (F) The physical constant representing the charge of 1 mol of electrons: $F = 96{,}485$ C/mol e^-. (923)
fatty acid A carboxylic acid that has a long hydrocarbon chain and is derived from a natural source. (646)
filtration A method of separating the components of a mixture on the basis of differences in particle size. (74)
first law of thermodynamics (See *law of conservation of energy.*)
fission The process by which a heavier nucleus splits into lighter nuclei with the release of energy. (1070)
fixation A chemical/biochemical process that converts a gaseous substance in the environment into a condensed form that can be used by organisms. (967)
flame test A procedure for identifying the presence of metal ions in which a granule of a compound or a drop of its solution is placed in a flame to observe a characteristic color. (269)
flotation A metallurgical process in which oil and detergent are mixed with pulverized ore in water to create a slurry that separates the mineral from the gangue. (974)
formal charge The hypothetical charge on an atom in a molecule or ion, equal to the number of valence electrons minus the sum of all the unshared and half the shared valence electrons. (371)
formation constant (K_f) An equilibrium constant for the formation of a complex ion from the hydrated metal ion and ligands. (844)
formation equation An equation in which 1 mole of a compound forms from its elements. (242)
formula unit The chemical unit of a compound that contains the number and type of atoms (or ions) expressed in the chemical formula. (64)
fossil fuel Any fuel, including coal, petroleum, and natural gas, derived from the products of the decay of dead organisms. (245)
fraction by mass (also *mass fraction*) The portion of a compound's mass contributed by an element; the mass of an element in a compound divided by the mass of the compound. (42)
fractional distillation A process involving numerous vaporization-condensation steps used to separate two or more volatile components. (524)
free energy (G) A thermodynamic quantity that is the difference between the enthalpy and the product of the absolute temperature and the entropy: $G = H - TS$. (881)
free radical A molecular or atomic species with one or more unpaired electrons, which typically make it very reactive. (373, 1063)
freezing The process of cooling a liquid until it solidifies. (426)
freezing point depression (ΔT_f) A lowering of the freezing point of a solvent caused by the presence of dissolved solute particles. (519)
frequency (ν) The number of cycles a wave undergoes per second, expressed in units of 1/second, or s^{-1} [also called hertz (Hz)]. (258)
frequency factor (A) The product of the collision frequency Z and an orientation probability factor p that is specific for a reaction. (696)
fuel cell (also *flow battery*) A battery that is not self-contained and in which electricity is generated by the controlled oxidation of a fuel. (935)
functional group A specific combination of atoms, typically containing a carbon-carbon multiple bond and/or carbon-heteroatom bond, that reacts in a characteristic way no matter what molecule it occurs in. (619)
fundamental unit (See *base unit.*)
fusion (See *melting.*)

fusion (nuclear) The process by which light nuclei combine to form a heavier nucleus with the release of energy. (1070)

G

galvanic cell (See *voltaic cell.*)
gamma emission The type of radioactive decay in which gamma rays are emitted from an excited nucleus. (1049)
gamma (γ) ray A very high-energy photon. (1047)
gangue In an ore, the debris, such as sand, rock, and clay, attached to the mineral. (973)
gas One of the three states of matter. A gas fills its container regardless of the shape. (4)
Geiger-Müller counter An ionization counter that detects radioactive emissions through their ionization of gas atoms within the instrument. (1055)
genetic code The set of three-base sequences that is translated into specific amino acids during the process of protein synthesis. (659)
geometric isomers (also *cis-trans isomers* or *diastereomers*) Stereoisomers in which the molecules have the same connections between atoms but differ in the spatial arrangements of the atoms. The *cis* isomer has similar groups on the same side of a structural feature; the *trans* isomer has them on opposite sides. (629, 1024)
Graham's law of effusion A gas law stating that the rate of effusion of a gas is inversely proportional to the square root of its density (or molar mass):

$$\text{rate} \propto \frac{1}{\sqrt{\mathcal{M}}} \tag{205}$$

gray (Gy) The SI unit of absorbed radiation dose; 1 Gy = 1 J/kg tissue. (1063)
green chemistry Field that is focused on developing methods to synthesize compounds efficiently and reduce or prevent the release of harmful products into the environment. (115)
ground state The electron configuration of an atom or ion that is lowest in energy. (266)
group A vertical column in the periodic table. (54)

H

Haber process An industrial process used to form ammonia from its elements. (755)
half-cell A portion of an electrochemical cell in which a half-reaction takes place. (910)
half-life ($t_{1/2}$) In chemical processes, the time required for half the initial reactant concentration to be consumed. (689) In nuclear processes, the time required for half the initial number of nuclei in a sample to decay. (1054)
half-reaction method A method of balancing redox reactions by treating the oxidation and reduction half-reactions separately. (904)
haloalkane (also *alkyl halide*) A hydrocarbon with one or more halogen atoms (X) in place of H; contains a $-\overset{|}{\underset{|}{C}}-\ddot{\underset{\cdot\cdot}{X}}:$ group. (640)
hard water Water that contains large amounts of divalent cations, especially Ca^{2+} and Mg^{2+}. (529)
heat (q) The energy transferred between objects because of differences in their temperatures only; thermal energy. (22, 227)
heat capacity The quantity of heat required to change the temperature of an object by 1 K. (235)
heat of combustion (ΔH_{comb}) The enthalpy change occurring when 1 mol of a substance combines with oxygen in a combustion reaction. (234)
heat of formation (ΔH_f) The enthalpy change occurring when 1 mol of a compound is produced from its elements. (234)
heat of fusion (ΔH_{fus}) The enthalpy change occurring when 1 mol of a solid substance melts. (234, 427)
heat of hydration (ΔH_{hydr}) (also *enthalpy of hydration*) The enthalpy change occurring when 1 mol of a gaseous species is hydrated. The sum of the enthalpies from separating water molecules and mixing the gaseous species with them. (504)
heat of reaction (ΔH_{rxn}) The enthalpy change of a reaction. (233)
heat of solution (ΔH_{soln}) (also *enthalpy of solution*) The enthalpy change occurring when a solution forms from solute and solvent. The sum of the enthalpies from separating solute and solvent molecules and mixing them. (503)
heat of sublimation (ΔH_{subl}) The enthalpy change occurring when 1 mol of a solid substance changes directly to a gas. The sum of the heats of fusion and vaporization. (427)
heat of vaporization (ΔH_{vap}) The enthalpy change occurring when 1 mol of a liquid substance vaporizes. (234, 427)
heating-cooling curve A plot of temperature vs. time for a substance when heat is absorbed or released by the system at a constant rate. (428)
Henderson-Hasselbalch equation An equation for calculating the pH of a buffer system:

$$\text{pH} = \text{p}K_a + \log\left(\frac{[\text{base}]}{[\text{acid}]}\right) \tag{820}$$

Henry's law A law stating that the solubility of a gas in a liquid is directly proportional to the partial pressure of the gas above the liquid: $S_{gas} = k_H \times P_{gas}$. (510)
Hess's law of heat summation A law stating that the enthalpy change of an overall process is the sum of the enthalpy changes of the individual steps of the process. (240)
heteroatom Any atom in an organic compound other than C or H. (619)
heterogeneous catalyst A catalyst that occurs in a different phase from the reactants, usually a solid interacting with gaseous or liquid reactants. (708)
heterogeneous mixture A mixture that has one or more visible boundaries among its components. (73)
hexagonal closest packing A crystal structure based on the hexagonal unit cell in which the layers have an *abab* . . . pattern. (452)
high-spin complex Complex ion that has the same number of unpaired electrons as in the isolated metal ion; contains weak-field ligands. (1032)
homogeneous catalyst A catalyst (gas, liquid, or soluble solid) that exists in the same phase as the reactants. (707)
homogeneous mixture (also *solution*) A mixture that has no visible boundaries among its components. (73)
homologous series A series of organic compounds in which each member differs from the next by a $-CH_2-$ (methylene) group. (623)
homonuclear diatomic molecule A molecule composed of two identical atoms. (412)
Hund's rule A principle stating that when orbitals of equal energy are available, the electron configuration of lowest energy

has the maximum number of unpaired electrons with parallel spins. (297)

hybrid orbital An atomic orbital postulated to form during bonding by the mathematical mixing of specific combinations of nonequivalent orbitals in a given atom. (400)

hybridization A postulated process of orbital mixing to form hybrid orbitals. (400)

hydrate A compound in which a specific number of water molecules are associated with each formula unit. (66)

hydration Solvation in water. (503)

hydration shell The oriented cluster of water molecules that surrounds an ion in aqueous solution. (490)

hydrocarbon An organic compound that contains only H and C atoms. (620)

hydrogen bond (H bond) A type of dipole-dipole force that arises between molecules that have an H atom bonded to a small, highly electronegative atom with lone pairs, usually N, O, or F. (439, 551)

hydrogenation The addition of hydrogen to a carbon-carbon multiple bond to form a carbon-carbon single bond. (708)

hydrolysis Cleaving a molecule by reaction with water, in which one part of the molecule bonds to the water —OH and the other to the water H. (647)

hydronium ion (H_3O^+) A proton covalently bonded to a water molecule. (768)

hydrosphere The liquid portion of Earth's crust. (963)

hypothesis A testable proposal made to explain an observation. If inconsistent with experimental results, a hypothesis is revised or discarded. (11)

I

ideal gas A hypothetical gas that exhibits linear relationships among volume, pressure, temperature, and amount (mol) at all conditions; approximated by simple gases at ordinary conditions. (183)

ideal gas law (also *ideal gas equation*) An equation that expresses the relationships among volume, pressure, temperature, and amount (mol) of an ideal gas: $PV = nRT$. (188)

ideal solution A solution whose vapor pressure equals the mole fraction of the solvent times the vapor pressure of the pure solvent; approximated only by very dilute solutions. (516) (See also *Raoult's law.*)

indicator (See *acid-base indicator.*)

induced-fit model A model of enzyme action that pictures the binding of the substrate as inducing the active site to change its shape and become catalytically active. (710)

infrared (IR) The region of the electromagnetic spectrum between the microwave and visible regions. (259)

infrared (IR) spectroscopy An instrumental technique for determining the types of bonds in a covalent molecule by measuring the absorption of IR radiation. (345)

initial rate The instantaneous rate occurring as soon as the reactants are mixed, that is, at $t = 0$. (677)

inner electrons (also *core electrons*) Electrons that fill all the energy levels of an atom except the valence level; electrons also present in atoms of the previous noble gas and any completed transition series. (303)

inner transition elements The elements of the periodic table in which *f* orbitals are being filled; the lanthanides and actinides. (303, 1010)

instantaneous rate The reaction rate at a particular time, given by the slope of a tangent to a plot of reactant concentration vs. time. (677)

insulator A substance (usually a nonmetal) that does not conduct an electric current. (463)

integrated rate law A mathematical expression for reactant concentration as a function of time. (686)

intensive property A property, such as density, that does not depend on the quantity of substance present. (20)

interhalogen compound A compound consisting entirely of halogens. (602)

intermolecular forces (also *interparticle forces*) The attractive and repulsive forces among the particles—molecules, atoms, or ions—in a sample of matter. (425)

internal energy (*E*) The sum of the kinetic and potential energies of all the particles in a system. (226)

interstitial hydride The substance formed when metals absorb H_2 into the spaces between their atoms. (555)

ion A charged particle that forms from an atom (or covalently bonded group of atoms) when it gains or loses one or more electrons. (57)

ion-dipole force The intermolecular attractive force between an ion and a polar molecule (dipole). (437)

ion exchange A process of softening water by exchanging one type of ion (usually Ca^{2+}) for another (usually Na^+) by binding the ions on a specially designed resin. (529)

ion–induced dipole force The intermolecular attractive force between an ion and the dipole it induces in the electron cloud of a nearby particle. (490)

ion pair A pair of ions that form a gaseous ionic molecule; sometimes formed when a salt boils. (338)

ion-product constant for water (K_w) The equilibrium constant for the autoionization of water:

$$K_w = [H_3O^+]\,[OH^-] \qquad (773)$$

ionic atmosphere A cluster of ions of net opposite charge surrounding a given ion in solution. (525)

ionic bonding The idealized type of bonding based on the attraction of oppositely charged ions that arise through electron transfer between atoms with large differences in their tendencies to lose or gain electrons (typically metals and nonmetals). (330, 544)

ionic compound A compound that consists of oppositely charged ions. (57, 551)

ionic radius The size of an ion as measured by the distance between the centers of adjacent ions in a crystalline ionic compound. (320)

ionic solid A solid whose unit cell contains cations and anions. (457)

ionization The process by which a substance absorbs energy from high-energy radioactive particles and loses an electron to become ionized. (1062)

ionization energy (IE) The energy (in kJ) required to remove completely one mole of electrons from one mole of gaseous atoms or ions. (309, 543)

ionizing radiation The high-energy radiation that forms ions in a substance by causing electron loss. (1062)

isoelectronic Having the same number and configuration of electrons as another species. (316)

isomer One of two or more compounds with the same molecular formula but different properties, often as a result of different arrangements of atoms. (100, 625, 1023)
isotopes Atoms of a given atomic number (that is, of a specific element) that have different numbers of neutrons and therefore different mass numbers. (50, 1046)
isotopic mass The mass (in amu) of an isotope relative to the mass of carbon-12. (51)

J

joule (J) The SI unit of energy; 1 J = 1 kg·m^2/s^2. (229)

K

kelvin (K) The SI base unit of temperature. The kelvin is the same size as the Celsius degree. (23)
Kelvin scale (See *absolute scale*.)
ketone An organic compound (ending, *-one*) that contains a carbonyl group bonded to two other C atoms,  . (644)
kilogram (kg) The SI base unit of mass. (19)
kinetic energy (E_k) The energy an object has because of its motion. (6)
kinetic-molecular theory The model that explains gas behavior in terms of particles in random motion whose volumes and interactions are negligible. (200)

L

lanthanide contraction The additional decrease in atomic and ionic size, beyond the expected trend, caused by the poor shielding of the increasing nuclear charge by *f* electrons in the elements following the lanthanides. (1006)
lanthanides (also *rare earths*) The Period 6 (4*f*) series of inner transition elements, which includes cerium (Ce; $Z = 58$) through lutetium (Lu; $Z = 71$). (304, 1010)
lattice The three-dimensional arrangement of points created by choosing each point to be at the same location within each particle of a crystal; thus, the lattice consists of all points with identical surroundings. (450)
lattice energy ($\Delta H^\circ_{\text{lattice}}$) The enthalpy change (always positive) that accompanies a solid ionic compound forming separate gaseous ions. (334)
law (See *natural law*.)
law of chemical equilibrium (also *law of mass action*) The law stating that when a system reaches equilibrium at a given temperature, the ratio of quantities that make up the reaction quotient has a constant numerical value. (726)
law of conservation of energy (also *first law of thermodynamics*) A basic observation that the total energy of the universe is constant: $\Delta E_{\text{universe}} = \Delta E_{\text{system}} + \Delta E_{\text{surroundings}} = 0$. (229)
law of definite (or constant) composition A mass law stating that, no matter what its source, a particular compound is composed of the same elements in the same parts (fractions) by mass. (42)
law of mass action (See *law of chemical equilibrium*.)
law of mass conservation A mass law stating that the total mass of substances does not change during a chemical reaction. (41)
law of multiple proportions A mass law stating that if elements A and B react to form two compounds, the different masses of B that combine with a fixed mass of A can be expressed as a ratio of small whole numbers. (43)
Le Châtelier's principle A principle stating that if a system in a state of equilibrium is disturbed, it will undergo a change that shifts its equilibrium position in a direction that reduces the effect of the disturbance. (745)
leaching A hydrometallurgical process that extracts a metal selectively, usually through formation of a complex ion. (974)
level (also *shell*) A specific energy state of an atom given by the principal quantum number *n*. (278)
leveling effect The inability of a solvent to distinguish the strength of an acid (or base) that is stronger than the conjugate acid (or conjugate base) of the solvent. (800)
Lewis acid-base definition A model of acid-base behavior in which acids and bases are defined, respectively, as species that accept and donate an electron pair. (800)
Lewis electron-dot symbol A notation in which the element symbol represents the nucleus and inner electrons, and surrounding dots represent the valence electrons. (331)
Lewis structure (also *Lewis formula*) A structural formula consisting of electron-dot symbols, with lines as bonding pairs and dots as lone pairs. (366)
ligand A molecule or anion bonded to a central metal ion in a complex ion. (844, 1017)
like-dissolves-like rule An empirical observation stating that substances having similar kinds of intermolecular forces dissolve in each other. (490)
limiting reactant (also *limiting reagent*) The reactant that is consumed when a reaction occurs and therefore the one that determines the maximum amount of product that can form. (110)
line spectrum A series of separated lines of different colors representing photons whose wavelengths are characteristic of an element. (265) (See also *emission spectrum*.)
linear arrangement The geometric arrangement obtained when two electron groups maximize their separation around a central atom. (377)
linear shape A molecular shape formed by three atoms lying in a straight line, with a bond angle of 180° (shape class AX_2 or AX_2E_3). (377, 381)
linkage isomers Coordination compounds with the same composition but with different ligand donor atoms linked to the central metal ion. (1024)
lipid Any of a class of biomolecules, including fats and oils, that are soluble in nonpolar solvents. (647)
lipid bilayer An extended sheetlike double layer of phospholipid molecules that forms in water and has the charged heads of the molecules on the surfaces of the bilayer and the polar tails within the interior. (499)
liquid One of the three states of matter. A liquid fills a container to the extent of its own volume and thus forms a surface. (4)
liquid crystal A substance that flows like a liquid but packs like a crystalline solid at the molecular level. (466)
liter (L) A non-SI unit of volume equivalent to 1 cubic decimeter (0.001 m^3). (17)
lithosphere The solid portion of Earth's crust. (963)
lock-and-key model A model of enzyme function that pictures the enzyme active site and the substrate as rigid shapes that fit together as a lock and key, respectively. (710)
lone pair (also *unshared pair*) An electron pair that is part of an atom's valence shell but not involved in covalent bonding. (340)

low-spin complex Complex ion that has fewer unpaired electrons than in the free metal ion because of the presence of strong-field ligands. (1032)

M

macromolecule (See *polymer*.)
magnetic quantum number (m_l) (also *orbital-orientation quantum number*) An integer from $-l$ through 0 to $+l$ that specifies the orientation of an atomic orbital in the three-dimensional space about the nucleus. (277)
manometer A device used to measure the pressure of a gas in a laboratory experiment. (181)
mantle A thick homogeneous layer of Earth's internal structure that lies between the core and the crust. (961)
mass The quantity of matter an object contains. Balances are designed to measure mass. (19)
mass-action expression (See *reaction quotient*.)
mass defect The mass decrease that occurs when nucleons combine to form a nucleus. (1071)
mass fraction (See *fraction by mass*.)
mass number (A) The total number of protons and neutrons in the nucleus of an atom. (50)
mass percent (also *mass %* or *percent by mass*) The fraction by mass expressed as a percentage. (42) A concentration term [% (w/w)] expressed as the mass in grams of solute dissolved per 100. g of solution. (512)
mass spectrometry An instrumental method for measuring the relative masses of particles in a sample by creating charged particles and separating them according to their mass-charge ratio. (51)
matter Anything that possesses mass and occupies volume. (2)
mean free path The average distance a molecule travels between collisions at a given temperature and pressure. (206)
melting (also *fusion*) The change of a substance from a solid to a liquid. (426, 1070)
melting point (mp or T_f) The temperature at which the solid and liquid forms of a substance are at equilibrium. (434)
metabolic pathway A biochemical reaction sequence that flows in one direction and in which each reaction is enzyme catalyzed. (754)
metal A substance or mixture that is relatively shiny and malleable and is a good conductor of heat and electricity. In reactions, metals tend to transfer electrons to nonmetals and form ionic compounds. (56)
metallic bonding An idealized type of bonding based on the attraction between metal ions and their delocalized valence electrons. (330, 544) (See also *electron-sea model*.)
metallic radius One-half the distance between the nuclei of adjacent individual atoms in a crystal of an element. (305)
metallic solid A solid whose individual atoms are held together by metallic bonding. (459)
metalloid (also *semimetal*) An element with properties between those of metals and nonmetals. (56)
metallurgy The branch of materials science concerned with the extraction and utilization of metals. (973)
metathesis reaction (also *double-displacement reaction*) A reaction in which atoms or ions of two compounds exchange bonding partners. (143)
meter (m) The SI base unit of length. The distance light travels in a vacuum in 1/299,792,458 second. (17)
milliliter (mL) A volume (0.001 L) equivalent to 1 cm^3. (17)
millimeter of mercury (mmHg) A unit of pressure based on the difference in the heights of mercury in a barometer or manometer. Renamed the *torr* in honor of Torricelli. (181)
mineral The portion of an ore that contains the element of interest, a mineral is a naturally occurring, homogeneous, crystalline inorganic solid, with a well-defined composition. (973)
miscible Soluble in any proportion. (490)
mixture A group of two or more elements and/or compounds that are physically intermingled. (40, 489)
MO bond order One-half the difference between the number of electrons in bonding and antibonding MOs. (411)
model (also *theory*) A simplified conceptual picture based on experiment that explains how an aspect of nature occurs. (11)
molality (m) A concentration term expressed as number of moles of solute dissolved in 1000 g (1 kg) of solvent. (511)
molar heat capacity (C) The quantity of heat required to change the temperature of 1 mol of a substance by 1 K. (235)
molar mass ($\mathcal{M}$) (also *gram-molecular weight*) The mass of 1 mol of entities (atoms, molecules, or formula units) of a substance, in units of g/mol. (89)
molar solubility The solubility expressed in terms of amount (mol) of dissolved solute per liter of solution. (834)
molarity (M) A concentration term expressed as the moles of solute dissolved in 1 L of solution. (117)
mole (mol) The SI base unit for amount of a substance. The amount that contains a number of objects equal to the number of atoms in exactly 12 g of carbon-12. (87)
mole fraction (X) A concentration term expressed as the ratio of moles of one component of a mixture to the total moles present. (196, 513)
molecular compounds Compounds that consist of individual molecules and whose physical state depends on intermolecular forces. (551)
molecular equation A chemical equation showing a reaction in solution in which reactants and products appear as intact, undissociated compounds. (141)
molecular formula A formula that shows the actual number of atoms of each element in a molecule. (62, 96)
molecular mass (also *molecular weight*) The sum (in amu) of the atomic masses of a formula unit of a compound. (70)
molecular orbital (MO) An orbital of given energy and shape that extends over a molecule and can be occupied by no more than two electrons. (410)
molecular orbital (MO) diagram A depiction of the relative energy and number of electrons in each MO, as well as the atomic orbitals from which the MOs form. (411)
molecular orbital (MO) theory A model that describes a molecule as a collection of nuclei and electrons in which the electrons occupy orbitals that extend over the entire molecule. (409)
molecular polarity The overall distribution of electronic charge in a molecule, determined by its shape and bond polarities. (387)
molecular shape The three-dimensional structure defined by the relative positions of the atomic nuclei in a molecule. (376)
molecular solid A solid held together by intermolecular forces between individual molecules. (456)
molecularity The number of reactant particles involved in an elementary step. (701)
molecule A structure consisting of two or more atoms that are chemically bound together and behave as an independent unit. (40)

monatomic ion An ion derived from a single atom. (57)
monomer A small molecule, linked covalently to others of the same or similar type to form a polymer, on which the repeat unit of the polymer is based. (472)
mononucleotide A monomer unit of a nucleic acid, consisting of an N-containing base, a sugar, and a phosphate group. (500, 658)
monosaccharide A simple sugar; a polyhydroxy ketone or aldehyde with three to nine C atoms. (501, 654)

N

nanotechnology The science and engineering of nanoscale (1–50 nm) systems. (477)
natural law (also *law*) A summary, often in mathematical form, of a universal observation. (11)
Nernst equation An equation stating that the voltage of an electrochemical cell under any conditions depends on the standard cell voltage and the concentrations of the cell components:

$$E_{cell} = E^0_{cell} - \frac{RT}{nF} \ln Q \qquad (926)$$

net ionic equation A chemical equation of a reaction in solution in which spectator ions have been eliminated to show the actual chemical change. (141)
network covalent solid A solid in which all the atoms are bonded covalently. (459, 551)
neutralization reaction An acid-base reaction that yields water and a solution of a salt; when a strong acid reacts with a stoichiometrically equivalent amount of a strong base, the solution is neutral. (144, 768)
neutron (n^0) An uncharged subatomic particle found in the nucleus, with a mass slightly greater than that of a proton. (49)
nitrile An organic compound containing the —C≡N: group. (649)
node A region of an orbital where the probability of finding the electron is zero. (281)
nonbonding MO A molecular orbital that is not involved in bonding. (417)
nonelectrolyte A substance whose aqueous solution does not conduct an electric current. (138, 515)
nonionizing radiation Radiation that does not cause loss of electrons. (1062)
nonmetal An element that lacks metallic properties. In reactions, nonmetals tend to bond with each other to form covalent compounds or accept electrons from metals to form ionic compounds. (56)
nonpolar covalent bond A covalent bond between identical atoms such that the bonding pair is shared equally. (353)
nuclear binding energy The energy required to break 1 mole of nuclei of an element into individual nucleons. (1071)
nuclear magnetic resonance (NMR) spectroscopy An instrumental technique used to determine the molecular environment of a given type of nucleus, most often ^{1}H, from its absorption of radio waves in a magnetic field. (634)
nuclear transmutation The induced conversion of one nucleus into another by bombardment with a particle. (1059)
nucleic acid An unbranched polymer consisting of mononucleotides that occurs as two types, DNA and RNA (deoxyribonucleic and ribonucleic acids), which differ chemically in the nature of the sugar portion of the mononucleotides. (500, 658)
nucleon A subatomic particle that makes up a nucleus; a proton or neutron. (1046)
nucleus The tiny central region of the atom that contains all the positive charge and essentially all the mass. (48)
nuclide A nuclear species with specified numbers of protons and neutrons. (1046)
***N/Z* ratio** The ratio of the number of neutrons to the number of protons, a key factor that determines the stability of a nuclide. (1050)

O

observation A fact obtained with the senses, often with the aid of instruments. Quantitative observations provide data that can be compared objectively. (11)
occurrence (also *source*) The form(s) in which an element exists in nature. (965)
octahedral arrangement The geometric arrangement obtained when six electron groups maximize their space around a central atom; when all six groups are bonding groups, the molecular shape is octahedral (AX_6; ideal bond angle = 90°). (381)
octet rule The observation that when atoms bond, they often lose, gain, or share electrons to attain a filled outer shell of eight electrons. (332)
optical isomers (also *enantiomers*) A pair of stereoisomers consisting of a molecule and its mirror image that cannot be superimposed on each other. (627, 1024)
optically active Able to rotate the plane of polarized light. (628)
orbital diagram A depiction of electron number and spin in an atom's orbitals by means of arrows in a series of small boxes, lines, or circles. (296)
ore A naturally occurring compound or mixture of compounds from which an element can be profitably extracted. (965)
organic compound A compound in which carbon is nearly always bonded to itself and to hydrogen, and often to other elements. (617)
organometallic compound An organic compound in which carbon is bonded covalently to a metal atom. (644)
osmosis The process by which solvent flows through a semipermeable membrane from a dilute to a concentrated solution. (520)
osmotic pressure (Π) The pressure that results from the inability of solute particles to cross a semipermeable membrane. The pressure required to prevent the net movement of solvent across the membrane. (520)
outer electrons Electrons that occupy the highest energy level (highest n value) and are, on average, farthest from the nucleus. (303)
overall (net) equation A chemical equation that is the sum of two or more balanced sequential equations in which a product of one becomes a reactant for the next. (109)
overvoltage The additional voltage, usually associated with gaseous products, that is required above the standard cell voltage to accomplish electrolysis. (943)
oxidation The loss of electrons by a species, accompanied by an increase in oxidation number. (151)
oxidation number (O.N.) (also *oxidation state*) A number equal to the magnitude of the charge an atom would have if its shared electrons were held completely by the atom that attracts them more strongly. (151)

oxidation number method A method for balancing redox reactions in which the change in oxidation numbers is used to determine balancing coefficients. (154)
oxidation-reduction reaction (also *redox reaction*) A process in which there is a net movement of electrons from one reactant (reducing agent) to another (oxidizing agent). (150)
oxidation state (See *oxidation number.*)
oxidizing agent The substance that accepts electrons in a reaction and undergoes a decrease in oxidation number. (151)
oxoanion An anion in which an element is bonded to one or more oxygen atoms. (66)

P

***p* block** The main-group elements that lie to the right of the transition elements in the periodic table and whose *p* orbitals are being filled. (542)
***p* orbital** An atomic orbital with $l = 1$. (281)
packing efficiency The percentage of the available volume occupied by atoms, ions, or molecules in a unit cell. (452)
paramagnetism The tendency of a species with unpaired electrons to be attracted by an external magnetic field. (318, 1009)
partial ionic character An estimate of the actual charge separation in a bond (caused by the electronegativity difference of the bonded atoms) relative to complete separation. (354)
partial pressure The portion of the total pressure contributed by a gas in a mixture of gases. (195)
particle accelerator A device used to impart high kinetic energies to nuclear particles. (1060)
pascal (Pa) The SI unit of pressure; 1 Pa = 1 N/m^2. (181)
penetration The process by which an outer electron moves through the region occupied by the core electrons to spend part of its time closer to the nucleus; penetration increases the average effective nuclear charge for that electron. (295)
percent by mass (mass %) (See *mass percent.*)
percent yield (% yield) The actual yield of a reaction expressed as a percent of the theoretical yield. (114)
period A horizontal row of the periodic table. (54)
periodic law A law stating that when the elements are arranged by atomic number, they exhibit a periodic recurrence of properties. (291)
periodic table of the elements A table in which the elements are arranged by atomic number into columns (groups) and rows (periods). (54)
pH The negative common logarithm of $[H_3O^+]$. (775)
phase A physically distinct portion of a system. (425)
phase change A physical change from one phase to another, usually referring to a change in physical state. (425)
phase diagram A diagram used to describe the stable phases and phase changes of a substance as a function of temperature and pressure. (434)
phlogiston theory An incorrect theory of combustion proposing that a burning substance releases the undetectable material phlogiston. (9)
photoelectric effect The observation that when monochromatic light of sufficient frequency shines on a metal, an electric current is produced. (263)
photon A quantum of electromagnetic radiation. (263)
photovoltaic cell A device capable of converting light directly into electricity. (247)
physical change A change in which the physical form (or state) of a substance, but not its composition, is altered. (2)
physical property A characteristic shown by a substance itself, without interacting with or changing into other substances. (2)
pi (π) bond A covalent bond formed by sideways overlap of two atomic orbitals that has two regions of electron density, one above and one below the internuclear axis. (407)
pi (π) MO A molecular orbital formed by combination of two atomic (usually *p*) orbitals whose orientations are perpendicular to the internuclear axis. (413)
Planck's constant (*h*) A proportionality constant relating the energy and the frequency of a photon, equal to 6.626×10^{-34} J·s. (262)
plastic A material that, when deformed, retains its new shape. (476)
polar covalent bond A covalent bond in which the electron pair is shared unequally, so the bond has partially negative and partially positive poles. (353)
polar molecule A molecule with an unequal distribution of charge as a result of its polar bonds and shape. (135)
polarimeter A device used to measure the rotation of plane-polarized light by an optically active compound. (628)
polarizability The ease with which a particle's electron cloud can be distorted. (440)
polyatomic ion An ion in which two or more atoms are bonded covalently. (66)
polymer (also *macromolecule*) An extremely large molecule that results from the covalent linking of many simpler molecular units (monomers). (472)
polyprotic acid An acid with more than one ionizable proton. (786)
polysaccharide A macromolecule composed of many simple sugars linked covalently. (501, 654)
positron ($^0_1\beta$) The antiparticle of an electron. (1049)
positron decay A type of radioactive decay in which a positron is emitted from a nucleus. (1049)
potential energy (E_p) The energy an object has as a result of its position relative to other objects or because of its composition. (6)
precipitate The insoluble product of a precipitation reaction. (141)
precipitation reaction A reaction in which two soluble ionic compounds form an insoluble product, a precipitate. (141)
precision (also *reproducibility*) The closeness of a measurement to other measurements of the same phenomenon in a series of experiments. (29)
pressure (*P*) The force exerted per unit of surface area. (179)
pressure-volume work (*PV* work) A type of work in which a volume change occurs against an external pressure. (228)
principal quantum number (*n*) A positive integer that specifies the energy and relative size of an atomic orbital. (277)
probability contour A shape that defines the volume around an atomic nucleus within which an electron spends a given percentage of its time. (277)
product A substance formed in a chemical reaction. (102)
property A characteristic that gives a substance its unique identity. (2)
protein A natural, linear polymer composed of any of about 20 types of amino acid monomers linked together by peptide bonds. (495, 655)
proton (p^+) A subatomic particle found in the nucleus that has a unit positive charge (1.60218×10^{-19} C). (49)

proton acceptor A substance that accepts an H^+ ion; a Brønsted-Lowry base. (778)
proton donor A substance that donates an H^+ ion; a Brønsted-Lowry acid. (777)
pseudo–noble gas configuration The $(n-1)d^{10}$ configuration of a *p*-block metal atom that has emptied its outer energy level. (316)
pure substance (See *substance*.)

Q

qualitative analysis The separation and identification of the ions in an aqueous mixture. (851)
quantum A packet of energy equal to $h\nu$. The smallest quantity of energy that can be emitted or absorbed. (262)
quantum mechanics The branch of physics that examines the wave motion of objects on the atomic scale. (275)
quantum number A number that specifies a property of an orbital or an electron. (262)

R

rad (*r*adiation-*a*bsorbed *d*ose) The quantity of radiation that results in 0.01 J of energy being absorbed per kilogram of tissue; 1 rad = 0.01 J/kg tissue = 10^{-2} Gy. (1063)
radial probability distribution plot The graphic depiction of the total probability distribution (sum of ψ^2) of an electron in the region near the nucleus. (277)
radioactivity The emissions resulting from the spontaneous disintegration of an unstable nucleus. (1046)
radioisotope An isotope with an unstable nucleus that decays through radioactive emissions. (1057)
radioisotopic dating A method for determining the age of an object based on the rate of decay of a particular radioactive nuclide. (1057)
radius of gyration (R_g) A measure of the size of a coiled polymer chain as the average distance from the center of mass of the chain to its outside edge. (474)
random coil The shape adopted by most polymer chains and caused by random rotation about the bonds joining the repeat units. (473)
random error Human error that occurs in all measurements and results in values *both* higher and lower than the actual value. (29)
Raoult's law A law stating that the vapor pressure of a solution is directly proportional to the mole fraction of solvent: $P_{\text{solvent}} = X_{\text{solvent}} \times P^0_{\text{solvent}}$. (516)
rare earths (See *lanthanides*.)
rate constant (k) The proportionality constant that relates the reaction rate to reactant (and product) concentrations. (680)
rate-determining step (also *rate-limiting step*) The slowest step in a reaction mechanism and therefore the step that limits the overall rate. (702)
rate law (also *rate equation*) An equation that expresses the rate of a reaction as a function of reactant (and product) concentrations. (679)
reactant A starting substance in a chemical reaction. (102)
reaction energy diagram A graph that shows the potential energy of a reacting system as it progresses from reactants to products. (698)
reaction intermediate A substance that is formed and used up during the overall reaction and therefore does not appear in the overall equation. (701)
reaction mechanism A series of elementary steps that sum to the overall reaction and is consistent with the rate law. (700)
reaction order The exponent of a reactant concentration in a rate law that shows how the rate is affected by changes in that concentration. (680)
reaction quotient (Q) (also *mass-action expression*) A ratio of terms for a given reaction consisting of product concentrations multiplied together and divided by reactant concentrations multiplied together, each raised to the power of their balancing coefficient. The value of Q changes until the system reaches equilibrium, at which point it equals K. (726)
reaction rate The change in the concentrations of reactants (or products) with time. (675)
reactor core The part of a nuclear reactor that contains the fuel rods and generates heat from fission. (1076)
redox reaction (See *oxidation-reduction reaction*.)
reducing agent The substance that donates electrons in a redox reaction and undergoes an increase in oxidation number. (151)
reduction The gain of electrons by a species, accompanied by a decrease in oxidation number. (151)
refraction A phenomenon in which a wave changes its speed and therefore its direction as it passes through a phase boundary. (260)
rem (*r*oentgen *e*quivalent for *m*an) The unit of radiation dosage for a human based on the product of the number of rads and a factor related to the biological tissue; 1 rem = 10^{-2} Sv. (1063)
resonance hybrid The weighted average of the resonance structures of a molecule. (370)
resonance structure (also *resonance form*) One of two or more Lewis structures for a molecule that cannot be adequately depicted by a single structure. Resonance structures differ only in the position of bonding and lone electron pairs. (369)
reverse osmosis A process for preparing drinkable water that uses an applied pressure greater than the osmotic pressure to remove ions from an aqueous solution, typically seawater. (530)
rms (root-mean-square) speed (u_{rms}) The speed of a molecule having the average kinetic energy; very close to the most probable speed. (204)
roasting A pyrometallurgical process in which metal sulfides are converted to oxides. (974)
round off The process of removing digits based on a series of rules to obtain an answer with the proper number of significant figures (or decimal places). (27)

S

***s* block** The main-group elements that lie to the left of the transition elements in the periodic table and whose *s* orbitals are being filled. (542)
***s* orbital** An atomic orbital with $l = 0$. (280)
salt An ionic compound that results from a classical acid-base reaction. (145)
salt bridge An inverted U tube containing a solution of nonreacting electrolyte that connects the compartments of a voltaic cell and maintains neutrality by allowing ions to flow between compartments. (910)
saturated hydrocarbon A hydrocarbon in which each C is bonded to four other atoms. (623)

saturated solution A solution that contains the maximum amount of dissolved solute at a given temperature in the presence of undissolved solute. (507)
scanning tunneling microscopy An instrumental technique that uses electrons moving across a minute gap to observe the topography of a surface on the atomic scale. (455)
Schrödinger equation An equation that describes how the electron matter-wave changes in space around the nucleus. Solutions of the equation provide allowable energy levels of the H atom. (275)
scientific method A process of creative thinking and testing aimed at objective, verifiable discoveries of the causes of natural events. (10)
scintillation counter A device used to measure radioactivity through its excitation of atoms and their subsequent emission of light. (1055)
second (s) The SI base unit of time. (24)
second law of thermodynamics A law stating that a process occurs spontaneously in the direction that increases the entropy of the universe. (870)
seesaw shape A molecular shape caused by the presence of one equatorial lone pair in a trigonal bipyramidal arrangement (AX_4E). (380)
selective precipitation The process of separating ions through differences in the solubility of their compounds with a given precipitating ion. (850)
self-ionization (See *autoionization.*)
semiconductor A substance whose electrical conductivity is poor at room temperature but increases significantly with rising temperature. (463)
semimetal (See *metalloid.*)
semipermeable membrane A membrane that allows solvent, but not solute, to pass through. (520)
shared pair (See *bonding pair.*)
shell (See *level.*)
shielding The ability of other electrons, especially inner ones, to lessen the nuclear attraction for an outer electron. (294)
SI unit A unit composed of one or more of the base units of the Système International d'Unités, a revised metric system. (16)
side reaction An undesired chemical reaction that consumes some of the reactant and reduces the overall yield of the desired product. (114)
side-to-side overlap Overlap of *p* with *p* (or sometimes with *d*) atomic orbitals that leads to a pi (π) bond. (545)
sievert (Sv) The SI unit of human radiation dosage; 1 Sv = 100 rem. (1063)
sigma (σ) bond A type of covalent bond that arises through end-to-end orbital overlap and has most of its electron density along the bond axis. (407)
sigma (σ) MO A molecular orbital that is cylindrically symmetrical about an imaginary line that runs through the nuclei of the component atoms. (411)
significant figures The digits obtained in a measurement. The greater the number of significant figures, the greater the certainty of the measurement. (26)
silicate A type of compound found throughout rocks and soil and consisting of repeating —Si—O groupings and, in most cases, metal cations. (578)
silicone A type of synthetic polymer containing —Si—O repeat units, with organic groups and crosslinks. (578)
simple cubic unit cell A unit cell in which a particle occurs at each corner of a cube. (450)
single bond A bond that consists of one electron pair. (340)
slag A molten waste product formed in a blast furnace by the reaction of acidic silica with a basic metal oxide. (981)
smelting Heating a mineral with a reducing agent, such as coke, to obtain a metal. (975)
soap The salt of a fatty acid and usually a Group 1A(1) or 2A(2) hydroxide. (498)
solid One of the three states of matter. A solid has a fixed shape that does not conform to the container shape. (4)
solubility (*S*) The maximum amount of solute that dissolves in a fixed quantity of a particular solvent at a specified temperature when excess solute is present. (490)
solubility-product constant (K_{sp}) An equilibrium constant for the dissolving of a slightly soluble ionic compound in water. (833)
solute The substance that dissolves in the solvent. (117, 490)
solution (See *homogeneous mixture.*)
solvated Surrounded closely by solvent molecules. (136)
solvation The process of surrounding a solute particle with solvent particles. (136, 503)
solvent The substance in which the solute(s) dissolve. (117, 490)
source (See *occurrence.*)
***sp* hybrid orbital** An orbital formed by the mixing of one *s* and one *p* orbital of a central atom. (400)
***sp*^{2} hybrid orbital** An orbital formed by the mixing of one *s* and two *p* orbitals of a central atom. (402)
***sp*^{3} hybrid orbital** An orbital formed by the mixing of one *s* and three *p* orbitals of a central atom. (402)
***sp*^{3}*d* hybrid orbital** An orbital formed by the mixing of one *s*, three *p*, and one *d* orbital of a central atom. (403)
***sp*^{3}*d*^{2} hybrid orbital** An orbital formed by the mixing of one *s*, three *p*, and two *d* orbitals of a central atom. (404)
specific heat capacity (*c*) The quantity of heat required to change the temperature of 1 gram of a substance by 1 K. (235)
spectator ion An ion that is present as part of a reactant but is not involved in the chemical change. (141)
spectrochemical series A ranking of ligands in terms of their ability to split *d*-orbital energies. (1031)
spectrophotometry A group of instrumental techniques that create an electromagnetic spectrum to measure the atomic and molecular energy levels of a substance. (269)
speed of light (*c*) A fundamental constant giving the speed at which electromagnetic radiation travels in a vacuum: $c = 2.99792458 \times 10^8$ m/s. (258)
spin quantum number (m_s) A number, either $+\frac{1}{2}$ or $-\frac{1}{2}$, that indicates the direction of electron spin. (293)
spontaneous change A change that occurs by itself, that is, without an ongoing input of energy. (864)
square planar shape A molecular shape (AX_4E_2) caused by the presence of two axial lone pairs in an octahedral arrangement. (381)
square pyramidal shape A molecular shape (AX_5E) caused by the presence of one lone pair in an octahedral arrangement. (381)
standard atmosphere (atm) The average atmospheric pressure measured at sea level, defined as 1.01325×10^5 Pa. (181)
standard cell potential (E^0_{cell}) The potential of a cell measured with all components in their standard states and no current flowing. (915)

standard electrode potential ($E^0_{\text{half-cell}}$) (also *standard half-cell potential*) The standard potential of a half-cell, with the half-reaction written as a reduction. (915)
standard entropy of reaction (ΔS^0_{rxn}) The entropy change that occurs when all components are in their standard states. (875)
standard free energy change (ΔG^0) The free energy change that occurs when all components are in their standard states. (882)
standard free energy of formation (ΔG^0_f) The standard free energy change that occurs when 1 mol of a compound is made from its elements. (883)
standard half-cell potential (See *standard electrode potential.*)
standard heat of formation (ΔH^0_f) The enthalpy change that occurs when 1 mol of a compound forms from its elements, with all substances in their standard states. (242)
standard heat of reaction (ΔH^0_{rxn}) The enthalpy change that occurs during a reaction, with all substances in their standard states. (242)
standard hydrogen electrode (See *standard reference half-cell.*)
standard molar entropy (S^0) The entropy of 1 mol of a substance in its standard state. (871)
standard molar volume The volume of 1 mol of an ideal gas at standard temperature and pressure: 22.4141 L. (187)
standard reference half-cell (also *standard hydrogen electrode*) A specially prepared platinum electrode immersed in 1 *M* $H^+(aq)$ through which H_2 gas at 1 atm is bubbled. $E^0_{\text{half-cell}}$ is defined as 0 V. (916)
standard states A set of specifications used to compare thermodynamic data: 1 atm for gases behaving ideally, 1 *M* for dissolved species, or the pure substance for liquids and solids. (242)
standard temperature and pressure (STP) The reference conditions for a gas:

0°C (273.15 K) and 1 atm (760 torr) (187)

state function A property of the system determined by its current state, regardless of how it arrived at that state. (230)
state of matter One of the three physical forms of matter: solid, liquid, or gas. (4)
stationary state In the Bohr model, one of the allowable energy levels of the atom in which it does not release or absorb energy. (265)
steel An alloy of iron with small amounts of carbon and usually other metals. (980)
stellar nucleogenesis The process by which elements are formed in the stars through nuclear fusion. (1078)
stereoisomers Molecules with the same connections of atoms but different orientations of groups in space. (627, 1024) (See also *geometric isomers* and *optical isomers.*)
stoichiometric coefficient (See *balancing coefficient.*)
stoichiometry The study of the mass-mole-number relationships of chemical formulas and reactions. (87)
strong-field ligand A ligand that causes larger crystal field splitting energy and therefore is part of a low-spin complex. (1030)
strong force An attractive force that exists between all nucleons and is about 100 times stronger than the electrostatic repulsive force. (1051)
structural formula A formula that shows the actual number of atoms, their relative placement, and the bonds between them. (62)
structural isomers (See *constitutional isomers.*)
sublevel (also *subshell*) An energy substate of an atom within a level. Given by the *n* and *l* values, the sublevel designates the size and shape of the atomic orbitals. (278)
sublimation The process by which a solid changes directly into a gas. (427)
substance (also *pure substance*) A type of matter, either an element or a compound, that has a fixed composition. (39)
substitution reaction An organic reaction that occurs when an atom (or group) from one reactant substitutes for one in another reactant. (636)
substrate A reactant that binds to the active site in an enzyme-catalyzed reaction. (709)
superconductivity The ability to conduct a current with no loss of energy to resistive heating. (463)
supersaturated solution An unstable solution in which more solute is dissolved than in a saturated solution. (507)
surface tension The energy required to increase the surface area of a liquid by a given amount. (443)
surroundings All parts of the universe other than the system being considered. (225)
suspension A heterogeneous mixture containing particles that are distinct from the surrounding medium. (527)
syngas Synthesis gas; a combustible mixture of CO and H_2. (245)
synthetic natural gas (SNG) A gaseous fuel mixture, mostly methane, formed from coal. (245)
system The defined part of the universe under study. (225)
systematic error A type of error producing values that are all either higher or lower than the actual value, often caused by faulty equipment or a consistent fault in technique. (29)

T

t_{2g} orbitals The set of orbitals (composed of d_{xy}, d_{yz}, and d_{xz}) that results when the energies of the metal-ion *d* orbitals are split by a ligand field. This set is lower in energy than the other (e_g) set in an octahedral field and higher in energy in a tetrahedral field. (1030)
T shape A molecular shape caused by the presence of two equatorial lone pairs in a trigonal bipyramidal arrangement (AX_3E_2). (380)
temperature (*T*) A measure of how hot or cold a substance is relative to another substance. (22)
tetrahedral arrangement The geometric arrangement formed when four electron groups maximize their separation around a central atom; when all four groups are bonding groups, the molecular shape is tetrahedral (AX_4; ideal bond angle 109.5°). (379)
theoretical yield The amount of product predicted by the stoichiometrically equivalent molar ratio in the balanced equation. (114)
theory (See *model.*)
thermochemical equation A chemical equation that shows the heat of reaction for the amounts of substances specified. (238)
thermochemistry The branch of thermodynamics that focuses on the heat involved in chemical reactions. (225)
thermodynamics The study of heat (thermal energy) and its interconversions. (225)
thermometer A device for measuring temperature that contains a fluid that expands or contracts within a graduated tube. (22)
third law of thermodynamics A law stating that the entropy of a perfect crystal is zero at 0 K. (871)

titration A method of determining the concentration of a solution by monitoring its reaction with a solution of known concentration. (146)
torr A unit of pressure identical to 1 mmHg. (181)
total ionic equation A chemical equation for an aqueous reaction that shows all the soluble ionic substances dissociated into ions. (141)
tracer A radioisotope that signals the presence of the species of interest by emitting nonionizing radiation. (1066)
transition element (also *transition metal*) An element that occupies the *d* block of the periodic table; one whose *d* orbitals are being filled. (301, 1003)
transition state (also *activated complex*) An unstable species formed in an effective collision of reactants that exists momentarily when the system is highest in energy and that can either form products or re-form reactants. (697)
transition state theory A model that explains how the energy of reactant collision is used to form a high-energy transitional species that can change to reactant or product. (694)
transuranium element An element with atomic number higher than that of uranium ($Z = 92$). (1061)
trigonal bipyramidal arrangement The geometric arrangement formed when five electron groups maximize their separation around a central atom. When all five groups are bonding groups, the molecular shape is trigonal bipyramidal (AX_5; ideal bond angles, axial-center-equatorial 90° and equatorial-center-equatorial 120°). (380)
trigonal planar arrangement The geometric arrangement formed when three electron groups maximize their separation around a central atom. (377)
trigonal planar shape A molecular shape (AX_3) formed when three atoms around a central atom lie at the corners of an equilateral triangle; ideal bond angle, 120°. (377)
trigonal pyramidal shape A molecular shape (AX_3E) caused by the presence of one lone pair in a tetrahedral arrangement. (379)
triple bond A covalent bond that consists of three bonding pairs, two atoms sharing six electrons; one σ and two π bonds. (340)
triple point The pressure and temperature at which three phases of a substance are in equilibrium. In a phase diagram, the point at which three phase-transition curves meet. (435)
Tyndall effect The scattering of light by a colloidal suspension. (528)

U

ultraviolet (UV) region The region of the electromagnetic spectrum between the visible and the x-ray regions. (259)
uncertainty A characteristic of every measurement that results from the inexactness of the measuring device and the necessity of estimating when taking a reading. (25)
uncertainty principle The principle stated by Werner Heisenberg that it is impossible to know simultaneously the exact position and velocity of a particle; the principle becomes important only for particles of very small mass. (274)
unimolecular reaction An elementary reaction that involves the decomposition or rearrangement of a single particle. (701)
unit cell The smallest portion of a crystal that, if repeated in all three directions, gives the crystal. (450)
universal gas constant (*R*) A proportionality constant that relates the energy, amount of substance, and temperature of a system; $R = 0.0820578$ atm·L/mol·K $= 8.31447$ J/mol·K. (188)
unsaturated hydrocarbon A hydrocarbon with at least one carbon-carbon multiple bond; one in which at least two C atoms are bonded to fewer than four atoms. (628)
unsaturated solution A solution in which more solute can be dissolved at a given temperature. (507)
unshared pair (See *lone pair.*)

V

V shape (See *bent shape.*)
valence band In band theory, the lower energy portion of the band of molecular orbitals, which is filled with valence electrons. (462)
valence bond (VB) theory A model that attempts to reconcile the shapes of molecules with those of atomic orbitals through the concepts of orbital overlap and hybridization. (399)
valence electrons The electrons involved in compound formation; in main-group elements, the electrons in the valence (outer) level. (303)
valence-shell electron-pair repulsion (VSEPR) theory A model explaining that the shapes of molecules and ions result from minimizing electron-pair repulsions around a central atom. (376)
van der Waals constants Experimentally determined positive numbers used in the van der Waals equation to account for the intermolecular attractions and molecular volume of real gases. (212)
van der Waals equation An equation that accounts for the behavior of real gases. (212)
van der Waals radius One-half of the closest distance between the nuclei of identical nonbonded atoms. (437)
vapor pressure (also *equilibrium vapor pressure*) The pressure exerted by a vapor at equilibrium with its liquid in a closed system. (431)
vapor pressure lowering (ΔP) The lowering of the vapor pressure of a solvent caused by the presence of dissolved solute particles. (516)
vaporization The process of changing from a liquid to a gas. (426)
variable A quantity that can have more than a single value. (11) (See also *controlled experiment.*)
viscosity A measure of the resistance of a liquid to flow. (445)
volatility The tendency of a substance to become a gas. (74)
volt (V) The SI unit of electric potential: 1 V = 1 J/C. (914)
voltage (See *cell potential.*)
voltaic cell (also *galvanic cell*) An electrochemical cell that uses a spontaneous reaction to generate electric energy. (908)
volume (*V*) The space occupied by a sample of matter. (17)
volume percent [% (v/v)] A concentration term defined as the volume of solute in 100. volumes of solution. (512)

W

wastewater (also *sewage*) Used water, usually containing industrial and/or residential waste, that is treated before being returned to the environment. (530)
water softening The process of removing hard-water ions, such as Ca^{2+} and Mg^{2+}, from water. (529)
wave function (See *atomic orbital.*)

wave-particle duality The principle stating that both matter and energy have wavelike and particle-like properties. (274)

wavelength (λ) The distance between any point on a wave and the corresponding point on the next wave, that is, the distance a wave travels during one cycle. (258)

weak-field ligand A ligand that causes smaller crystal field splitting energy and therefore is part of a high-spin complex. (1030)

weight The force exerted by a gravitational field on an object. (19)

work (*w*) The energy transferred when an object is moved by a force. (227)

X

x-ray diffraction analysis An instrumental technique used to determine spatial dimensions of a crystal structure by measuring the diffraction patterns caused by x-rays impinging on the crystal. (455)

Z

zone refining A process used to purify metals and metalloids in which impurities are removed from a bar of the element by concentrating them in a thin molten zone. (521, 977)

Index

Page numbers followed by *f* indicate figures; *mn*, marginal notes; *n*, footnotes; and *t*, tables.

A

AB block copolymer, 477
Absolute temperature scale, 23, 185
Absolute zero, 185
Absorption spectrum, 269
Abundance, of elements, 961–65
Accuracy, in measurement, 29–30
Acetaldehyde, 438, 639*t*, 644*f*
Acetamide, 639*t*
Acetaminophen, 648
Acetate ion, 816, 817
Acetic acid
  acid-base buffer systems, 816–17
  acid-dissociation constant, 771*t*
  as base, 800
  catalysts, 707*t*
  chemical formula, 99*t*
  equilibrium constant, 775*t*
  functional group, 639*t*
  gas-forming reactions, 149
  household uses, 767*t*
  molecule, 72*f*
  reversible reactions, 166
  solvents, 518*t*
  weak acids, 149
Acetone, 634–35, 639*t*, 644*t*
Acetonitrile, 438*f*, 639*t*
Acetylene, 406, 408*f*, 639*t*
Acetylide ion, 198
Acetylsalicylic acid, 72
Acid(s). *See also* Acid-base behavior; Acid-base reactions; Ionic equilibrium; Strong acids; Weak acids
  acid-dissociation constant, 769–71
  Arrhenius acids, 768, 803
  autoionization of water and pH scale, 773–77
  balancing of redox reactions, 905–6
  Brønsted-Lowry acids, 602, 777–82, 799–800, 802, 803
  classification of relative strengths, 772
  conjugate acid-base pairs, 778–79, 781*f*, 791–93, 817*f*, 822
  covalent compounds in water, 138–39
  definition, 144, 547, 767, 768–69, 777–82, 799–804
  displacement reactions, 161
  equilibrium constants, A8
  household uses, 767*t*
  Lewis acids, 570, 800–804, 844
  molecular properties and strength of, 793–95
  naming, 67–68
  proton transfer, 148–49, 777–82
  salt solutions, 796–97
  in water, 768
Acid anhydride, 646
Acid rain, 31, 72*f*, 240, 577, 683, 729, 815, 842–43. *See also* Air pollution
Acid-base behavior, 314–15, 547, 796–99. *See also* Acid(s); Acid-base reactions; Base(s)
Acid-base buffer systems, 815–24
Acid-base catalysis, 710
Acid-base equilibrium, 782–93. *See also* Acid-base indicator; Acid-dissociation constant; Autoionization; Base-dissociation constant; Brønsted-Lowry acid-base definition; Lewis acid-base definition
Acid-base indicator, 146–47, 777, 824–25
Acid-base reactions, 144–50, 166, 232, 314–15
Acid-base titration, 146–47
Acid-base titration curves, 824–32
Acid-dissociation constant (K_a), 769–71, 795*t*
Acidic amino acids, 655*f*
Acidic oxide, 547
Acid-insoluble sulfides, 853
Acidophilic microbes, 840
Acrylates, 472*t*
Acrylonitrile, 346, 707*t*
Actin, 468*f*
Actinides, 55, 304, 1011
Activated complex, 697
Activation analysis, 1068
Activation energy (E_a), and reaction rates, 692, 694–96, 697
Active site, of enzyme, 709, 754
Activity, and radioactive decay, 1054
Activity series, and displacement reactions, 161–63
Activity series of metals, 163, 921–22
Actual yield, 114
Addition, of significant figures, 28
Addition polymers, 651–52
Addition reaction, 635–36
Adduct, and Lewis acid-base definition, 801, 843
Adenine, 641*f*, 658
Adenosine diphosphate (ADP), 889, 947
Adenosine triphosphate (ATP), 585, 591, 889–90, 930*mn*, 947–48
Adiponitrile, 707*t*
ADP. *See* Adenosine diphosphate
Advanced materials, and intermolecular forces, 464–79
Aerosol, 527*t*
Aerosol propellants, 711
Air, composition of, 208*t*. *See also* Atmosphere
Air pollution. *See also* Acid rain; Global warming; Greenhouse effect; Smog
  carbon monoxide, 72*f*
  chlorofluorocarbons (CFCs or Freons), 577
  density of gas, 193*mn*
  nitrogen dioxide, 72*f*
  ozone and ozone layer, 72*f*, 711
  polycyclic aromatic compounds, 633*mn*
  solvents, 493*mn*
  sulfur dioxide, 596*mn*
  temperature inversion, 208
  thermal pollution, 509*f*
  types of, 72*f*
Air-conditioning coolants, 711
Alanine, 627, 655*f*
Alchemy, 8
Alcohol(s)
  bond energy, 350
  functional group, 70, 638, 639*t*, 640
  solvents, 138, 492
Alcohol dehydrogenase, 1036*t*
Aldehydes, 639*t*, 643–44, 707*t*
Aliphatic hydrocarbons. *See* Alkanes
Aliquot, 681
Alizarin, 824*f*
Alkali metals
  and alkaline earth metals, 562–63
  atomic number, 308
  atomic, physical, and chemical properties, 558–59, 560–61*f*
  electron configuration, 300, 316
  ion groups, 853
  ionization energy, 309*f*, 310
  isolation and industrial uses, 978–80
  macronutrients, 61–62
  metallic bonding, 358
  periodic table, 56
Alkaline battery, 932
Alkaline earth metals, 57, 62, 358, 562–63, 564–65*f*
Alkanes, 69, 623–26
Alkenes, 628–29, 639*t*, 643
Alkoxide ion, 638
Alkyl group, 634
Alkyl halides, 640
Alkylmagnesium halides, 565

Alkynes, 631, 639*t*, 649
Allotropism, 573, 583, 594
Alloys, 358, 494, 495*f*, 977–78, 985, 988
Alpha (α) decay, 1048–49
Alpha (α) particles, and radioactivity, 1047, 1063
Aluminosilicate, 580, 842, 984

state functions, 231
Wright, Joseph, 8*f*
Wüthrich, Kurt, 635

X

Xenon fluorides, 605
Xenon tetrafluoride, 381, 605*f*
Xenopus laevis, 931*mn*
Xerography, 594*mn*
Xylenes, 632
X-ray diffraction analysis, 455–56
X-rays
barium solution, 838*f*
electromagnetic spectrum, 259
electron diffraction, 273*f*
radiation dose, 1064*t*, 1065

Y

Ytterbium, 50*mn*
Yttrium, 50*mn*, 1010*mn*
Yucca Mountain (Nevada), 1077

Z

Zeolite, 581, 989, 1011
Zero
absolute temperature scale, 23*f*, 185
significant figures, 26
Zero order, of reaction, 682, 686–87, 689, 691*t*
Zero point, of atom energy, 267
Zewail, Ahmed H., 697
Ziegler, Karl, 652
Ziegler-Natta catalysts, 652
Zinc
activity series, 162
atomic size, 306
corrosion protection, 938
diamagnetism, 319
dietary trace elements, 1036
electron configuration, 302
industrial uses, 1003
reaction rate with strong and weak acids, 770
redox reactions, 904*f*
standard cell potentials, 915
voltaic cells, 909–10, 911–12, 913, 927–28
Zinc blende structure, 458
Zinc iodate, 834*t*
Zinc oxide, 469–70, 1017
Zinc sulfate heptahydrate, 1009*f*
Zinc sulfide, 458*f*, 846
Zircon, 471, 578
Zirconium, 1003, 1010
Zone refining, 521, 977
Zwitterion, 831
